Background

Natural meat proteolysis seems to be one of the main factors that contribute to tenderisation process during meat aging. Two enzymatic systems are involved in meat tenderness: calpains and cathepsins. However, there are some discrepancies regarding to the cooperative action of both enzymatic systems. It is accepted that these proteolytic systems are similar in all muscles, independently of animal species. Calpain activation could be done by injecting or dipping the meat with/in $CaCl_2$ solutions. Many meat cuts considered as tough due to their high collagen content have a relatively low price during commercialisation. An alternative to obtain more tender meat is the calcium chloride marination, by means of the activation of the calcium dependent or calpain proteolytic system. Acidulating agents produce a high pH reduction. In this way, glucono-δ-lactone in water is hydrolyzed to gluconic acid, and is employed to produce gels in many conditions. In other hand, lactic acid bacteria has been suggested to become protective cultures in meat products due their ability to inhibit the growth of other microorganisms by many ways, like lowering pH by lactic and acetic acid production, competition for the nutrients, or producing hydrogen peroxide, bacteriocins, or antibiotics.

Objectives

We are proposing the calcium chloride marination beside to the application of acidulating agents in order to, first, activate the calpain system, and secondly, decrease pH enough, affecting on a remaining cathepsin activity or a protein degradation by the denaturing effect of low pH, and thus improving meat tenderness.

Materials and methods

A complete factorial design was employed to determine the effect of the acidulating agent, lactic acid bacteria (LAB) or glucono-δ-lactone (GDL), and storage time on texture, water holding capacity, pH and myofibrillar fragmentation index of meat samples. The PROC GLM procedure of the SAS Statistical System v. 8 (SAS Institute, Cary, NC) was employed in order to determine significant differences. Results are the means of three replications. Bovine *brachiocephalicus* muscle was obtained within 48 h *postmortem* in a local slaughterhouse. Muscles were cut in 150 g samples and were marinated in a 150 mM CaCl2 solution at 4°C in a vacuum tumbling machine. After marination, one lot of samples were immersed in a LAB suspension with an optical density of 1.0 (*Pedioccocus pentosaceus* PC-111016, Christian Hansen A/S, Hoersholm, Denmark) at 4°C during 15 minutes. Other lot of marinated samples was immersed in a GDL solution (1% w/v, Lot: 070199-22, Glocona America Inc., Janesville, WI) at 4°C during 30 minutes. Finally, a third lot of samples were keep as control under same storage conditions. All samples where then vacuum packed and stored at 4°C during 1, 5, 10 and 15 days. Warner-Bratzler shear force (WBSF) was determined in a texture analyser model TA-HDi (Texture Technologies, Scarsdale, NY/ Stable Micro Systems, Surrey, UK) equipped with a 50 kg load cell. Samples of approx. 6.0x1.2x1.2 cm were cooked in hot water until an internal temperature of 70°C, as described by Wheeler et al. (1979). Cooked samples were compressed at a constant speed rate of 120 mm/min with the Warner-Bratzler razor, reporting maximum force detected during the test. The pH value was determined using 10 g of sample homogenized with 100 ml of distilled water in a Warning blender during one minute with an Oakton potentiometer EP 2500 (Oakton Corp., Singapore). Water holding capacity (WHC) was determined in agree to the methodology reported by Hamm (1975), with some modifications. Meat samples (300 mg) were placed between two Whatman No. 1 filter papers and compressed during 10 minutes with 1 kg weight between two Plexiglas plates. Water holding

capacity was reported by weigh difference as the percentage of humidity retained in the paper. Sodium dudecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE), in denaturing conditions, was performanced in a Mini Protean II Slab cell (Bio Rad, Richmon, CA). Acrylamide concentrations were 4% for stacking and 12% for resolving gels (Bollag & Edelstein, 1991). Myofibrillar fragmentation index was determined using the technique reported by Olson et al. (1976). In order to determine the effect of inoculated LAB on microbial populations, a microbiological analysis were made during storage time. Total coliforms were determined in violet red bile (VRB) agar plates incubated at 35°C during 24 h. LAB were determined in Mann-Rugose-Sharp (MRS) agar plates incubated at 35°C during 24 h. After pertinent dilutions, the colony forming units (CFU) per g of sample were reported in control and LAB treated samples.

Results and discussion

Control pH remained constant during all the storage period since after 48 h *postmortem* and vacuum packed little biochemical changes are expected at 4°C. As expected, LAB and GDL had a significantly effect ($P<0.01$) on pH. WHC was significantly affected ($P<0.01$) by the LAB or GDL treatments during the storage (Figure 1). Control samples (only marinated with $CaCl_2$ solution) presented a little increase in WHC during storage time. LAB treated samples presented higher WHC values than the GDL treatments. The results indicate that the samples treated with acidulating agents had lower WHC values than control sample, since the acidity reduced the pH close to the myofibrillar proteins isoelectric point. Furthermore, low pH values could result in a myofibrillar protein denaturation altering their ability to retain water (Aktas & Kaya, 2001). The texture of the samples was affected by the treatment ($P<0.01$), but not by the storage time ($P>0.05$). GDL treated samples were tougher (high shear force values) than LAB or control (Figure 1). Meat control tenderness increased with storage time, mainly by the $CaCl_2$ effect (Pérez-Chabela et al., 1998). LAB samples force presented a drastic reduction after the 5-day of storage, reaching the same WBSF values than control samples at the 15 day. GDL samples were stronger and more difficult to shear, almost twofold than control samples. In our experiment, GDL samples were tougher than LAB ones. It could be explained from the view that the GDL reduced drastically and quickly the pH, denaturing proteins instead to promote some kind of myofibrillar weakening. When meat pH is below 5.5, meat could be softer due to protein degradation or loss of the structure. MFI increases with storage time and was higher for control samples than for LAB or GDL samples ($P<0.01$)(Figure 2). Control samples presented higher values on the first storage day, with an important increase on day 10. LAB and GDL samples were similar during the first 10 days but LAB had high values at the end of the sampling period. Lin et al. (2000) reported that a high MFI in mule duck marinated in red wine correspond to the acidic environment provided by the red wine, where the cathepsins or lysosomal enzymes could be responsible for protein degradation of myofibrils in acid environment (Saunders, 1994), and MFI is directly related to tenderness (Culler et al., 1978). Microbial population evolution was depicted in Figure 3, where the LAB population increased in LAB treated samples and control, whereas the coliforms population was decreasing in LAB samples. The reduction in coliforms population was important due to inoculated LAB after $CaCl_2$ marination, whereas in control samples in spite of the detection of an relatively high naturally occurred LAB population, coliforms grew with storage time with no apparent relationship with the native LAB. An important natural occurring LAB population was found in control samples. LAB inoculation could contribute in extending shelf life of meat products due to their ability to inhibit pathogens and deteriorative microorganisms by the nutrient competition, displacing them form their ecologic niche and/or the production of antimicrobial substance as lactic or acetic acids, diacetyl, hydrogen peroxide and bacteriocines (Requena & Peláez, 1995; Helander et al. 1997).

Conclusions

The GDL concentrations not affected meat tenderness, probably because of high acidic conditions generated. LAB incorporation had a minor effect on meat tenderness, but reduced the coliforms population. In the present experimental conditions employed, a maximum degradation, and hence tenderness, were reached at the 5th day of storage with LAB as acidulating agent.

COMPETITIVE INHIBITION OF MEAT SPOILAGE BACTERIA AND PATHOGENS

Greer, G.G. and Dilts, B.D.

Agriculture and Agri-Food Canada, Lacombe Research Centre, 6000 C & E Trail, Lacombe, Alberta, Canada T4L 1W1

Background

Brochothrix campestris was isolated from soil and grass and first described in detail by Talon and co-workers (1988). Subsequently, it was found to produce a broad spectrum bacteriocin (brochocin-C) inhibitory to a range of gram-positive bacteria including *Brochothrix thermosphacta*, *Listeria* spp. and lactic acid bacteria (Siragusa and Cutter, 1993). Purified brochocin-C was also active against vegetative cells and spores of *Bacillus* and *Clostridium* spp., including *C. botulinum* (McCormick *et al*., 1998).

The cost associated with the production of bacteriocins and inactivation in food environments often precludes their practical application as food preservatives. Thus, the use of viable, bacteriocin-producing cells as biopreservatives in meats is a reasonable alternative (Lücke, 2000). Unfortunately, it has been assumed that *B. campestris* would not be an acceptable strain for use in meats and research has been undertaken to heterologously express brochocin-C in "food grade" lactic acid bacteria such as *Carnobacterium piscicola* (McCormick *et al*., 1998; Garneau *et al*., 2003). This technique is tedious and it is difficult to develop strains in which the heterologous expression of brochocin-C is stable.

Preliminary, inoculation studies had shown that *B. campestris* could grow on pork adipose tissue at 4°C without producing undesirable odours or changes in the appearance of the fat. Also, there were no known published reports of the competitive inhibition of bacteria by *B. campestris* in broths. Thus, the current study was designed to provide needed data on the competitive effects of *B. campestris* co-inoculated with gram-positive spoilage bacteria and pathogens.

Objectives

This study was undertaken to determine the ability of *B. campestris* ATCC 43754 to control the growth of *B. thermosphacta* B2, *Lactobacillus sake* 1218 and *Listeria monocytogenes* when co-cultured in APT broth at 4°C.

Materials and methods

B. campestris ATCC 43754 was purchased from the American Type Culture Collection (Manassas, VA, USA). *L. sake* 1218 (Leisner *et al*., 1996) and *B. thermosphacta* B2 (Greer and Dilts, 2002) were meat spoilage strains. Two of the *L. monocytogenes* strains were isolated from a pork processing facility, one was a poultry isolate (ATCC 19111) and the fourth was a clinical isolate of *L. monocytogenes* Scott A. (Health Canada, Ottawa, ON). Inocula were prepared by growing the individual strains in APT broth (Difco, Becton Dickinson Co., Sparks, MD, USA) at 25°C for 18 h.

Growth studies were conducted in APT broth incubated at 4°C for 7 to 13 d. All experiments were conducted under aerobic conditions with the exception of mixed cultures with *L. sake* where growth was also determined under anaerobic conditions in a BBL anaerobic jar with 5-10% CO_2 (BBL Anaerobic System, Becton Dickinson). *B. campestris* ATCC 43754 was diluted to give an initial population of about 6 to 7 log CFU/ml and the target species were at initial numbers of 3 to 4 log CFU/ml. Prior to dilution, the 4 *L. monocytogenes* strains were mixed by combining equal volumes of the individual 18 h cultures.

The growth of the 3 target species (*B. thermosphacta* B2, *L. sake* 1218 or the 4 strain mixture of *L. monocytogenes*) was determined alone and in mixed culture with *B. campestris* ATCC 43754. To recover and enumerate *B. thermosphacta* during co-culture with *B. campestris* a modified MRS medium (Wilkinson and Jones, 1977) was utilized in the presence or absence of 0.1% potassium tellurite. *B. thermosphacta* B2 grows to produce black colonies on this medium while the growth of *B. campestris* ATCC 43754 is inhibited. Tryptone-phytone-yeast extract agar containing 0.02% erioglaucine (TPYE, Greer and Dilts,

1997) was used to enumerate *L. sake* 1218 during co-culture with *B. campestris* ATCC 43754. This medium would inhibit the growth of *B. campestris* ATCC 43754 while *L. sake* 1218 would produce pale green colonies. PALCAM-agar (Difco) was used to enumerate *L. monocytogenes* during co-culture with *B. campestris* ATCC 43754. *L. monocytogenes* produced black colonies on this medium (Corry *et al*., 1995) and *B. campestris* ATCC 43754 was inhibited. Streptomycin-thallous acetate-actidione agar (STAA, Corry *et al*., 1995) enabled the recovery of *B. campestris* ATCC 43754 while not permitting the growth of *L. sake* 1218 or *L. monocytogenes*. All media were inoculated using the spread plate technique with the exception of TPYE where Hydrophobic Grid Membrane Filtration was used.

Bacterial numbers were converted to common logarithms and reported as log CFU/ml. The significance of treatment differences was determined by analysis of variance using the general linear model procedures of the SAS Institute.

Results and discussion

Biopreservation of meats with bacteriocinogenic lactic acid bacteria (LAB) and their bacteriocins has been the subject of authoritative reviews (Stiles, 1996; Lücke, 2000). Although *B. campestris* ATCC 43754 was known to produce a broad spectrum bacteriocin (Siragusa and Cutter, 1993) the current study was the first to show that this organism could competitively restrict the growth of meat spoilage bacteria and pathogens in mixed cultures at 4°C (Tables 1 to 4) resulting in a significant reduction in bacterial numbers ($P < 0.05$).

The competitive strain, *B. campestris* ATCC 43754, increased by 2 log CFU/ml by about 5 d of incubation to reach a maximum population approximating 9 log CFU/ml. During co-culture with *B. thermosphacta* (Table 1) or *L. monocytogenes* (Table 2), *B. campestris* was bacteriostatic. This was evident in a reduction in the rate of growth of the target strains producing a 3-4 log CFU/ml reduction ($P < 0.05$) in bacterial numbers by the end of the incubation period. Lactobacilli have also been shown to inhibit the growth of *B. thermosphacta* (Shay *et al*., 1984) and *L. monocytogenes* (Schillinger *et al*., 1991) in broths and meat products.

In mixed culture with *L. sake* 1218 under aerobic conditions, *B. campestris* ATCC 43754 was initially bactericidal and *L. sake* could not be recovered from the culture media after 1 and 4 d of incubation (Table 3). Thereafter, *L. sake* 1218 began to grow but the numbers remained at least 4 log CFU/ml lower by the end of the incubation period when compared to those determined during the growth of *L. sake* 1218, alone (Table 3). Under anaerobic conditions, *B. campestris* ATCC 43754 demonstrated a prolonged bactericidal effect and no *L. sake* 1218 could be recovered from mixed cultures with *B. campestris* ATCC 43754 following 2 to 12 d of incubation at 4°C (Table 4), while *L. sake* 1218 alone grew to 9 log CFU/ml. Leisner *et al*. (1996) reported that *L. sake* 1218 could be inhibited in APT broth and in vacuum packaged beef by *Leuconostoc gelidum* UAL 187 and the inhibition of bacterial growth was of a sufficient magnitude to delay the sulphide spoilage by *L. sake* 1218.

Conclusions

The growth of *B. thermosphacta* B2, *L. sake* 1218 or a 4 strain mixture of *L. monocytogenes* was significantly inhibited in mixed culture with *B. campestris* ATCC 43754 during the incubation of APT broth at 4°C. Depending upon the target strain in the mixture and the gaseous atmosphere, the inhibition was either bacteriostatic or bactericidal. Additional research is necessary to transfer the system to meats and to insure that the competitive organism, *B. campestris* ATCC 43754, does not produce spoilage.

THE EFFECT OF DISINFECTANTS ON *LISTERIA MONOCYTOGENES* ADHERENT TO MEAT BIOFILM

Annemarie Gunvig
Danish Meat Research Institute, Maglegaardvej 2, DK-4000 Roskilde

Background

Listeria monocytogenes is the major problem concerning the safety of ready-to-eat (RTE) cooked meat products. When L. monocytogenes occurs in RTE cooked meat products, it is due to after-contamination when the products are handled and packed, because L.monocytogenes occurs in the environment. The occurrence in the environment can be persistent, because L. monocytogenes has the ability to form biofilms on food-processing surfaces. Biofilm is composed of meat residues and microbial polymers formed during bacterial growth. Bacteria adherent to a biofilm is highly protected against chemical compounds such as disinfectants.
It is very important to be aware of the ability of the disinfectants to penetrate a biofilm, so that the right disinfectant can be chosen when problems with biofilm arise in the production plant. It is important that the disinfectants are evaluated in an experimental set-up closely related to the environment in the production plant.
Fatemi et al.(1999) and Krysinski et al. (1992) measured the effect of disinfectants and sanitizers on L. monocytogenes cells adherent to a biofilm attached to stainless steel. Both methods included a biofilm produced in tryptone soya broth (TSB). When using the laboratory broth, the nutrients are different from the nutrients available for the microorganisms in the production plant. Krysinski et al. (1992) enumerated surviving L. monocytogenes by the plate count method after dislodging the cells from the stainless steel. Fatemi et al. (1999) enumerated viable L. monocytogenes in the biofilm by the direct agar overlay method.
The present study introduces a method to create a L. monocytogenes biofilm composed of meat residues normally present on the surfaces of equipment in meat production plants and describes a method to measure the bacterial counts on stainless steel using a Malthus apparatus.

Objectives

The objective of this study is to test the ability of five different disinfectants to inactivate *L. monocytogenes* cells adherent to a biofilm under simulated production site conditions.

Materials and methods

L. monocytogenes DMRICC 3001, originally isolated from the meat environment, was grown in BHI broth at 30°C.
Biofilm was formed on stainless steel coupons (1cm x 2.5cm) by immersing the coupons in a meat sausage/water emulsion (1:4) inoculated with 1% *L. monocytogenes* and incubated at 30°C for 6 days. The coupons were then rinsed with sterile water to remove unattached cells and meat.
Detergents: 4% Deptal FM2, alkaline detergent (NaOH, KOH), Hypred and 5%, P3-topax, 66, sanitizer (NaOH: 5-15%, sodium hypochlorite: <5% active chlorite, alkylaminoxide: <5%), Ecolab.
Cleaning methods: Before disinfection, coupons with biofilm were cleaned in the alkaline detergent or the sanitizer by scrubbing for one minute with a cloth soaked in one of the detergents or by soaking the coupons in the detergent solution for 15 minutes. After cleaning the coupons were rinsed in 10 ml sterile water.
Disinfectants: Deptal Mycoside S (QAC) (Didecyldemethylammoniumchloride) 0.3% for 20 minutes (Hypred), Betane Plus (QAC) (QAC compounds: 5-15%, poly(hexamethylen)biganid, HCl:<5%) 1% for 10 minutes (Ecolab), Desinfect Maxi (QAC) (N,N-didecyl-N,N-dimethylammoniumchloride:5-15%, propan-1-nol:<5%) 1% for 5 minutes (Novodan), sodium hypochlorite (12.4% active chlorite), 0.16% for 5 minutes (Novadan), P3 oxysan (Acetic acid: 15-30%, H_2O_2:5-15%, alkylsulfonate: 5-15%, peraceticacid: <5%, phosphonacid: <1%) 0.1% for 5 minutes (Ecolab).
Disinfection: The coupons were disinfected by soaking in the disinfectants. The concentration and time treatment were chosen from the respective data sheets from the chemical manufacturer. After disinfection, the coupons were rinsed with 10 ml sterile water and air-dried for 5 minutes. Untreated coupons were soaked

in sterile phosphate buffer (pH 7.2) for 5 minutes. All coupons were soaked in a neutralizing liquid for 5 minutes before they were analyzed in the Malthus apparatus
Growth of *L. monocytogenes* was determined by measuring the time until *Listeria monocytogenes* started producing CO_2 in the Malthus apparatus. The correlation between time and cfu/g biofilm was calculated to be: X (log cfu/g)=÷0.29 xY(time until growth) + 9.32 (R=0.99).

Results and discussion

Cleaning with the sanitizer followed by disinfection with pH neutrale quaternary ammonium chloride compounds (QACs) resulted in a complete inactivation of L. monocytogenes adherent to the meat biofilm (see figure 1). There was no difference between the two cleaning methods. QAC is a large four-chain molecule with a central N-atom. The chemcial composition of the three investigated QACs varied in two of the sidechains, but this did not affect the ability of the QACs to inactivate L. monocytogenes. The most important properties for the QAC's ability to penetrate biofilms are resistance to organic matter and low surface tension. The cleaning method could not be evaluated because of the complete inactivation of L. monocytogenes.
The same results were seen when cleaning with an alkaline detergent before disinfection with QACs (figure 2).
Cleaning with the sanitizer by scrubbing followed by disinfection with sodium hypochlorite reduced the count of *L. monocytogenes* by 3.5 log cfu/g compared to untreated coupons (figure 1). Cleaning by soaking the coupons in the sanitizer resulted in a 1 log reduction compared to untreated coupons (figure 1). This indicates that a mechanical treatment is an important factor in reducing bacterial counts.
Cleaning with the alkaline detergent by scrubbing, followed by disinfection resulted in a 1.7 log reduction compared to untreated coupons (figure 2). This is a lower reduction compared to cleaning with the sanitizer, the reason being that the sanitizer contained disinfectant (hypochlorite), which meant that the coupons were disinfected twice.
The lower inactivation of *L. monocytogenes* resulting from disinfection with hypochlorite compared to QACs can be explained by the fact that sodium hypochlorite is very sensitive to the presence of organic matter, especially protein.
Disinfection with peroxide after cleaning with the sanitizer resulted in a 1.5 log reduction of *L. monocytogenes* compared to untreated coupons (figure 1). The cleaning method (soaking or scrubbing) had no influence on the inactivation of *L. monocytogenes*.
When cleaning with the alkaline detergent by scrubbing followed by disinfection with peroxide, the reduction of *L.monocytogenes* was 1.5 log cfu/g, which is similar to cleaning with the sanitizer followed by disinfection.
Soaking in an alkaline detergent, followed by disinfection with peroxide only reduced the count of *L. monocytogenes* by log 0.5 cfu/g compared to the untreated coupons. When scrubbing before disinfection with peroxide, a minor increase in log reduction was seen. This could be explained by the fact that some of the organic matter was removed and the scrubbing opened the biofilm, which meant that the peroxide could penetrate the biofilm more easily. The main explanation for peroxides low capability to inactivate *L. monocytogenes* is that peroxide is very sensitive to the presence of organic matter.
In the present study in a strong biofilm the effect of sodium hypochlorite and peroxide is almost the same, and the effect of the QACs is much higher than that of sodium hypochlorite and peroxide. The result for peroxide differed from the results of Fatemi et al. (1992), who reported a better effect of peroxide compared to hypochlorite in TSB biofilm covered with a layer of milk. Kysinski et al. (1999) reported a high effect of peroxide and one neutral QAC and a low effect of hypochlorite on *L. monocytogenes* culture attached to stainless steel in a TSB biofilm. Hypochlorite generally has a low ability to inactivate bacteria in biofilm. The ability of peroxide to penetrate and inactivate bacteria biofilms seems to vary according to the chemical matrix of the biofilm.
The results of these experiments demonstrate how important it is to be aware of the disinfectant's ability to inactivate bacteria adherent to biofilm. The disinfectants used in this study are normally capable of inactivating planktonic cells completely (LeChevallier et al.,1988). The knowledge from this study is useful when high bacterial counts are detected after cleaning and disinfection, since could indicate problems with biofilm in the production site. In such a situation, it is important to choose the right disinfectant to solve the problem.

Conclusions

From the experiments, the following conclusions can be made:
QACs can completely inactivate L. monocytogenes adherent to a strong meat biofilm with approximately log 7 cfu/g.
Sodium hypochlorite and peroxide have a low ability to inactivate L. monocytogenes in a strong meat biofilm.

Background

Previous studies have shown that many *Listeria monocytogenes* isolates from heat-treated meat products seem to have other origins than fresh meat (Boerlin and Piffaretti., 1991; Nesbakken et al., 1996).

Objectives

The purpose of this investigation was to obtain knowledge of sources, routes of contamination and genetic types of *L. monocytogenes* present along the production line in the meat processing industry, and to compare meat industry isolates and human isolates.

Materials and methods

We have investigated the molecular epidemiology of *L. monocytogenes* from the meat processing industry producing cold cuts and from cases of human listeriosis by discriminative pulsed-field gel electrophoresis (PFGE). A subset of the isolates was also investigated for susceptibility to a disinfectant based on quaternary ammonium compounds (QAC) frequently used in the meat processing industry. Of the 218 isolates from four meat-processing plants, 197 were from two plants responsible for nearly 50% of the production of cold cuts in the Norwegian market. The strain collection included historical routinely sampled isolates (1989-2002) and isolates systematically sampled through a one year period (November 2001-November 2002) from fresh meat and production environments in three plants in Norway. Human strains included all available reported isolates from Norwegian patients in selected time periods.

Results and discussion

No isolates were obtained in samples from employees (throat (n=70), faeces (n=45)). The *L. monocytogenes* PFGE data showed a large genetic heterogeneity, with isolates separated into two genetic lineages and further subdivided into 56 different PFGE profiles. Certain profiles were observed on both sides of production (before and after heat treatment) indicating contamination of end products by fresh meat or fresh meat environments. While fresh meat isolates almost exclusively grouped within lineage I, isolates from end products showed a more balanced distribution between lineage I and II. Ten profiles were common among isolates from human and meat industry. Typing of human isolates identified a previously unrecognised outbreak. Generally, a higher QAC resistance incidence was observed among isolates from the meat processing industry than among human isolates although large plant to plant differences were indicated. No correlation between resistance and PFGE profile or resistance and persistence was observed.

Conclusions

Additional factors than fresh meat seem to be responsible for contamination at the end product side. No positive samples detected from throat and faeces of employees indicated employee carriage as a minor factor in colonisation and spread of *L. monocytogenes* in the plants. The results indicate an overall higher prevalence of resistant clones in the food industry compared to isolates from human cases.

HYGIENIC CONDITIONS OF A MEXICAN LOCAL SLAUGHTERHOUSE

Hernandez S.[1], Zúñiga A.[1], Rovira J.[2], Jaime I.[2], Sanchez I.[1], Santos E.M.[1]

Background

Healthy cattle are a reservoir for the major foodborne pathogens like *Escherichia coli* O157, *Salmonella spp*., *Listeria spp*. and *Campylobacter spp*. and these microorganisms may be transferred onto the meat during slaughter and dressing of the carcasses (Vanderlinde and Shay, 1998). Apart from pathogenic bacteria, isolated spoilage microorganisms include lactic acid bacteria, *Pseudomonas spp.*, *Acinetobacter spp.* and *Moraxella spp.* (Kraft, 1992). Microorganisms are in the intestinal tract of the animals, on its hide, hair and hooves (Gill and Newton, 1978). Generally, the internal surfaces of the carcasses are sterile, but during the slaughtering process, defects on dressing and skinning led to the contact of carcasses with dust, dirt and feces, and facilitate the contamination of the meat with the microorganisms deposited on the surface of the animals.

Equipment and utensils used in the slaughtering plants play an important role in the cross-contamination of carcasses. For example, in the case of swine cattle although bacteria on the skin are largely destroyed by scalding, the skin is recontaminated with spoilage and pathogenic bacteria during passage of the carcass through the dehairing equipment (Gill and Bryant, 1993). Workers could be also another microbial contamination source.

In this way, safety programs have been adopted in the slaughtering plants in order to improve meat safety. Good manufacturing practices (GMP) emphasize sanitary effectiveness and hygienic practices during the processing of foods. Hazard analysis critical control point (HACCP) is mainly directed to identify and control foodborne pathogens. In USA every slaughter plant that operates under federal inspections is committed to establish and carry out a HACCP program as well as to apply sanitation standard operating procedures (SSOP) (USDA, 1996). In the European Union the UE Commission Decision (2001/471/EC) requires validated HACCP systems in the slaughter plants and conduct regular checks on general hygiene. However none of these safety programs are compulsory in slaughterhouses in Mexico, especially in non TIF (Federal Inspection Type) slaughterhouses. Therefore, microbial counts in these establishments are expected to be quite high but no studies are related to the subject.

Objectives

The aim of this work was to conduct a microbiological evaluation of the slaughtering process at a small slaughterhouse located in Hidalgo State, Mexico.

Materials and methods

The slaughter house involved in the study is located in Pachuca, Hidalgo State, Mexico, and it has one line for pigs and one line for cattle. Over a nine-month period the local slaughtering establishment was sampled eight times, four times in each line. At each sampling time, nine carcasses were randomly selected immediately after slaughter and dressing and sampled. Four zones of 100 cm^2 were strongly swabbed with cheese cloth previously moistened with buffered peptone and placed in a same sterile Stomacher bag constituting a single composite sample. In case of swine, zones swabbed were ham, back, belly and jowl and in beef carcasses the zones swabbed were leg, belly, breast and jowl. Also knives used for the bleeding, scrapping, skinning and evisceration as well as saws used to split the sternum and carcasses of beef and hands of different personnel working were sampled by swabbing technique. The water from the scalding process and used to wash the carcasses was also analysed.

The swab samples were cultured and enumerated for the presence of total viable count (TVC), coliforms, *E. coli*, *Salmonella* and *Staphylococcus aureus*. Plate count agar (PCA) was used to enumerate total viable count, Petrifilm Coliforms/*E. coli* (3M) was used to enumerate coliforms and *E. coli* and Baird Parker agar to enumerate *Staphylococcus aureus.*

For detection of *Salmonella spp.*, 100 ml of buffered peptone water was used for preenrichment at 37ºC for 18 h. Selective enrichment was done in Rappaport-Vassiliadis (RV) broth and tetrathionate broth. Isolation and identification were performed by plating on xylose lysine desoxycholate (XLD) agar and modified brilliant green agar (BGAM). One suspect colony on each plate was inoculated on triple sugar iron agar (TSI) and lysine iron agar (LIA) for identification. Also multivalent serum agglutination was performed to confirm the presence of *Salmonella*.

Results and discussion

A total of 158 samples were analysed (74 samples in pork line and 84 samples in beef line). Results of TVC (total viable count), coliforms and *E. coli* are shown in tables 1 and 2. Total viable counts were recovered from all samples and coliforms and *E. coli* from most samples. Generally speaking, carcasses, utensils and workers were more contaminated in pig line than in beef line. However, counts in carcasses were higher than those found by Gill et al. (2000) in beef and pig carcasses. Anyway TVC values found in pig carcasses were all higher than 4 Log cfu/cm^2 which for example according to Commission Decision 2001/471/EC would be considered unacceptable. In beef carcasses TVC counts ranged from 3.26 to 7.00 Log cfu/cm^2 and but coliforms were lower than 1.5 Log cfu/cm^2 or were not present except in five samples and *E. coli* counts were not detected in half samples. High counts in utensils and worker hands indicated absence of good manufacturing practices which facilitate the contamination of carcasses. Respecting the water used to clean the carcasses the presence of coliforms and *E. coli* could be explained due to the fact that the water prior to be used is placed in an open container and could be contaminated during the slaughtering process.

Respecting *Salmonella*, 31% of the samples were positive for *Salmonella spp* in the porcine line and 11% were positive in the bovine line. It is well documented that *Salmonella* enters into the slaughterhouse through the animals, especially pigs and although scalding step could reduce the presence of this pathogen, subsequent operations as dehairing, manual scraping and polishing and evisceration contribute significantly to cross-contamination and could explain the prevalence of *Salmonella* in the carcasses, knives and hands of the workers. The percentage value found in pork line is slightly higher than the value found by Korsak et al. (1998) in four pork slaughterhouses; however, these authors did not found *Salmonella spp* in the beef slaughterhouses sampled. *Staphylococcus aureus* was not detected in any sample. This microorganism in foods usually indicates contamination from skin, mouth or nose of food handlers.

Conclusions

High microbial counts present in carcasses, utensils and personnel working indicated poor hygienic conditions in the slaughtering establishment and implementation and maintenance of Good Manufacturing Practices (GMP) and Hazard Analysis Critical Control Points (HACCP) should be the strategy in order to assure the microbial safety of meat.

Background

Staphylococcus aureus is part of the microflora of chickens, commonly associated with bruised or infected tissue, nasal passages, skin surfaces, and arthritic joints (Mead and Dodd, 1990; NACMCF, 1997). Low levels of *S. aureus* are commonly found on the surface of poultry and throughout poultry processing premises (Thompson *et al*., 1980; Noterman *et al*., 1982; Mead and Dodd, 1990). Typically, these are poultry-associated strains which can be differentiated from human isolates (Gibbs *et al*., 1978a,b). Poultry strains do not seem to be important in the aetiology of poultry product-associated staphylococcal intoxications and may be considered as unimportant in terms of food safety (Isigidi *et al*., 1992). Instead, most staphylococcal outbreaks appear to be related to contamination of cooked products by infected food handlers followed by improper holding temperatures (Bryan, 1980). Prevalence of *S. aureus* in broiler carcasses in the United States was found to be 64% based on a nationwide baseline survey (USDA FSIS, 1996a). The survey did not identify whether the isolates were poultry-associated strains or human strains. A New Zealand survey found *S. aureus* to be present in 3.6% of 48 ready-to-eat poultry product samples tested with 7 samples (0.5%) found to contain excessive numbers (Campbell and Gilbert).

Objectives

The purpose of this study was to detect of prevalence rate, variation of contamination level contamination frequency of *Staphylococcus aureus* and critical points on slaughtering line.

Materials and methods

30 samples is taken in each of slaughtering stages of poultry slaughter house in the city of Tabriz. Samples were :

A. 50ml water of scalder.
B. 25cm^2 skin swab
C. meat sample after defethering
D. meat sample after eviscerating
E. meat sample after cold water washing.
F. water of chiller.
G. meat sample after chilling.
H. meat sample from markets.

For sample preparations and culture of *Staphylococcos aureus* with standard plate count is used standard methods of Institue of standards and Industrial Research of Iran, no: 356,1194. T-test for quantitative data and Mc nemar test for qualitative data are used.

Results and discussion

Staphylococcus aureus count (spc) in each of premises sampling indicated in table 1

Increasing the mean of *staphylococcus aureus* contamination level after each of premises such as defethering, eviscerating and immersion chilling is significant ($p<0.05$). But, decrease of staphylococal contamination level in cold water spray washing is not significant ($p>0.05$)(chart1)

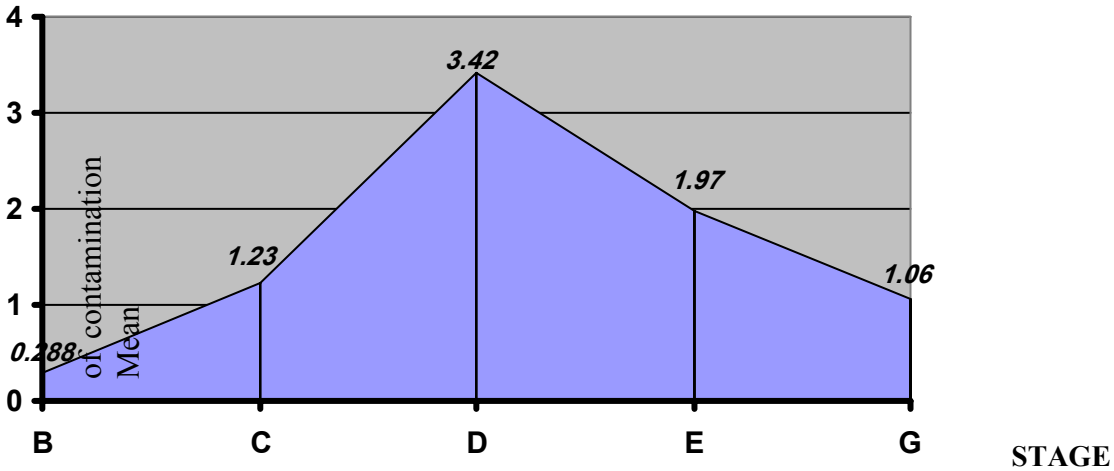

CHART 1: Variation of *staphylococcus aureus* contamination level in B) skin swab, C) meat sample after defethering , D) meat sample after eviscerating E) meat sample after cold water washing, G) meat sample after chilling,

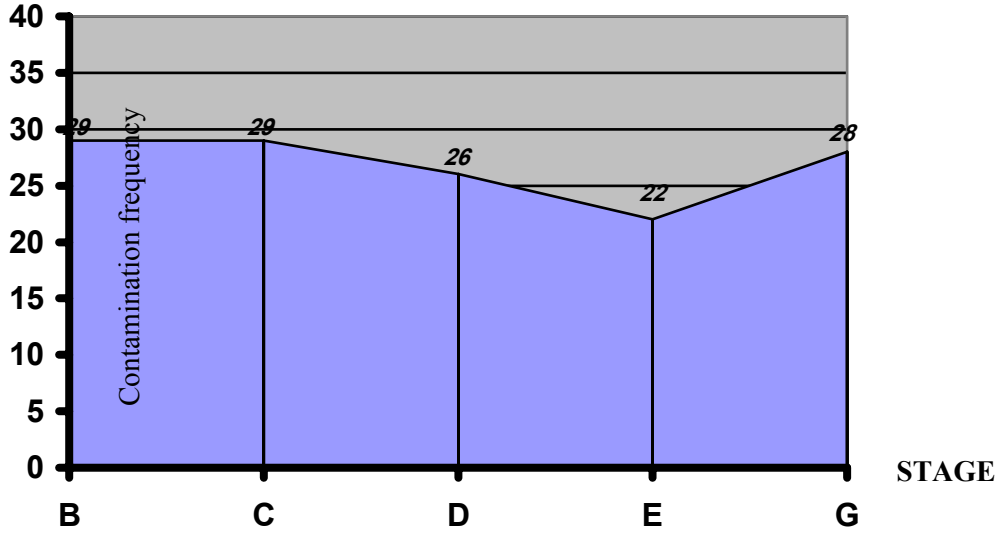

CHART 2: Variation of *staphylococcus aureus* contamination frequency in B) skin swab, C) meat sample after defethering, D) meat sample after eviscerating E) meat sample after cold water washing, G) meat sample after chilling,

Staphylococal contamination frequency after immersion chilling compared with cold water spray washing was showed significant increase ($p<0.05$)(chart 2). Finally *Staphylococcus aureus* contamination prevalence rate in each of poultry slaghter premises is showed in chart 3.

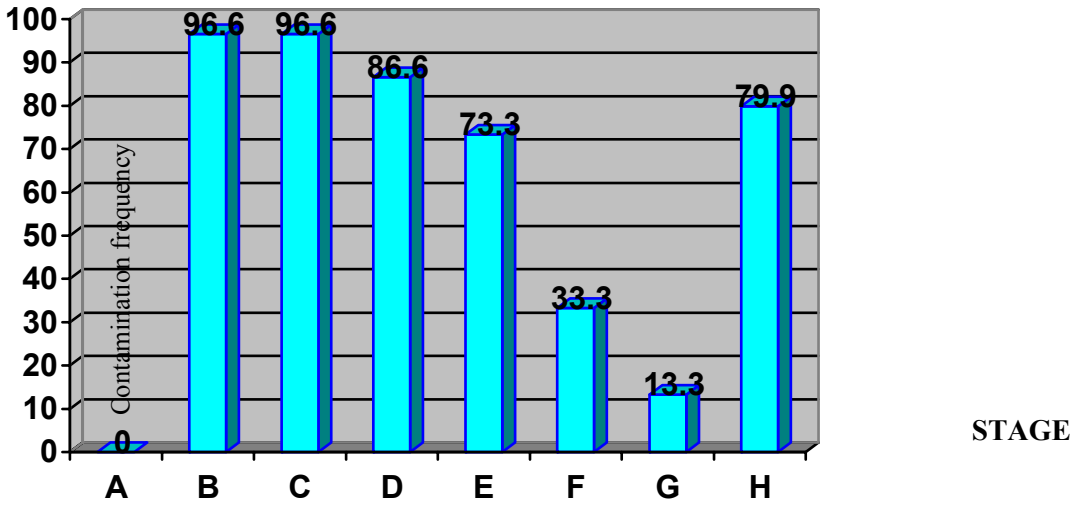

Chart 3: A) water of scalder, B) skin swab, C) meat sample after defethering , D) meat sample after eviscerating E) meat sample after cold water washing, F) water of chiller, G) meat saple after chilling, H) meat sample from market

Conclusions

Finally results show that, stages of defethering, eviscerating cold spray washing and immersion chilling are seriously critical points in slaughter houses. Any control processes were not applied on them. Thus, they result in increasing contamination in poultry meat.

KINETICS OF COLOUR LOSS FOR SLICES OF FERMENTED SAUSAGE DISPLAYED IN LIGHT OF VARYING INTENSITY

Jydegaard, A-M.[1], Nielsen, H.J.S. [1], Dawson, P.L[2]. and Acton, J.C. [2]

[1]The Technical University of Denmark, DK-2800 Lyngby, Denmark
[2]Department of Food Science & Human Nutrition, Clemson University, Clemson, South Carolina 29634-0316 USA

Background

Surface colour is an important attribute that consumers use to judge acceptability of meat and meat products. For cured meats, the pink, pink-red, to red-maroon colour is viewed as an indicator of product freshness (Issanchou, 1996). Nitrosylhemochrome, the pigment of cured meats, is sensitive to light in the presence of oxygen. Protecting sliced cured meats, such as fermented sausages, from oxygen is normally done by proper packaging. Colour stability of cured meats is retained for 5-8 weeks when low oxygen transmission rate (OTR) films, generally <17 cc/m^2/24 hr, are utilized with vacuum packaging (Lin et al., 1980; Yen *et al*., 1988; Kartika *et al*., 1998). Light-induced fading occurs more rapidly if residual oxygen remains in packaged cured meats (Andersen *et al*., 1988) as can occur with inadequate vacuum-packaging and if the packaging film has too high an oxygen transmission rate (Lin *et al*., 1980, Yen *et al*., 1988, Kartika *et al*., 1998).

Since colour fading of cured meats is basically a chemical reaction in which nitrosylhemochrome is gradually destroyed by oxidation, the rate of colour change due to destruction could be evaluated as a function of storage temperature of the product. The Arrhenius relationship describes rate constant dependency on temperature and is very useful in determining quality losses in foods (Labuza, 1984). Since a time-temperature relationship reflects an energy input, a light intensity-time relationship would also reflect an energy input at the product surface and potentially resemble an Arrhenius type of relationship for reactions associated with colour loss.

Objectives

The objective of this study was to determine if an Arrhenius-type relationship exists for surface colour fading or colour loss for packaged slices of product placed in light display with lighting of different intensities. Rate constants for CIE L*a*b* as well as CIE C*and h* were obtained for product packaged in a non-oxygen barrier film so that O_2 was not restricted as a reactant in degradation of nitrosylhemochrome.

Materials and methods

Fresh commercial fermented sausage was obtained that analyzed 47.7% moisture, 17.1% protein, 29.7% fat, 3.36% ash, 4.06% NaCl (AOAC, 1995) and had a pH of 4.6. The sausage was classed as “summer sausage” and had been stuffed in chub form weighing approximately 1.36 kg each. The sausage was approximately 7 cm in diameter and was sliced to provide samples 3 mm in thickness. Two slices, each an experimental sample, were vacuum-packaged (72.4 cm Hg) side-by-side in a flexible film pouch using a Turbovac packaging machine (Turbovac B.V., Netherlands). The packaging film had an oxygen transmission rate (OTR) of 12,000 cc/m^2/24hr at 23^{o}C, 0%RH and 1 atm (Cryovac Division of Sealed Air Corporation, Duncan, SC). A high OTR film was used so that oxygen was not a limiting factor for colour fading. This made it possible to examine colour fading or loss of colour stability due to light intensity effects.

The packaged samples were immediately placed in the dark at 2±1^{o}C for 25 min and then initial colour values (0 hr) were measured. The packages were then placed on display under four light intensities: 660, 927, 1822 and 3172 lux at 2±1^{o}C. Continuous lighting was provided by Cool White fluorescent lights. Two packages (4 slices) were placed under each light intensity. Within each of three study replications, a new set of four slices in two packages as described above were prepared and used for colour evaluation.

CIE L* (lightness), +a* (redness), and +b* (yellowness) were measured using a Minolta Chroma Meter CR-300 (Minolta Corporation, Ramsey, New Jersey) at 0.5 hr intervals during display for 2.5 hr using 5 randomly chosen surface points on each slice. CIE C* (chroma), related to colour intensity, and CIE h* (hue

angle), the measure of colour in the CIE L*C*h* space were calculated based on +a* and +b*. The Chroma Meter was calibrated with a white calibration plate and CIE Illuminant C was the illuminant source.

Kinetic analysis was conducted using the general linear model regression analysis procedure of SAS (1996). First order reaction kinetics were applied and a linear fit of colour characteristic data at each light intensity was tested using the following first order relationship: $\log y = b_o + b_1 x$, where y is the specific colour coordinate value, x is the time of light display (hr), b_1 is the slope and b_o is the intercept. First order rate constants were calculated from the slopes and then used in a second regression analysis to test for an Arrhenius-type relationship due to light intensity given as: $\log k = b_o + b_1(1/\text{lux})$, where k is the rate constant (hr^{-1}), b_1 is the slope, and b_o is the intercept. The coefficient of regression (R^2) and significance of b_1 in the Arrhenius type relationship were used in determining acceptance or rejection of the fit of the data to first order kinetics. In addition to regression analysis, Arrhenius-type plots were prepared from the data.

Results and discussion

The main effects of light intensity, time of display, and the light intensity*time of display interaction were significant factors ($P<0.001$) for decreases in summer sausage surface lightness (CIE L*), redness (CIE +a*) and chroma (CIE C*) and an increase in hue (CIE h*) as determined by general linear models analysis of variance (SAS, 1996). For surface yellowness (CIE +b*), only the interaction was significant. Northcutt et al. (1990) reported that time of light exposure was significant for L*, a* and b* when vacuum-packaged turkey bologna was similarly displayed in a high OTR film. Generally, as light intensity for display increased in the present study, there was a decrease in colour intensity (CIE C*) as the visual colour (CIE h*) shifted from its initial "redness" toward "brown" discoloured characteristics. The major visual hue change shown to occur was associated principally with the redness (CIE +a*) component, typical for highly pigmented cured products, and not the yellowness (CIE +b*) aspect of the hue.

The regressions for rate of change in surface redness, chroma, and hue (TABLE 1), fit a first order reaction mechanism rather than zero or other order and this is in agreement with previous studies of Northcutt et al. (1990) and Mattos et al. (2003). Summer sausage surface lightness (CIE L*) had non-significant ($P>0.05$) slope changes and there was no overall consistent slope pattern for yellowness (CIE +b*) as light intensity increased. All slopes for the response variable redness (CIE +a*), hue (CIE h*), and chroma (CIE C*) were significant ($P<0.0001$). The major observation of the first order rate constants for the significant colour components is that ***the rate constants increase as light intensity increases***. Therefore, light intensity is similar to the temperature effect usually studied for effects on traditional chemical reactions.

In the Arrhenius relationship, a linear relationship exists between the log of the rate constants and the reciprocal of the absolute temperature. When the rate constants of each colour characteristic were used in linear regression analysis for relationship to the reciprocal of light intensity, the coefficients of determination (R^2) showed an acceptable relationship for CIE +a*, h* and C* but not for CIE L* and b* (TABLE 2). Data from TABLE 1 were used to generate Arrhenius-type plots for redness (CIE a*) and hue (CIE h*) (FIGURE 1) to demonstrate that the Arrhenius concept for reaction dependency on temperature is also valid for dependency on light intensity, another form of energy affecting surface colour stability of summer sausage.

Conclusions

Fermented summer sausage slices vacuum-packaged in a high oxygen transmission film and placed in display at 2^oC under fluorescent light intensities in the range of 660 to 3173 lux produced decreases in product surface redness and chroma and increases in hue. Plotting first order rate constants of the colour attributes against the reciprocal of light intensity indicated an Arrhenius-type reaction rate fit. This finding confirmed that the Arrhenius concept for reaction dependency on temperature is also valid for dependency on light intensity, another form of energy that can negatively affect the colour stability of cured meats.

QUANTITATIVE ASSESMENT OF ANTIBIOTIC AND ANABOLIC AGENTS IN BROILER CHICKEN MEAT

Kadim, I.T., Mahgoub, O., Al-Magbaly, R.S. and Annamali, K.

Department of Animal & Veterinary Sciences, College of Agricultural and Marine Sciences, Sultan Qaboos University , PO Box 34, Al-Khoud, 123, Muscat, Sultanate of Oman

Background

Antibiotics and anabolic agents are widely used for treatment of bacterial diseases or as growth promoters in intensive poultry production. Although most of the countries around the world banned a wide range of antibiotics and growth promoters, many of those are still being indiscriminately used (Weirup, 2001). Administration of antibiotics or anabolic agents to broiler may lead to deposition of residual material in meat and consequently presents a potential human health hazard. Over-use of antibiotics in poultry feeding and /or treatments and its contribution to the generation of antibiotic-resistant strains of bacteria has become a worldwide problem in the treatment of human infectious diseases (Millar et al., 1998; Neely and Holder, 1999).

Objectives

The objectives of this study were to detect and quantify residue levels of some widely used antibiotics (streptomycin and tetracycline) and anabolic agents (oestradiol and testosterone) in broiler chicken meat.

Materials and methods

Thirty-four fresh and frozen broiler chicken carcasses representing 16 local and imported products collected between April and May 2003 were used. Four samples (10 to 20 grams) from the breast muscles including meat and skin were homogenized then stored in sealed plastic bags at -80^0C. The samples were randomly allocated to one of four residual assays; streptomycin, tetracycline, oestradiol and testosterone. The Enzyme Linked Immunosorbent Assay (ELISA) technique was used to detect residues in the samples. For each assay, a specific kit was used to provide quantitative negative or positive detecting results after extracting and preparing samples according to the type of the residue. The sample was mixed thoroughly and then kept in a sealed plastic bag at -80^oC. Frozen samples were left at room temperature (20^oC) for two hours before starting extraction. Five to ten grams from each sample were mixed with 10-25 ml of special buffer (organic solvent), which has been prepared specifically for each analysis, for 30 minutes using a shaker, and then it was homogenized. The homogenized sample was transferred to screw cap glass test tube and centrifuged at 3000 to 4000 rpm for 10 minutes at 15^oC. The supernatant was decanted into another flask, then the buffer was dried using rotary evaporator. The residue was redissolved in the solvent. Finally, 5 ml of the filtrate were purified with RIDA C18 column and stored at -20^oC. The concentration of the hormone or antibiotic in ppb/ppt corresponding to the absorbance of each sample was read from the calibration curve.

Results and discussion

The results of oestradiol-17-ß, testosterone, streptomycin, and tetracycline concentration levels in broiler chicken meat samples are presented in Table 1. Fifteen out of 16 samples (94%) contained oestradiol-17ß but of these only four samples (24%) contained residues that exceeded tolerance levels of 100 nanogram/kg specified by the National Residue Control Plan. Salem, et al. (2003) found that feeding 100 µg/bird/day of ethynyl oestradiol to chickens resulted in the highest residue levels of 81.9 µg/kg in the skin rather than in the muscle (22.9 µg/kg). They concluded that the use of oestradiol resulted in its accumulation in different tissues and organs, even if the treatment was stoped for 4 weeks and even when the chicks meat was boiled for one and a half hours. In the present study, seven samples contained 52.4 micrograms/kg of oestradiol-17-ß, which were above the average level in muscle and skin chicken sample reported by Salem (2003). Although, most of oestrogenic compounds have been now banned in most countries because of their apparent carcinogenic (cancer-causing) activity (McCutcheon, 1989), this study revealed that residues of oestradiol-17-ß were present in broiler meat. The naturally occurring androgen testosterones, and its synthetic analogues such as trenbolon acetates (Finaplix®), are effective growth-promoting agents in

domestic animals. Fifteen (94%) out of 16 samples contained testosterone residues, but all were less than the tolerance level of 100 nanogram/kg. These values were less than the limit specified for meat samples by the German Residue Control Plan (100 nanogram/kg).

All meat samples (100%) tested in the present study showed residues of streptomycin (75-155 ppb), but these were below tolerance levels of 500 microgram/kg as specified by the maximum residue limit-European Union regulation. Tetracyclines are also extensively used throughout the world for treatment of bacterial infections in poultry. They act by modifying metabolism of bacteria in the intestine and consequently suppress sub-clinical disease and improving digestive efficiency. All the samples tested in the present study contained showed various levels of tetracycline concentrations. All samples contained tetracycline that ranged between 46.2- 47.2 micrograms/kg, which was lower than the maximum residue limit specified for meat samples by European union (100 micrograms/kg). This indicates that tetracycline was used at least once during chicken lifetime as treatment against bacterial infections or as growth promoters.

Conclusions

This study indicated that broiler chicken meat products contained various amounts of residues of antibiotic and anabolic agents. Although, levels of some of these did not exceed the maximum residue limit in most cases, they still poise human health hazard. Residues of antibiotics may cause development of resistant pathogenic strains.

DNA-FINGERPRINTING OF *CAMPYLOBACTER* SPP. FROM POULTRY AND GENETIC RELATIONSHIP OF SELECTED STRAINS TO HUMAN ISOLATES

Klein, G.[1], Beckmann, L.[2], Luber, P.[2] and Bartelt, E.[2]
[1]Institute of Food Quality and Safety, School of Veterinary Medicine, Bischofsholer Damm 15, D-30173 Hannover, Germany
[2]Federal Institute for Risk Assessment, Diedersdorfer Weg 1, D-12277 Berlin, Germany

Background

An important source of infection with *Campylobacter* is considered to be raw poultry meat. A lot of broiler flocks are infected with *Campylobacter* spp. (Newell & Wagenaar, 2000), in Germany about 41% (Atanassova & Ring, 1999). Chicken colonized with *Campylobacter* spp. excrete large amounts of bacteria (Stern et al., 1995). After colonized birds have entered the slaughterhouse processing lines *Campylobacter* can be found on the chicken carcasses throughout the slaughtering process and result in contamination of equipment, working surfaces, process water and air (Jacobs-Reitsma, 2000). On the other hand case-control studies have identified the handling and consumption of poultry as a major risk factor for *Campylobacter* infections. To evaluate the spread of *Campylobacter* through the slaughterline and possible genetic relationship between isolates from poultry products and human isolates DNA fingerprint techniques are needed. Macrorestriction analysis by pulsed-field gel electrophoresis (PFGE) has been used successfully for inter- and intraspecies differentiation of *Campylobacter* (Ribot et al., 2001) and PFGE is one of the most discriminatory genotypic typing methods currently available for subtyping *Campylobacter* species.

Objectives

The aim of this study was to differentiate isolates of *Campylobacter* spp. at various stages throughout processing with DNA fingerprinting techniques. Genotyping of the selected strains by PFGE should determine subtypes which were common for carcasses and offal and prove if cross-contamination within and between flocks occured. To assess the impact of poultry products as vectors for sporadic *Campylobacter* infections in Germany, in this study the relatedness of *Campylobacter* spp. strains occurring in a 3-month period within the city of Berlin on retail chicken products and in cases of human campylobacteriosis by pulsed-field gel electrophoresis (PFGE) were analysed.

Materials and methods

Eight poultry flocks from different farms were sampled at different dates: flock „a“ and „b“ in June, flock „c“ and „d“ in July,; flock „e“ in August, flock „f“,„g“ and „h“ in September, and flock „g“ in October. Cloacal swabs were taken at the beginning of the slaughter, and neck skin samples before evisceration were taken from each flock. Crates for living birds were sampled before and after washing, carcasses after scalding and neck skin after air spray chilling in some flocks, additionally.
Detection of thermophilic *Campylobacter* spp. was performed by selective enrichment in Preston-broth (Bolton, 1983) following isolation on Preston-agar (Oxoid, CM 67 plus selective supplements SR 117 + SR 48. Oxoid GmbH, Wesel, Germany). One presumptive *C.* isolate from each selective agar plate was identified to species level on the basis of phase-contrast microscopy (characteristic morphology and motility), Gram stain, catalase and oxidase production, growth at 25°C and 43°C, indoxyl acetate hydrolysis, hippurate hydrolysis, and susceptibility to nalidixic acid and cephalotin. All isolates were stored at -80°C in a freezer using the Microbank™ system (PRO-LAB Diagnostics, Cheshire, UK). *C. jejuni* type-strain ATCC 33560^T and *C coli* type-strain ATCC 33559^T were used as controls.
A subset of 154 *Campylobacter* spp. strains were choosen from each flock at each processing station for ribotyping in a previous study (Vollmer, 1996) and the same strains were collected for subtyping with pulsed-field gel electrophoresis.
For the evaluation of the genetic relationship between poultry product isolates and human isolates *Campylobacter* spp. strains were isolated in Berlin, Germany, from January to March 2002. 31 *C. jejuni* and 6 *C. coli* from chicken product samples and 40 *C. jejuni* and 7 *C. coli* from cases of human campylobacteriosis were subtyped.

Poultry food samples (chicken) were taken at retail level. Besides different meat samples (breasts, drumsticks, and wings), sampling included liver, gizzard and heart, presenting the broad range of chicken products consumed regularly by german consumers. Isolation of *C.* spp. from foods was performed in general accordance with the guideline ISO 10272 (International Organization for Standardisation, 1995). Human isolates originated from ambulant cases of diarrhea (stool samples) occurring in Berlin and have been isolated following standard laboratory methods.
Isolates were subtyped by PFGE using the restriction enzyme *Sma*I and *Kpn*I. Strains from poultry products and human isolates were only additionally analysed with with *Kpn*I when identical *Sma*I profiles were found. Preparation of DNA-containing agarose blocks for PFGE was adapted to a "CAMPYNET" prototype standard protocol (http.//campynet.vetinst.dk/PFGE.html) with following exceptions: 500mµl of cell suspension were mixed with 500µl warm 2% inCert-agarose (FMC BioProducts). DNA was cut for 18h with *Sma*I and *Kpn*I at appropriate temperature according to manufacturers instructions (New England Biolabs). Digested DNA plugs were loaded on a 1% SeaKem GTG agarose gel (FMC BioProducts). DNA fragments were separated on a CHEF DR-III apparatus (BioRad) in 0.5xTBE-buffer at 10°C for 22.5h (*Sma*I) or 23h (*Kpn*I). Ribotyping was performed and described in a previous study (Vollmer, 1996).
Computer analysis was carried out with GelCompar 4.1 (Applied Maths). Macrorestriction profiles were evaluated and assigned to arbitrarily-defined "profile groups", using a cut off of 90%.

Results and discussion

A number of genetically distinct *Campylobacter* strains were isolated at different sampling stations per flock. Twenty-one different ribotypes (RT), 24 *Sma*I macrorestriction profiles (MRP)-types and 25 different *Kpn*I MRP-types or profile groups (PGs) were identified. Regarding the distribution of types within the two *Campylobacter* spp. the 13 *C. coli* isolates yielded two different PFGE patterns (PFGE (*Sma*I / *Kpn*I), types X / X and Y / Y), and two different ribotypes (RT 14 and RT 16, respectively). 141 *C jejuni* isolates were divided into 22 distinct PFGE *Sma*I, 23 different PFGE *Kpn*I, and 19 distinct RT profiles, respectively. During the processing line at least one *Campylobacter* subtype appeared only in one flock, and was mainly isolated from cloacal swabs, e.g. PG P/P from flock „f", (Tab. 1). In nearly all flocks sampled, at least one additional *Campylobacter* subtype was recovered from the carcasses or offal at different processing steps compared to the subtypes isolated from cloacal swabs (Tab. 1). Some *Campylobacter* strains with identical profile groups were isolated from different flocks at different times. Strains with PG U / U (*Sma*I / *Kpn*I) were recovered in flock „b" and „h", and strains with PG C / C in flock „b" and „e"in June and September.
It is assumed that *Campylobacter* isolates on carcasses and offal with identical macrorestriction profiles (MRPs) like those detected in cloacal swabs were flock-specific and derived from cross-contamination within flocks during processing, e.g. defeathering or evisceration. The detection of farm-specific *Campylobacter* clonal isolates that occurred in successive rotations strongly indicates that those clones persist on the individual farms, either inside the broiler house or in the near environment (Petersen & Wedderkopp, 2001). Analysis of *Campylobacter* colonization of one flock during the rearing period and contamination of the carcasses at the slaughterhouse by *flaA* typing showed that for example in studies of Rivoal et al. (1999) seven of eight strains isolated from the chicken feces at the farm were also present at the slaughterhouse at neck skins taken directly after evisceration at the processing plant. In addition four other *fla*A-types were collected from these batch only at the slaughterhouse. These results confirm that contamination of broilers during processing was mainly due to the rupture of the gastrointestinal tract during evisceration (Rivoal et al., 1999) and to a lesser extent from other sources. In our study for example, in flock "d" we found only the MRP F and the RT 07 from cloacal swabs on carcasses and offal.
Genotyping by PFGE of poultry product isolates and human isolates identified 15 *Sma*I patterns that occurred in more than one isolate (n=50). As shown in table 2, the same *Sma*I pattern was found in up to 7 isolates. After the second analysis using the restriction enzyme *Kpn*I, 56 of the 84 isolates in total had a unique *Sma*I/*Kpn*I PFGE-profile, whilst 28 had a profile they shared with 1 to 5 other strains. The *Sma*I/ *Kpn*I -profiles III-6, V-12, and XI-24 encompassed human and poultry isolates. Two subtype groups with identical profiles were formed by strains of human origin only (VIII-19 and XIV-31) and 4 groups encompassed only strains of poultry origin (I-1, II-4, VI-15, XII-25). Genotyping by PFGE revealed a high degree of diversity, which is a well-known phenomenon for bacteria of the genus *Campylobacter*. But despite the weak clonality of *C.* spp., 10.6% of human isolates were genetically identical with isolates found in the same geographical region and time frame on retail chicken products.

Conclusions

The populations of *C. jejuni* and *C. coli* are extremely diverse and this diversity is refelcted in a broad spectrum of subtypes. Distinct flocks could be colonized with different types of *Campylobacter*. One flock could be colonized by multiple genotypes whereas strains within individual flocks coexisted rather than excluding each other. In addition more than one strain in each flock may have potential epidemiological importance. Concerning the possible genetic relationship of poultry product isolates and human isolates it can be concluded that retail chicken products are an important source for sporadic human infections with *C.* spp. in Germany.

INFLUENCE OF FERMENTATION ON CREATINE AND LACTATE CONCENTRATIONS IN WHITE EFFLORESCENCES ON DRY FERMENTED SAUSAGE

Kröckel, L.

Institute for Microbiology and Toxicology, Federal Research Centre for Nutrition and Food
E.-C.-Baumann-Str. 20, D-95326 Kulmbach, Germany

Background

Undesired white efflorescences or surface blooms on packaged dry fermented sausages have been repeatedly observed in recent years. Since around the mid-1980ies this phenomenon was noticed with products packed in polyethylene (PE) bags under protective atmospheres such as nitrogen. The problem is observed worldwide wherever dry fermented sausages are produced (Kroeckel, unpublished). The efflorescences are known to be due to racemic magnesium-di-lactate derived from microbially produced D,L-lactate and meat-borne L-lactate (Kuehne *et al.*, 1986) and/or meat-borne creatine (Kroeckel *et al.*, 2003). Dew point changes during storage of the packaged sausages apparently favour the formation of these blooms.

Objectives

There is no published work so far on the nature of efflorescences on different types of dry fermented sausages. Also, it is not clear how the formation of the coatings can be prevented. To get more insight into the conditions necessary for the generation of the efflorescences their appearance and composition have to be related to sausage parameters such as type of sausage, physical characteristics as well as chemical and microbiological composition. The present study aimed at collecting this kind of informations and detecting links between these parameters and bloom formation.

Materials and methods

Different types of sausages with characteristic efflorescences were obtained from various national and international manufacturers. From all sausages the composition of the blooms were analysed. On a limited number of samples further analyses were performed to varying extent. Creatine and lactate were determined as described earlier (Kroeckel *et al.*, 2003). Physical (pH, a_w, water content) and microbiological parameters were determined using standard methods. Mg^{++} in the efflorescences was determined complexometrically.

Results and discussion

Rapidly fermented smoked salamis produced in Germany

Paprika salamis of manufacturer H. All salamis (samples no. 1 – 6 in Tab. 1) were vacuum packed upon arrival. The white efflorescences became visible within minutes after removal of the packaging foil and reached maximum intensity within 3 – 4 hours. According to the manufacturer, the sausage recipe contained pork, nitrite curing salt, spices (including paprika extract), sugars (lactose, maltodextrine, dextrose). The white blooms were found to contain 60 – 64 % of D,L-lactate and only 0.3 % of creatine (Tab. 1). The magnesium content in the blooms of sausage no. 2 was 8.7 %. The sausage with the strongest efflorescence (80-90 % of the casing surface affected) had the lowest water activity (sample no. 2 in Tab. 1). The sausage with the highest water activity and the highest water content (sample no. 1 in Tab. 1) showed almost no efflorescence, although the lactate content inside the sausage was even higher than in sample no. 2. Bloom formation was stronger in older sausages, i.e. those with lower residual shelf life (RSL). Therefore, bloom formation does not only depend on water activity but also on storage time after packaging. The extent of blooming was higher in sausages without dry fringe which indicates that the formation of a dry fringe possibly reduces blooming. Microbiological analysis showed remainder of starter culture lactic acid bacteria (*Pediococcus pentosaceus* and *Lactobacillus plantarum*) and other LAB. D(-) and L(+) lactate were found in similar ratios in the blooms and inside the sausages. However, the concentrations outside were 13 – 20 times higher than inside. D(-) lactate is derived exclusively from microbial activities, in contrast to L(+) lactate which is present already to some extend in *post rigor* muscles, usually at concentrations below 1%. Taking into account the participation of magnesium and considering the hydrated form of Mg-D,L-lactate, the tri-

hydrate, the value of 63.9 % of lactic acid for sample no. 6 would correspond to about 91 % of [Mg-D,L-lactate] x 3 H_2O in the white blooms.

Tab. 1: Chemical and microbiological characteristics of paprika salamis from manufacturer H showing white surface blooms after removal from the vacuum packs.

Paprika salami of manufacturer R. One sample (calibre: 45 mm, pH 5.0) was obtained in modified atmosphere package. In the bloom a lactic acid concentration of 57.9 % (D : L = 1.0) was found. Magnesium amounted to 7.0 % and creatine was below the detection limit (< 30 µg/g). Inside the sausage D,L-lactic acid amounted to 2.0 % (D : L = 0.95). Thus, the scraped off crystalls corresponded to 58 - 69 % Mg-D,L-lactate or 74 - 87 % of its tri-hydrate. Microbial analysis revealed 2 x 10^7 CFU/g LAB and 10^4 CFU/g *Micrococcaceae*.
Smoked salami of manufacturer GH. Blooms from three sausages (calibre: 50 mm) were found to contain 50.5 % D,L-lactic acid (D : L = 1.0), 7.8 % magnesium and 23.4 % creatine. Assuming that racemic Mg-di-lactate is present as its tri-hydrate, the analytical results explain 100 % of the composition of the efflorescences.

Slowly fermented salamis and thin calibre dry fermented sausages

French saucisse of manufacturer B. All salamis arrived packed in PE foils under modified atmosphere. Recommended storage was below 18 °C. White efflorescences were visible already before removal of the sausages from the packages. According to the manufacturer, the sausage recipe contained pork, common salt plus nitrate, spices, sugars (lactose, dextrose, sucrose), lactic acid bacteria (LAB) and ascorbate. Microbiological analysis showed reminder of starter culture bacteria (*Lactobacillus plantarum, Micrococcaceae*) and other LAB (Tab. 2). Both, D(-) and L(+) lactic acid were present in the sausages in similar ratios but in comparatively small concentrations indicating that only a mild fermentation had taken place before further ripening (drying). The relatively high pH of 5.7 is a typical result of this kind of salami

technology. The residual shelf life was comparable to the paprika salami sample no. 2 in Tab. 1 while the water activity was even lower.

[a] residual shelf life; [b] estimatet by eye; [c] $\log_{10}$ CFU/g sausage;

Tab. 2: Slow fermented salamis (saucisses) in modified atmosphere packages showing white surface blooms already before removal from the packages.

The creatine concentration inside the sausage was at the upper limit of what should be expected and, the efflorescence was composed of creatine only. Magnesium was not detected in the blooms. These results suggest that at pH values around 5.7 only minor amounts of Mg-D,L-lactate is formed. Also, creatine is more stabile at pH 5.7 than at pH 4.5 (see paprika salamis in Tab. 1).

German thin calibre dry fermented sausages. Salami-style sausages in sheep gut casings (10 mm calibre) were obtained in a PE package under protective atmosphere with a residual shelf life of 24 days. According to the product label the sausages were smoked and were composed of pork, nitrite curing salt, spices, glucose, taste enhancer and wort. The surface blooms were not visible upon arrival but were inducible by subjecting the packages to repeated temperature changes (8 °C / 20 °C). The efflorescences formed consisted almost entirely of creatine (83 %) and did not contain any lactate. The pH value of the sausages was around 5.8 – 5.9, i.e. even higher than the pH of the French saucisse in Tab. 2. The concentration of D,L-lactate in the sausage was 10.9 mg/g (D : L = 0.36). The D:L ratio indicated that hardly any microbial lactic acid formation had taken place, i.e. the sausages were more dried than fermented. The LAB count was less than 10^4 CFU/g, probably because of the low water activity of 0.812. The creatine and creatinine contents of the sausage were 2.4 mg/g and 0.4 mg/g, respectively.

Other thin calibre sausages. Creatine was present in the surface crusts of vacuum packaged ‘beersticks’ from New Zealand and, in the efflorescences of four loose sausages that apparently had been subjected to storage conditions favouring bloom formation. The pH values of the sausages ranged from 5.4 to 6.1. The white coating obtained from sample no. 1 in Tab. 3 also contained some D,L-lactate which, however, was about 10 times lower in concentration than creatine. Interestingly, there was hardly any D(-) lactate inside this sausage. This finding is in agreement with the low LAB count which suggests a drying-type process rather than a fermentation-type process. However, the LAB count also may have been reduced by the low water activity in this sample. In contrast, samples no. 3 – 5 showed a typical bacterial count of a fermentation microflora.

Tab. 3: Characteristics of some thin calibre dry fermented sausages from different origin.

Conclusions

The fermentation process determines the nature of the surface blooms on dry fermented sausages while bloom formation itself is determined by physical factors such as water activity of the sausages and storage conditions. Racemic lactic acid is the major component of efflorescences on dry sausages which were subjected to a rapid fermentation in the presence of added starter cultures and fermentable carbohydrates. In contrast, slowly fermented dry sausages and thin calibre dry sausages which are more dried than fermented may contain creatine as the sole component. High pH values in the sausage favour creatine blooms while low pH values favour Mg-di-lactate blooms. Appearance of the efflorescences is correlated with water activities of the sausages in the range of 0.81 – 0.88. Some efflorescences may contain both, creatine and Mg-D,L-lactate. The results of this study may help to develop strategies for preventing undesired efflorescences on dry fermented sausages.

PHYSIOCHEMICAL PROPERTIES OF DRY-CURED HAMS FROM TAIWAN BLACK PIGS AND LYD HYBRID PIGS

Deng-Cheng Liu[1], Pai-Chan Huang[1], Chen-Lung Shiao[1] , Ming-Tsao Chen[1] and Fa-Jui Tan[2]

[1]Department of Animal Science, National Chung-Hsing University, Taichung, Taiwan
[2]Department of Diet and Restaurant Management, Chung-Shan Medical University, Taichung, Taiwan

Background

Taiwan black pigs is a local two-way crossed pig breed in Taiwan area, which is crossbred by Taoyuan pigs and Duroc pigs (75%)(Tai *et al.*, 1992). Taiwan black pigs need be fed for 10-12 months and the average marketing live weight is 140-150kg. Meanwhile, LYD hybrid pigs are generally raised for meat pigs in there and need be fed for 5.5-6.0 months for marketing (average live weight: 110-115 kg). According to Tai *et al.*(1997) and Liu and Hsu (2000) the fat content and marbling degree of Taiwan black pigs were higher than that of LYD pigs but the moisture content was lower than LYD pigs.
Dry-curd ham constitutes one of the most traditional meat products, which after a long processing time become a tasty and flavorful products as a consequence of a great number of both physico-chemical and biochemical transformation such as an increase of small peptides, free amino acids and free fatty acids. A clear relationship has been established between the quality of the raw ham from different pig breeds and the sensory quality of the dry cured products (Antequer *et al.*, 1994; Aristory and Toldr'a, 1995; Berdague' *et al*., 1993 ; Gou et al., 1995; Parolari et al., 1994).

Objectives

The purposes of this study was to manufacture dry-cured ham from ham part of Taiwan black pigs (Taoyuan pigs x Duroc pigs(75%), feeding period: 10months) and LYD hybrid pigs (Landrace x Yorkshire x Duroc(50%), feeding period: 5.5 months) and investigate the change of the physiochemical properties of dry-cured hams during processing and ripening (300days).

Materials and methods

Ham : twenty Taiwan black pigs hams weighing 12-14kg and twenty LYD crossbreed pigs hams weighing 10-11kg were selected to manufacture dry –cured ham in this study. Processing: The hams were refrigerated for one day at 2-4℃ and then nitrified with a dry salt mixture of 10g of NaCl, 0.1g of $NaNO_2$ and 0.15g $NaNO_3$, per kg of ham. After 24hr they were covered with salt for a period. Afterwards the hams were washed in cold water and hung at 3-5 ℃in an atmosphere with a relative humidity between 80-85% for 60days, increasing the temperature to 13-15℃ and decreasing relative humidity to 65-70% then they remained at these conditions until the end of ripening period (300days). Sampling: three Taiwan black pigs and three LYD crossbreed pigs hams were sampled at each of the following periods: 24hr postmortem, resting (60days=aging 0 day) and aging (60, 120, 180, 300). When fat and skin had been removed the lean tissue (including *M. rectus femoris, M. vastus medialis, M. vastus lateralis, M. semitendinosus, M. semimembranosus, M. biceps femoris*) was taken out by a stainless sampling tube (cone dimeter:2.5cm) from meat side of hams, the lean tissues were divided into two parts , one centimeter distance from meat side was external part sample, overpassed one centimeter was internal part sample. Physicochemical assay: yield and weight losses of hams were evaluated relative to their initial fresh weight. The proximate contents of raw hams were determined by AOAC (1990). The moisture, NaCl concentration, water activity (A_w), protein hydrolysis index of the dry hams were tested in this experiment. Finally, the sensory panel test of dry-cured hams was evaluated after the ripening of 300 days. A scale from seven to zero was employed for all sensory attributes in this study.

Results and discussion

The results showed that the crude fat of raw and the end dry-cured hams from Taiwan black pigs were higher than that of LYD hybrid pigs, but moisture protein and ash content were not significantly different between the two breeds ($p > 0.05$). The yield of dry-cured ham was 62.35% for Taiwan black pigs and 63.43% for

LYD hybrid pigs, respectively. The pH value of dry cured ham from the two breeds significantly increased with ripening time ($p<0.05$) but no difference was found between the breeds. In the meantime, the moisture, internal and external water activity of dry-cured ham from the two breeds had no significant difference but significantly decreased ($p < 0.05$) during ripening period. The color of raw hams from the two breeds showed light red color, and then became dark red in the end products. The salt content of dry cured ham from the two breeds significantly increased with ripening time ($p < 0.05$) and was 6.97and 6.90% respectively in the end products. The nitrite residue of dry cured ham from the two breeds significantly decreased with time ($p < 0.05$). The proteolysis index was 25.97% for the end products of Taiwan back pigs, and 24.82% for the end products of LYD hybrid pigs at the ripening 300 day. However, the sensory panel scores of dry cured ham from Taiwan black pigs were better than those of LYD hybrid pigs.

Conclusions

Hams from Taiwan black pigs have some advantages over those from LYD hybrid pigs in dry cured ham production: a higher fat content and marbling and a higher proteolysis index. The only sensory difference between hams was found in flavor trial. The Taiwan black pig is possibly better for dry-cured ham production under the processing condition used in this study.

CHARACTERIZATION OF *STAPHYLOCOCCUS AUREUS* ISOLATED FROM A SLAUGHTERHOUSE FOR PIGEONS BY RAPD-PCR AND REA-PFGE

Losito P.[1], Blaiotta G.[2], Vergara A.[1], Villani F.[2], Ianieri A.[1]

[1] Department of Food Science, Piazza Aldo Moro 45, 64100, University of Teramo, Italy;
[2] Department of Food Science, Via Università, 100, 80055 Portici, University of Naples "Federico II", Italy.

Background

S. aureus is a common etiologic factor of foodborne infections and intoxication and is a significant marker of food quality and surface cleanliness (Losito *et al*., 2004). Recently, a variety of molecular methods have been used to clarify staphylococcal identification, including RAPD-PCR and REA-PFGE (Restriction Endonucleases Analysis-Pulsed Field Gel Electrophoresis) (Matthews *et al*., 1997). However, no information is available concerning the intraspecies differentiation of *S. aureus* isolated from a slaughterhouse for pigeons by these genetic procedures.

Objectives

In the present study, RAPD-PCR and REA-PFGE were used to characterize *S. aureus* strains originating from a slaughterhouse for pigeons and to assess the practical value of these typing methods for the discrimination among strains.

Materials and methods

Bacterial strains. The source of isolation of the 38 wild strains used in this study is shown in Table 1. Strains were grown in Brain Heart Infusion broth (BHI) (Oxoid Ltd., Basingstoke, Hampshire, UK) at 37°C. Before DNA extraction, cultures were streaked on BHI agar plates and grown overnight at 37°C.

DNA isolation for PCR assays. DNA extraction was carried out from a single colony by using an InstaGene Matrix (Bio-Rad Laboratories, Hercules, CA) following the conditions described by the supplier. About 25 ng of DNA were used for PCR amplification.

Identification of *S. aureus* strains by PCR. The thermostable nuclease (*nuc*) was amplified for the identification of *S. aureus* strains. Sequences of the primer set for the *nuc* gene were first described by Brakstad *et al*. (1992) (Table 2).
PCR mixtures were prepared as described in Blaiotta *et al*. (2004). After the denaturing step for 3 min at 95°C, 35 amplification cycles (5 s at 95 °C for the denaturing step, 30 s at 58 °C for the annealing-extension step) were performed for detection of *nuc* gene. The PCR products were resolved by agarose (2 % w/v) gel electrophoresis at 7 V cm^{-1} for 2 h.

RAPD-PCR amplifications. RAPD-PCR analysis was performed in a total volume of 25 µl using primers PRIM 239 (CTGAAGCGGA) and XD9 (GAAGTCGTCC) in the same reaction. RAPD-PCR mixtures were prepared as reported by Moschetti *et al*. (2000). Amplification was carried out in a programmable heating incubator for 40 cycles (1 min at 94 °C, 1 min at 31 °C, 2 min at 72 °C per cycle). Finally, a 7 min extension period at 72 °C was performed. Amplified products (25 µl) were resolved by electrophoresis on a 2 % (wt/vol) agarose gel at 7 V cm^{-1} for 2 h.

REA-PFGE (Restriction Endonucleases Analysis-Pulsed Field Gel Electrophoresis). Genomic DNA of high molecular weight was prepared as previously described Blaiotta et al. (2001). Inserts of intact DNA were digested in 200 µl of appropriate buffer supplemented with 40 U of *Sma* I (Promega). Electrophoresis of the restriction digests was performed by using the CHEF system (Bio-Rad Laboratories, Hercules, CA, USA) with 1% (wt/vol) agarose gels and 0.5 x TBE as running buffer, at 10 °C. Restriction fragments < 560 kb were resolved in a single run, at constant voltage of 6 V cm^2 and an orientation angle of 120° between electric fields, by a single phase procedure for 24 h with a pulse ramping between 1 and 50s.

Results and discussion

Results obtained by RAPD-PCR and REA-PFGE are depicted in Table 3. Examples of RAPD PCR and REA-PFGE patterns are showed in Fig.1 and Fig.2 respectively. RAPD PCR technique produced 9 different pattern-types among the 38 strains of *S. aureus* analysed. The most common RAPD PCR profile was the A one. The strains mostly isolated from the defeathering machine and worker's overall during all samplings produced this pattern. The number of the patterns went up to 25 using REA-PFGE. The strains isolated from the defeathering machine during the three samplings showed six different REA-PFGE patterns; one of them was isolated before slaughtering. The four strains from worker's hand produced three REA-PFGE patterns. The profile G was the only one common to different samplings. It was found on worker's overall during the first and the third sampling.

Conclusions

Results obtained during this study confirm that REA-PFGE technique is more discriminatory than RAPD (Raimundo *et al*., 2002; Al-Thawadi *et al*., 2003). A good discrimination among the strains is a very important step for the contamination monitoring above all in the slaughterhouse environment where the microbial contamination levels are always high. Our results underline the elevated differentiation percentage of the strains of *S. aureus* present in a slaughterhouse for pigeons. The findings also point out that the REA-PFGE technique could be a useful tool to reveal the contamination sources.

COLONISATION OF PIGLETS BY GENOTYPES OF *CAMPYLOBACTER COLI*

Madden, R. H.[1] and Soultos, N[2].

[1]Food Microbiology Branch, DARD, Newforge Lane, Belfast BT9 5PX, Northern Ireland. [2]Department of Hygiene and Technology of Foods of Animal Origin, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki 540 06, Greece

Background

In Northern Ireland (NI) *Campylobacter* spp. are the principal cause of gastro-enteritis (Anon. 1995) with *Campylobacter jejuni* responsible for 90-95% of cases and *Campylobacter coli* causing the majority of the remainder, as is the case in most developed countries. A local survey of campylobacters in deep tissues of freshly eviscerated porcine liver (Moore and Madden, 1998) showed that 50% of the *Campylobacter* spp. isolated were *C. coli* however only 6% of livers were contaminated. In contrast 71.7% of samples of retail pig liver in England and Wales carried *Campylobacter* spp. with *C. coli* dominant, being found in 42.4% of samples. Subsequent investigations of pig faeces showed high *C. coli* carriage rates, as reported elsewhere (Blaser *et al.* 1983). Pigs are a natural reservoir of *C. coli* (Weijtens *et al*. 1993) and hence pork products may represent a risk to consumers. Skirrow (1991) concluded that *C. coli* from pigs are probably an important source of clinical infection in countries where pork is eaten salted or lightly cooked.

Objectives

Pigs are known to carry a wide range of *C. coli* genotypes and one pig may carry several (Weijtens *et al*. 1997). A detailed sampling of a single litter, and their mother, over the first 10 weeks of life was undertaken to allow a better understanding of the colonization of pigs by distinct *C. coli* genotypes.

Materials and methods

All media used were obtained from Oxoid, Basingstoke, UK, and all chemicals from Sigma-Aldrich, Fancy Road, Poole, UK.

Sampling of pigs. Pigs were sampled in the farrowing unit of an experimental farm. Litters were not allowed to associate but no exceptional measure were made to avoid cross-infection of the litters. Anal sampling of pigs was based on the method previously described (Madden *et al*. 2000). Swabs were locally made and consisted of cotton gauze fixed to a flat wooden support and had a surface area of approximately 6cm^2. Swabs were moistened in sterile peptone saline diluent prior to use and each pig was swabbed once. The swab was then broken into a sterile disposable universal. All samples were stored at 4^{0}c for transport to the laboratory and analysis commenced within two hours of sampling.

Six specific piglets in a single litter were selected using the unique identifier tattooed on its ear and sampled 6 times, using anal swabs, over the first 10 weeks of life. The sow was also sampled on each visit.

Isolation of *Campylobacter* spp. Swabs were streaked onto modified charcoal cefoperazone desoxycholate agar (mCCDA) (Bolton and Robertson, 1984) and incubated (42^{0}C) in a Don Whitley Mk III anaerobic cabinet (Don Whitley Scientific Ltd, Shipley, Yorks., UK) using a gas mix of 5% O_2, 10% CO_2, 85% N_2. Plates were examined daily for up to 5d and colonies characteristic of *Campylobacter* spp. selected and purified. Five isolates per plate were picked from each of the six piglet samples and twenty from those of the sow. All colonies morphologically characteristic of campylobacters were subjected to initial phenotypic characterisation and all *Campylobacter* spp. identified to species level using standard biochemical tests (Bolton and Robertson, 1982). They were then stored using 'Cryovials' (Technical Service Consultants, Heywood, Lancs. GB) at -80^{0}C.

Genotyping. Polymerase chain reaction/restriction fragment length polymorphism (PCR/RFLP) typing of the *flaA* gene was conducted using the method of Nachamkin *et a.l* (1993) whilst random amplification of polymorphic DNA (RAPD) was performed as previously described (Madden *et al*. 1996). Pulsed field gel electrophoresis (PFGE) was by the method of Thomson-Carter *et al*. (1993) using *Sma* 1. All profiles were analysed using Gelcompar (V 4.1) software.

Results and discussion

Sampling was initiated 3d after the piglets were born and at that time the sow and 3 piglets carried *Campylobacter coli*, the remaining 2 piglets yielded no campylobacters. Subsequently *Campylobacter* spp. were isolated from all samples. All isolates from the piglets (n=165) were identified as *C. coli*. The carriage rate of 100% from 17d of age onwards is higher than that reported by Weijtens *et al.* (1997), who found 85% positive after 4 weeks and Steinhauserova *et al.* (2001) who reported 41% of healthy piglets up to 8 weeks old. However Weijtens *et al.* (1997) noted that significant differences in carriage rates were found between farms, hence this could account for the differences reported. The sow died when the piglets were 14d old and was replaced by a foster sow. The latter was sampled when the piglets were 17d and 31d old and carried *Campylobacter lanienae*, with 20 isolates and 19 isolates being found out of 20 samples taken on the respective days. One *C. coli* isolates was found on the second sampling and subsequently all isolates were of this species. Overall 120 isolates from the sows were studied.
When the piglets were 27d old some piglets from a neighbouring litter briefly gained access to the pen, and on day 31 four of the neighbouring piglets were sampled to obtain isolates for comparative purposes.
Genotyping was conducted by RAPD, PCR-RFLP and PFGE and *C. coli* isolates were characterized according to their initial source of isolation i.e. mother, neighbour or other. Based on this characterization the genotypes isolates obtained from the piglets and the sow showed the same trend hence the mean is shown below, Figures 1 and 2.

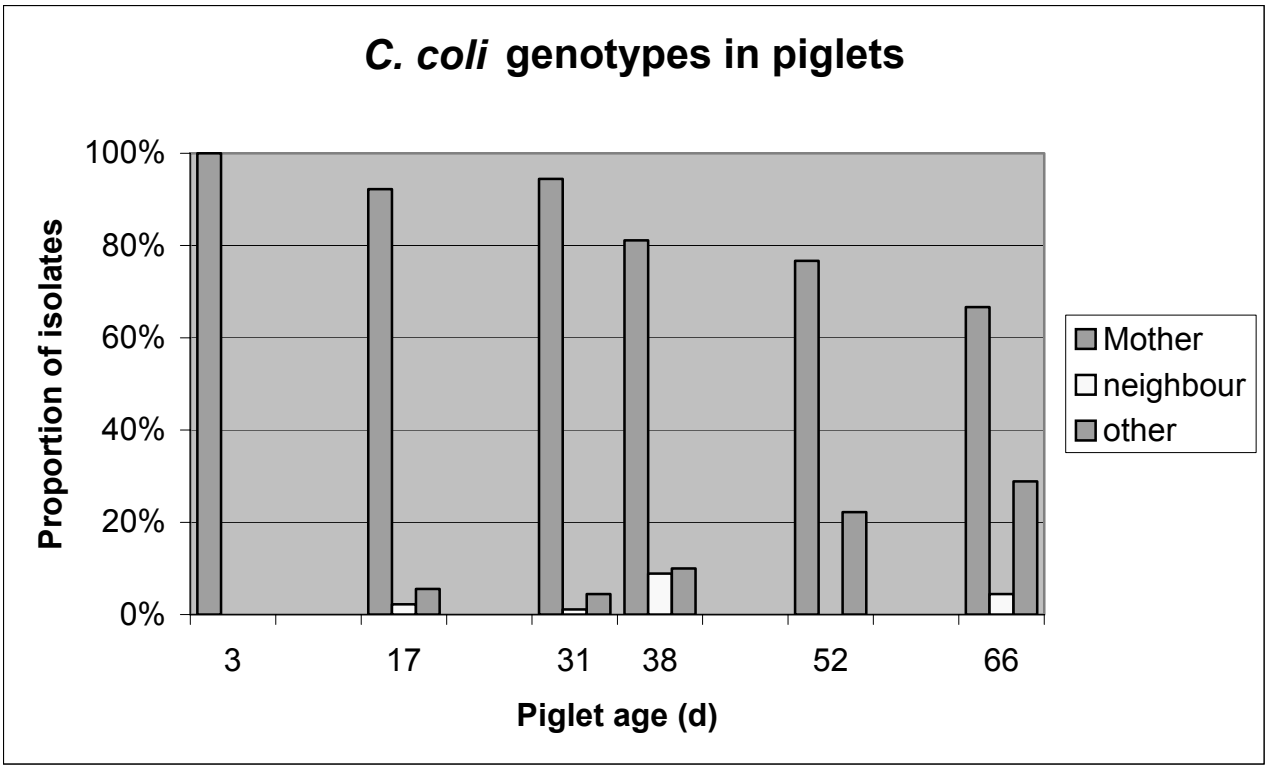

Figure 1. Distribution of *C. coli* isolates from piglets time (piglet age), based on the mean number of genotypes from three methods applied (PCR-RFLP of *flaA*, PFGE and RAPD).

The piglets show a clear trend of initially being colonized solely by *C. coli* strains from the mother but then, over the study period of 66 days, acquiring some from other sources causing replacement of the maternal genotypes. These results contrast with those of Hume et al. (2002) who reported that, in a study of 99 C. coli isolates from 3 sows and 17 piglets, there was no pattern of shared PFGE genotypes between sows and their respective piglets, nor between littermates. However in that study broth enrichment was used and enrichment conditions can affect the range of *Campylobacter* species (Madden *et al.* 2000) and genotypes (Madden et al. 2003) found. Weijtens *et al.* (1997) reported that a large diversity of campylobacter genotypes (determined by ERIC-PCR and RFLP) was found in piglets and their sows, as was the case in this study. In addition they noted that identical genotypes were found in piglets and their mothers and hence suggested that piglets became infected via their mothers, which is in agreement with the findings of this study (Fig. 1). However ,

the study reported here also shows that colonization is highly dynamic and point sampling will only record what is happening at one instant, in a very dynamic situation.

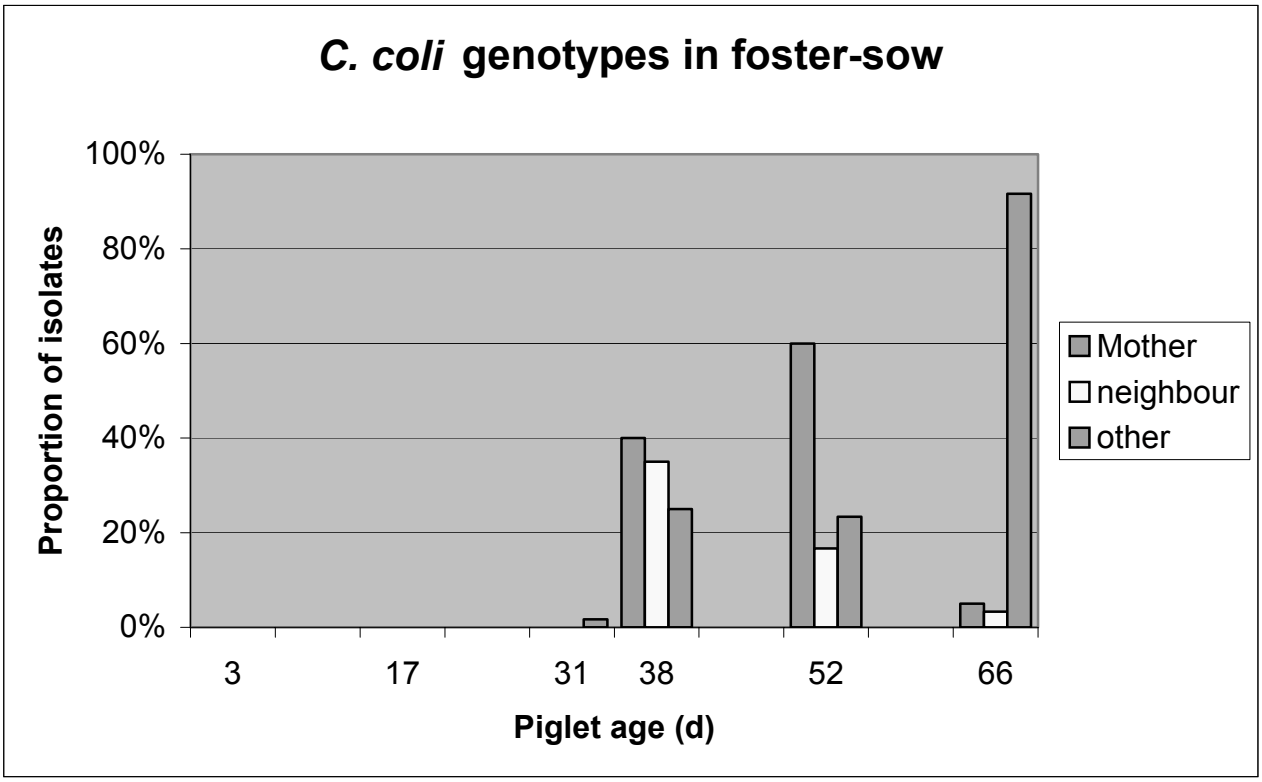

Figure 2. Distribution of *C. coli* isolates from foster-sow (introduced at age 15d of piglets) with piglet age, based on the mean number of genotypes from three methods applied (PCR-RFLP of *flaA*, PFGE and RAPD). Sampling on 17d and 31 d of age yielded 39 campylobacters, but only 1 *C. coli*.

The dynamic nature of colonization is illustrated by the results seen with the foster mother, (Fig 2). On arrival this sow was dominated by a *Campylobacter* spp. which was completely replaced (within 24d) by *C. coli* genotypes, the majority of which had been found in the original mother or the neighbouring litter. Thus whilst transmission from the sow to the litter appears to occur the process can also occur in reverse with the sow being infected from the litter, or nearby litters. Colonization by *C. coli* is highly dynamic in nature and displacement of dominant genotypes appears to occur regularly, even in adults.

Conclusions

Pigs and piglets have been reported as carrying several genotypes of *Campylobacter coli.* This study confirms that finding and shows that piglets are infected by their mother but can subsequently acquire other genotypes in a matter of days. The dominant genotypes in the piglets studied changed constantly over the 10 week sampling period, but the trend was for other genotypes to replace the maternal ones. In addition the sow can acquire new genotypes from her piglets and surroundings, and also displays a constant change in the dominant genotypes detected. Such a dynamic system means that attempts to use genotyping of *C. coli* in epidemiological studies involving pork products are unlikely to succeed. However piglets may prove a useful system in which to study genetic changes of *C. coli.*

OPTIMISATION OF THE ISOLATION OF *CAMPYLOBACTER SPP.* FROM RETAIL PACKS OF RAW POULTRY

Madden, R. H.[1, 2], Moran, L.[1] and Scates, P.[1]

[1]Food Microbiology Branch, DARD, Newforge Lane, Belfast BT9 5PX, Northern Ireland. [2]Department of Food Science, Queen's University of Belfast, Newforge Lane, Belfast BT9 5PX, Northern Ireland.

Background

In Northern Ireland (NI) *Campylobacter* spp. are the principal cause of gastro-enteritis (Anon. 1995) with *Campylobacter jejuni* responsible for 90-95% of cases and *Campylobacter coli* causing the majority of the remainder, as is the case in most developed countries. Local surveys of campylobacters in retail packs of poultry have shown levels of 65% (Flynn *et al.* 1994) and 57% (Wilson, 2002). In order to conduct a survey to determine the current level the most effective current isolation procedures were required. Accordingly one of the most commonly used campylobacter enrichment broths, Preston broth, was selected for comparison in a trial with a much newer medium, Bolton broth. Locally Preston broth had shown up to 100% efficiency in recovering campylobacters from pigs (Madden *et al.* 2000).

Objectives

This investigation sought to compare Bolton (Oxoid, Basingstoke, UK) and Preston (Bolton and Robertson, 1982) enrichment broths for their ability to recover campylobacters from retail packs of raw poultry using the manufacturers protocols. Both overall recovery rates and species diversity were to be evaluated. With the more efficient medium defined a study could then be undertaken to determine the effect of enrichment broth volume (90ml or 225ml) on recoveries of campylobacters. The standard 1:9 ratio of samples to broth (w/v) was to be used in both cases. Use of the lower volume would significantly reduce costs where large numbers of samples were to be analysed. Finally the consequences of the choice of incubation temperature, 37^{O}C or 42^{O}C, and duration, 24h or 48h, on the subsequent isolation rates of campylobacter species were to be investigated.

Materials and methods

All media used were obtained from Oxoid, Basingstoke, UK, and all chemicals from Sigma-Aldrich, Fancy Road, Poole, UK.

Sampling of retail poultry packs.

Retail packs of chilled poultry were purchased from local supermarkets and butchers. In supermarkets the EC processor codes and pack 'sell by ' dates were used to ensure a diverse range of samples. Analyses commenced within 2h of purchase.

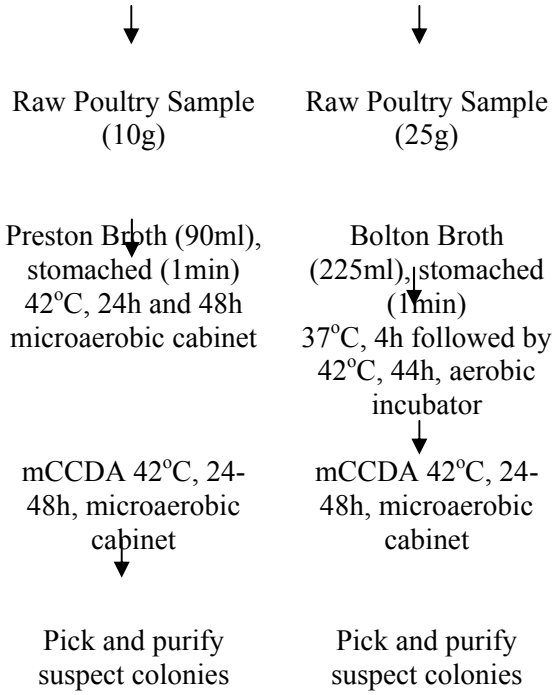
Comparison of methods for the isolation of *Campylobacter* spp.

Modified charcoal cefoperazone deoxycholate agar (mCCDA) was used as the plating medium with both Preston and Bolton broth. Figure 1 shows the enrichment protocols as used to compare Preston and Bolton broths (n=40), The former was based on a previous local study (Scates *et al.* 2003) and the latter was as described by Bayliss *et al.* (2000). In addition Preston medium was evaluated with 25g of sample and 225 ml of broth whilst Bolton broth (90ml) was inoculated with 10g of sample. The samples in Bolton broth were enriched for both 24h and 48h in a microaerobic atmosphere (85% N_2, 10% CO_2 and 5% O_2 in a Don Whitley Scientific Mk III anaerobic cabinet (Don Whitley Scientific, Shipley, UK)) to allow the effect of the incubation time on recoveries to be observed. Levels of contamination on mCCDA were assessed by using a standard plating technique and scored according to the apparent level of non-campylobacter growth in each streak (Bayliss *et al*. 2000). Presumptive *Campylobacter* isolates were characterised using a PCR method in order to determine genus (Linton *et al.* 1996) and a multiplex PCR method (Vandamme *et al.* 1997) to speciate *C. jejuni* and *C. coli.*

Local practice has been to incubate the enrichment broth under microaerobic conditions, as well as the selective solid medium. A comparison of microaerobic and aerobic incubation of 10g samples (n=21) in Bolton broth (90ml) was conducted to determine if this practise had any effect on recoveries .

With the selection of the optimal medium and sample size a trial sampling of 100 retail packs was undertaken using two incubation regimes, 37°C, 48h and 37°C, 4h followed by 42°C, 44h.

Figure 1. Comparison of the two methods compared for the isolation of *Campylobacter* spp. from retail packs of raw poultry. All incubations were microaerobic.



Results and discussion

Forty retail packs of poultry were studied to compare recoveries of campylobacters using the manufacturers recommended protocols, Figure 1. Included in the trial was a comparison of the effect of using 90ml and 225ml of both enrichment broths with a 1:9 sample:broth (w/v) ratio. Analysis of variance showed significantly more samples were positive for campylobacters using Bolton broth (n=27) than with Preston (n=24) using the protocols in Figure 1 (p=0.004). This is in agreement with findings of Bayliss *et al.* (2000) who used 25g samples inoculated into 225ml volumes of both enrichment broths. Bolton broth was more efficient at suppressing non-campylobacter flora than Preston broth which, when incubated for 24 and 48 h, yielded 2.4 and 3.6 times more contaminants respectively.

There was no statistically significant difference (p=0.439) between recoveries of campylobacters from 10g samples incubated in 90ml, as opposed to 25g in 225ml, with either medium. Hence the more economical lower volume could be adopted with no significant loss of sensitivity with either Preston or Bolton broth. This result may reflect the relatively high level of contamination of retail poultry with *Campylobacter* spp. (Jorgensen, 2002)

One *Campylobacter* isolate was obtained from each positive sample obtained using the two enrichment media, and two sample weights, and identified, Table 1. Again Bolton broth was seen to be superior as it allowed the detection of a significant number of *C. coli* isolates. Note that mixed cultures of *C. jejuni* and *C. coli* were detected by this procedure indicating that the preliminary picking and re-streaking procedure did not yield a pure culture. This is a frequent observation with this genus in our laboratory, indicating that repeated streaking is essential to ensure that a pure culture is obtained for subsequent studies.

Normally in our laboratory all *Campylobacter* incubations are conducted in a microaerobic atmosphere therefore the effect of microaerobic versus aerobic incubation was investigated. Samples of raw poultry (n=21) were inoculated into Bolton broth, using 10g inoculum, and incubated at 37°C for 4h followed by 44h at 42°C both aerobically and microaerobically. Microaerobic incubation of the enrichment broth was

seen to give the higher recovery of campylobacters with 62% of samples positive, whilst in air 52% of samples were positive. Thus microaerobic incubation of Bolton broth was seen to be the more efficient method .

Table 1. Identification of *Campylobacter* isolates from Preston (n=48) and Bolton broth (n=58) using PCR-based procedures. Bolton broth was superior, as it allowed the isolation of a wider range of species and detected more positive samples

.

	Multiplex PCR speciation			
Enrichment medium	*C. jejuni*	*C. coli*	Both *coli* and *jejuni*	Genus only positive
Preston broth (24h)	88%	0%	8%	4%
Bolton broth (48h)	63%	38%	6%	12%

However the incubation temperature of an enrichment broth had been shown to markedly influence the types of campylobacters subsequently isolated (Scates *et al*. 2003), hence incubation at 37^{O}C as well as 42^{O}C could prove beneficial and a trial to compare the two temperatures was designed. This necessitated determining the optimal incubation time for Bolton broth at the lower temperature, and the study was also used to compare the effect of incubation time on recoveries from the broth incubated at 42^{O}C, using the protocol of Figure 1. Samples of raw poultry (n=21) were prepared and streaked out onto mCCDA after 24 and 48h, 37^{O}C, and 42^{O}C. Plates were incubated at the same temperature as the enrichment broths. The 24h incubation time gave higher recoveries, at both temperatures, whilst 48h incubations allowed significantly more non-campylobacters to grow on the mCCDA plates. This is similar to the results seen in previous work with Preston broth where campylobacter recoveries from porcine ileal contents were higher with shorter incubation times (Madden *et al.* 2000).

A survey of 100 samples of retail packs of poultry was then undertaken using the optimised procedures of 10g of sample and 90ml of Bolton broth incubated at 37^{O}C and 42^{O}C for 24h and streaked on mCCDA with the plates being incubated at the same temperature as the enrichment broth. Plates were examined after 24 and 48h. Overall 82% of samples were positive, with incubation at 37^{O}C giving 73% and 42 ^{O}C 75% .

Conclusions

Bolton broth was seen to be better than Preston broth for detecting Campylobacter spp. in retail packs of raw poultry. The former medium also detected significantly more *C. coli* than did Preston broth. The use of a smaller sample size, 10g as opposed to 25g, had no significant effect on recoveries of campylobacters when used at a 1:10 ratio (w/v) with the enrichment broth, but markedly reduced costs. Incubation of Bolton broth for 24h gave better recoveries of *Campylobacter* spp. with fewer contaminants than did 48h.
Incubation of Bolton broth at 37^{O}C and 42^{O}C (with an initial 4h incubation at 37^{O}C), yielded similar number of positive samples but combining the results of both incubations significantly increased the total number of positive samples found.
Overall, therefore, the optimal method in terms of efficiency and cost was the use of 10g sample added to 90ml of Bolton broth and incubated for 24h at either 37^{O}C or 42^{O}C (with an initial 4h incubation at 37^{O}C). The use of both incubation temperatures would be necessary to maximise recoveries.

IDENTIFICATION OF IMPORTANT SPOILAGE BACTERIA AND FUNGI FROM TWO TYPES OF PORTUGUESE SMOKED DRY SAUSAGES AFTER SHELF-LIFE PERIOD IN MODIFIED ATMOSPHERE PACKAGE

Teresa J.S. Matos[a], Bent B. Jensen[b], António Barreto[c] and Ole Hojberg[b]

[a] Escola Superior Agrária de Santarém, Quinta do Galinheiro, 2000 Santarém, Portugal. [b] Department of Animal Nutrition and Physiology, Danish Institute of Agricultural Sciences, Research Centre Foulum, 8830 Tjele, Denmark. [c] Faculdade de Medicina Veterinária. CIISA. UTL. R. Prof. Cid dos Santos - Polo Universitário, Alto da Ajuda, 1300-477 Lisboa, Portugal.

Background

The microbiology of dry smoked sausages is variable and complex and the rate of spoilage of these meat products can reduce the shelf life and cause substantial financial losses to manufacturing companies. Several studies were conducted to identify the bacterial populations in fermented dry sausages, however, despite increasing interest for modified atmosphere package (MAP), the effect of MAP on the spoilage bacteria and fungi of these meat products is not yet clear. Besides identifying the bacterial and fungal contamination during the manufacture processing, it is further important to identify the spoilage micro-organisms that will remain or proliferate during the storage period in MAP, and which might decrease shelf life and compromise product safety.

Objectives

The purpose of this study was to determine important spoilage bacteria and fungi in two types of Portuguese dry smoked sausages (chouriços) packaged in modified atmosphere (45% CO_2 and 55% N_2), which do not yet show clear spoilage changes at the end of the producer-defined shelf life period (120 days at 20±5ºC).

Materials and methods

Samples studied for this project were "chouriços" type Alentejano (A) and Ribatejano (R) produced by a large factory in Portugal as outlined by Matos et al. (2003). Identification and characterisation of bacterial species were based on phenotypic [cell morphology and fermentation profile according Jensen and Jorgensen (1994) and Jensen et al. (1995)] and genotypic (16S rDNA sequencing) characters according Knarreborg (2002). Identification of fungi was performed according conventional mycological methods based on morphological and physiological characterisation using taxonomic tables. The near-full-length sequences of the isolates have been deposited in GenBank under accession numbers AY587776 - AY587843. The phylogenetic relationship of the different bacterial species was determined by comparative sequence analysis of their 16S rDNA genes.

Results and discussion

A total of 30 fungi isolates were obtained from Alentejano (12) and from Ribatejano (18) types of smoked dry sausage, and the distribution of recovery from the CRB media is given together with the viable counts in Table 1. In Fig. 1 are shown microscopic photographs of five representative mould isolates. Fig. 2. shows the 16S rDNA-based tree reflecting the relationship of bacterial species. A total of 77 bacterial isolates were obtained from Alentejano (35) and from Ribatejano (42) types of sausage. In both types of sausages, and among the mould strains identified, *Penicillium*, *Fusarium* and *Aspergillus* species constituted the predominant mycoflora, with 50%, 16.6% and 16.6% for Alentejano variety and with 61.1%, 11.1% and 16.6% for Ribatejano sausage, respectively. Although contributions from other bacteria than the ones isolated can not be excluded, *Enterococcus faecium* (24.7%), *Bacillus subtilis* (23.4%), *Staphylococcus epidermidis* (14.3%), *B. cereus* (7.8%), *Pediococcus acidilactici* (6.5%) *Bacillus pumilus* (6.5%), *Clostridium bifermentans* (3.9%), *Bacillus licheniformis*, and *Enterococcus faecalis* (2.6%) were found in varieties A and R of Portuguese chouriço after 120 days at 20±5ºC in MAP. Major differences observed between the two varieties of chouriço were the absence of *Pediococcus* species and the presence of high numbers of isolates identified as *Staphylococcus epidermidis* in product A and, the high incidence of *Bacillus* species in sausage type R. Considering that MAP applied to both types of product was constituted

by the same percentage of gases and, the storage conditions, maturation period and smoke treatment were the same, differences found between products may be due to spices formulation in each type of product, the type of natural casings used and, the hygienic quality of the raw meat.

Conclusions

The presence of aerobic *Bacillus* related species and fungi in these MAP chouriços, where the air in the package was replaced by a specific mixture of carbon dioxide and nitrogen (45% CO_2 and 55% N_2), can be explained considering that oxygen is not always completely removed and may also permeate through the packaging material (Vermieren et al., 1999). In fact, the level of residual oxygen in MAP packs may be due to factors such as the oxygen permeability of the packaging material, the ability of the food to trap air, poor heat sealing ability of the packaging material causing air to leak in ineffective evacuation and/or ineffective gas flushing (Smith et al., 1986), the storage period and temperature (Smiddy et al., 2002). Further studies must be carried out to confirm the results obtained in this work in order to establish the spoilage population which might decrease shelf life and compromise product safety.

Background

An estimated 30% of fresh produce is lost by microbial spoilage from the time of harvest, through handling, storage, processing, transportation, shelving and delivery to the consumer (web1). To preserve food pathogens need to be destroyed or inactivated and the non-pathogenic microorganisms and enzymes responsible for food spoilage need to be eliminated or at least reduced (web2). Several techniques to extend food's shelf-life have been developed over the years for example heating, drying, irradiation and treatment with ozone. All these methods have their advantages, drawbacks and limitations depending on the type of the food, the kind of microorganisms, national regulations and the public demands (like unaltered taste, aroma, colour and vitamin content with no chemical residues after treatment). The use of ozone to treatment of the food using ozone gas meets these requirements quite well.

Ozone is a strong oxidant that kills many microbacterial organisms without leaving any toxic by-products or residues (web3, web4). Ozone has also been used for many years to treat pathogens such as bacteria and algae in water for applications such as drinking water supplies (web4) - ozone should therefore be a useful agent for the destruction of pathogens which are active in microbial spoilage of meat. Despite these advantages the use of ozone in the food industry has not been exploited as extensively since ozone must be manufactured on-site and until recently ozone generators were bulky and expensive (web5). However new developments in the design of small scale in situ ozone generators (using either UV lamps or electrical discharges) now make it practical to develop ozone treatment for food preservation on a commercial scale.

To date there have been only a few studies to quantify the ozone concentrations needed to ameliorate microbial spoilage. To fill the gap in this knowledge the aim of this study is to investigate the influence of ozone on microbial spoilage using the technique of PTR-MS to analyse VOC emissions derived from microbial spoilage in real-time.

RH Dainty's group has shown that it is possible to get information about the spoilage status by chemical measures e.g. analysis of VOCs. The products of microbial metabolism depend on the types of bacteria growing, the substrate on which they are growing and on the storage conditions (air, vacuum or modified atmosphere) (Dainty, 1996). This is confirmed by another study (Mayr *et al.*, 2003) that has shown that the emission of some specific VOCs are characteristic of microbacterial activity, for example emissions detected at mass 63 (dimethylsulphide and diethylsulphide) correlate with total number of aerobic bacteria and enterobacteriaceae respectively in air-packaged beef and ethanol is highly correlated with the bacterial counts of lactic acid bacteria in vacuum packed beef hence monitoring VOC emissions from the food provides a direct methodology for assessing bacterial activity. In contrast to technique of counting bacteria (requiring the incubation period of 1-3 days) detection of VOCs may be performed online and with rapid sampling rates. The use of a PTR-MS system provides an on-line measurement of VOCs with concentrations as low as a few parts per trillion in volume (pptv) and thus may detect bacterial activity when it is just beginning. Another advantage of PTR-MS is that the samples containing the volatile compounds do not need any preparation (pre-sampling, pre-concentration or sample dehydration) before being admitted to the PTR-MS. Thus some problems inherent to sampling in alternative methods used for VOC detection (e.g.: gas chromatography) are avoided, since the food itself is not disturbed and the measured mass spectral profiles closely reflect genuine headspace distributions (Yeretzian *et al.*, 2002). The PTR-MS system and measuring procedure has been described in detail in Refs. (Lindinger *et al.*, 1998) and (Hansel *et al.*, 1995).

Objectives

The purpose of the study was to investigate if ozone treatment affects microbial spoilage of pork.

Materials and methods

Two sets of measurements were performed six months apart. In each case retailed pork cutlets that were air packaged in an oxygen-permeable polyethylene film were bought in a supermarket in Innsbruck on the day when the respective measurements were started. Their expiry date was listed as two (first set of measurements, i.e. Experiment (Exp) 1 and 2) and three (second set, i.e. Exp 3) days after purchase.
Pieces of about the same shape (approx. 35x50x10mm), weight and consistency were cut out of a single cutlet for Exp 1-3, respectively. Each sample was placed into a glass flask (volume V=300ml) with a metal cover containing two gas inlets through which gas could be passed over the meat sample. The control samples were flushed with oxygen/air the others exposed to different concentrations of ozone (see table 1) for ten minutes. All the treated flasks were subsequently stored under identical conditions at room temperature. Measurements of the VOC emissions from the samples were then made at regular intervals over the period of several hours (see table 1). Headspace air was drawn through a heated teflon transfer line into the PTR-MS system for on-line VOC analysis. The mass spectrometric data being collected over a range of masses (m) with m/z=20–150 amu, where z is the charge of the measured ions (in our case z=1), different m being characteristic of different VOCs - in turn a monitor of different microbacterial processes.

Results and discussion

The effect of ozone treatment on the pork's decay behaviour was monitored through the observation of the concentration detected at mass 63 assumed to be dimethylsulphide (DMS) as this signal has been shown to have the largest correlation (up to 99%) with the bacterial contamination of meat (Mayr et al., 2003).
Figure 1 shows the results of the Exp 1-3. After a certain time lag the DMS signal detected from the oxygen treated sample in Exp 1 strongly increased with time whereas the low dose ozone treated sample showed only a slight increase, and the signal of the high dose treated pork piece remained almost constant. The same emission behaviour was found for the first part (t=0-30h) of Exp 2. However, the oxygen treated sample was exposed to a high dose of ozone at t=30h and the DMS concentration was found to strongly decrease, indeed, it took about 9 hours until the initial concentration was reached again. Comparing the results of Exp 1 and 2 one can see the strong influence of the additional ozone treatment on the emissions of the oxygen treated pork samples. The DMS concentrations of the both oxygen treated samples in Exp 1 and 2 were similar before the exposure to ozone at t=30 h. In Exp 1 signals from the non ozone treated sample reached a concentration of $1.3x10^3$ppb at the end of the measurements (t=46h, Fig. 1) whereas in Exp 2 the DMS concentration of the ozone treated sample was only 90ppb at t=46h. The online monitoring in Exp 2 was concluded at t=100h (not shown in Fig.1). The highest DMS signal (with a concentration of 300ppb) of ozone treated meat was reached at t=68h and stayed constant for six hours and was much lower than the highest measured DMS signals from the non ozone treated samples in Exp 1. The trends seen in the first two experiments were confirmed by the results of Exp 3. The DMS signal of the untreated and oxygen treated samples strongly increased with time – less strongly for the oxygen treated pieces. The oxygen treated samples were exposed to ozone after 42 hours with a subsequent decrease in the detected DMS signal and the concentrations remained low until the end of the experiment. The highest ozone exposure resulted in the detected DMS signal showing nearly no increase during the whole measurement time.
The microbiological analysis revealed that microbial counts were very high, independent of the treatment (Mayr *et al.,* submitted).

Conclusions

In the present work we have shown the strong effect of ozone exposure on pork cutlet's emissions, which have been found earlier to be highly correlated to the bacterial contamination, suggesting its usefulness as a remedial action for microbial spoilage to extend food shelf life. Even a later treatment with ozone strongly delayed the bacterial activity. The reduction of VOCs on one hand and the high microbial counts on the other hand indicate that the treatments applied in this study were effective to inhibit and thus reduce physiological activities, but are not necessary effective enough to produce a lethal effect on microorganisms present in meat. Further studies are needed to optimize the use of ozone in order to reduce microbial spoilage of meat.

Table 1: Samples were cut out of a single pork cutlet for Experiment (Exp) 1-3 respectively, treated in the different ways for 10 min and stored under identical conditions at room temperature. The emissions were regularly measured over the given time period. A microbiological analysis was performed for the samples of Exp 3 at the end of the analysis period.

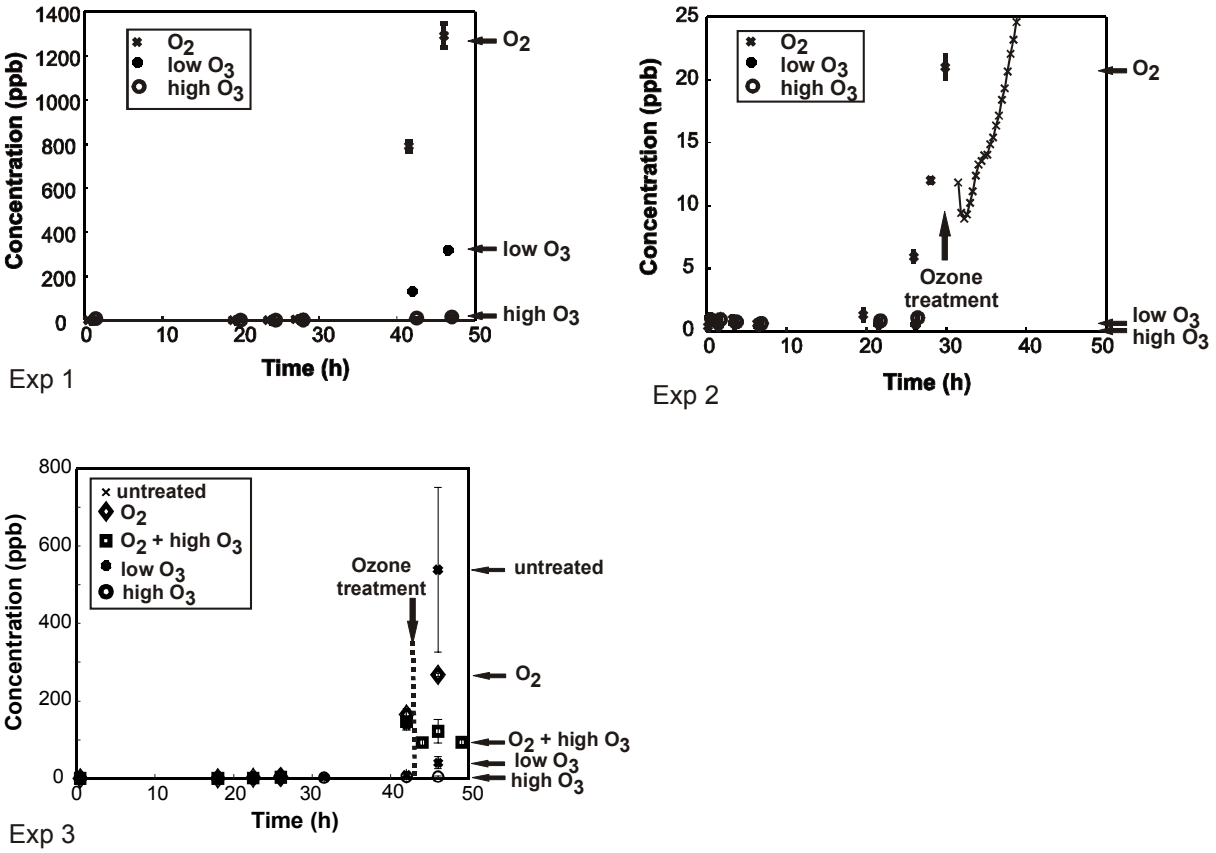

Fig. 1: Concentrations detected by PTR-MS at mass 63 as a function of time emitted by pork samples that were differently treated for 10 min prior to the first measurement at time t=0. These results suggest ozone significantly retards microbial spoilage.

APPLICATION OF LACTATE AND DIACETATE TO IMPROVE THE SHELF-LIFE OF THE BLOOD SAUSAGE "MORCILLA DE BURGOS"

Molinero, C[1]., Diez, A. M[1]., González, L[1]., Santos, E.M[2]., Jaime, I[1]., Rovira, J[1].

Background

Morcilla de Burgos is a typical blood sausage from Spain. It is made of a mixture of onion, rice, animal fat (mainly lard), blood and spices. All these ingredients are mixed and stuffed in natural casings and then cooked in water at 94 ºC during 45-60 min, after this cooking step they are air cooled at room temperature. *Morcilla* is sold without packaging in local markets and vacuum packaged in retailing shops. Preservation of *morcilla* is quite difficult, because it is a product with a high water activity (0.984), moisture (around 60%) and pH (up to 6.1) together with a rich nutrient composition (Santos et al., 2003). Vacuum packaged *morcilla* usually lasts around 21 to 30 days depending on the initial contamination and the storage conditions. In general, the spoilage of *Morcilla de Burgos* is due to the growth of heterofermentative lactic acid bacteria that produce changes in the coloration of the casing from black to pink or greenish, blowing of packages and forming ropy slime.
Sodium lactate has been used for several years, in the meat industry because of capability to increase flavour, shelf life and increase the microbiological safety of these products. The antimicrobial effects of lactate are due to their water activity lowering ability and the inhibitory effect of the lactate ion (Koos, 1992; Houstma, 1993). In that sense, they have been successfully applied in the extension of the shelf life of cooked ham by reducing the counts of psychrotrophs, faecal streptococci and enterobacteria and reducing as well the formation of ropy slime (Rondinini et al., 1996). Apart from this role in the extension of the shelf life of meat products, lactate plays and important role inhibiting the growth of foodborne pathogens as *E. coli* O157:H7, *B. cereus*, *L. monocytogenes*, *Clostridium botulinum*, *Staphylococcus aureus*, *Y. enterocolitica* and so on (Bolton, 1998; Shelef, 1994; Miller and Acuff, 1994). One of the problems derivate of using sodium lactate is the salty taste, when it is used in high concentration (> 3%). This problem may be overcome using other lactate derivates as potassium lactate, and adjusting the salt content in the product (Wilmink, 2000). Recent studies have shown the synergic effect of using together lactate derivates and diacetate, against several foodborne pathogens (Mbandi and Shelef, 2001; Glass et al., 2002).

Objectives

The aim of this work was to investigate the effect of several lactate derivates, and the combination of lactate and diacetate, on the extension of the shelf life and microbial quality of the blood sausage *morcilla de Burgos*. The improvement of the shelf life of this product is very important in order to expand the selling market, because *morcilla de Burgos* has a very popular market in Spain as a "tapa". It is also very important to prove that the use of these substances as preservatives do not decrease the sensory properties of the final product.

Materials and methods

Samples: Two trails of four batches of 25 K of *morcilla* with the same composition were elaborated in a typical *morcilla* factory. In batch A we added 3% potassium lactate (Purasal P Hipure. Purac.); in batch B 3% mixture of sodium lactate and potassium lactate (Purasal LITE. Purac.); batch C was considered as control and no lactate derivates was added; and finally batch D was elaborated with 2,5% of a mixture of potassium lactate and diacetate (Purasal P Optiform. Purac.). After the mixtures were made, they were stuffed in beef natural casings and open air cooked at 94ºC during almost 1 hour. After cooking step they were air cooled before being individually vacuum packaged. In that moment, they were brought to the lab in ice boxes to keep them at cool temperature. Packages were kept in a dark place at 4ºC for 32 days, and two packages of each batch were analysed at 0, 5, 10, 15, 20, 27 and 32 days.

Microbial analysis: A slice of 25 g of *morcilla* were sterile weighted, diluted in 225 ml of Ringer solution (Oxoid. Basingstoke, UK), and homogenised before preparing 1/10 serial dilutions. According to the results obtained in a previous work (Santos, 2001), six different microbiological parameters were chosen to evaluate the effectiveness of the treatments:
Total Viable Count plated on PCA agar plates (Oxoid) and incubated at 30ºC during 48 hours.
Enterobacteria were tested in VRBGA agar (Oxoid) incubated at 30ºC during 48 hours.
Pseudomonads were plated on Pseudomonads agar (Oxoid) supplemented with CFC (Cetrimide, Fucidine, Cefaloridine, Oxoid) at 30ºC during 48 hours.
Lactic acid bacteria (LAB) were grown in MRS agar (Biokar Diagnostics, Beauvais, France) and incubated at 30ºC for 48 hours in anaerobic conditions.
Pyschrotrophs were deep plated on PCA agar and plates were incubated at 7ºC during 10 days.
Clostridium perfringens were tested inoculating 1ml of sample dilution in a tube with 20 ml of TSN agar (Tryptone Sulfite Neomycin, Biokar Diagnostics) and incubated at 45ºC during 24-48 hours, in anaerobic conditions. Black colonies were considered as positive.
After taking the sample for microbial analysis, pH was measured in four different points of the *morcilla*, with a penetrating probe.

Sensory analysis: to evaluate if the treatments proposed could introduce some sensory changes in the products, triangle and ranking test were carried out twice for each trial, using a consumer panel (n=30). *Morcilla* were cut in 1.5 cm slices width and microwave heated till 70ºC. Triangle test were only made to evaluate differences between treatments C (control) and D (lactate-K + diacetate), because we thought we obtained the best results with treatment D due to the synergic effect between both preservative substances, according with the literature. The results of this test were analysed in the correspondent tables. Ranking test was made with all four batches of *morcilla* in the same panel session after the triangle test, to evaluate the preference between all four batches. The results were analysed with the aid of Kramer's tables and Friedman test.

Results and discussion

The evolution of pH and the microbiological results during the storage time are shown in table 1. It is possible to observe that pH drops more quickly in batch C than in the others and in 27 days of storage the pH is below 5.00, while in the other batches it keeps above this value. This fact was easily observed; when samples from batch C were opened due to the penetrating sour smell they produce.
On day 0, the same day that *morcilla* were made and packaged, only some colonies grew on PCA agar (TVC). These colonies were irregular in shape and some of them were mucous and they were associated to members of the sporulating genera *Bacillus*, because there are some vegetable ingredients in the composition of *morcilla de Burgos* than can harbour these bacteria, and because after the cooking step it seems that only sporulating bacteria can survive. In the remaining parameters no growth were detected for this sampling day. These results are in accordance with the results obtained by Santos (2001) and Borek et al. (2002) in our lab with same product.
Remarkable rapid growth of bacteria in the product was observed in the first five days, especially in TVC, LAB and Psychrothrophs. This growth could be the quick development of LAB that had favourable conditions to grow. In fact, it is possible to observe that counts of TVC, LAB and Psychrotrophs are quite similar from day 5 to the end of the storage time. Santos described in previous works (2001) the same situation in this product, as well as the static evolution of enterobacteria and pseudomonads during all the storage time. The presence of these microbial populations that appears 24 hours after packaging is due to the post-cooking contamination in the cooling and packaging steps (Santos, 2001; Borek et al., 2002).
LAB is the spoilage dominating population, especially members of the genera *Leuconstoc* and *Weisella* (Santos, 2001). It is in this microbial group where the effects of the different treatments were more significant. In batch C *morcilla*, the spoilage came about around the days 20-25 of the storage time, while in the other treatments spoilage took place later, especially in *morcilla* of batch B; in that case there was a difference of almost two logs in TVC at the end of the storage time. Less effective seems to be the combination of potassium lactate and diacetate. A similar evolution can be seen for psychrotrophs. No growth in TSN agar was detected.

Triangle test done on the second and 7 day of storage showed only a significant difference ($p<0.05$) in one of the four test performed between *morcilla* of batch C and D. Regarding to the ranking test no significant differences were detected on the test days with both statistical methods (Kramer and Friedman).

Conclusions

According to the results found in this study, it seems that the application of a combination of potasium lactate and sodium lactate may have a possitive effect, in the extension of the shelf life of *morcilla de Burgos* this effect could be around 12 days, from 20 to 32 days. Besides this combination does not seem to affect the sensory properties of the product. Something similar happens with treatment A (potassium lactate), however the combination of potassium lactate and diacetate seems to have no effect in improving the shelf life of *morcilla de Burgos*. New studies shoud be done to prove the effectivines of lactate derivates on foodborne pathogens in this product.

EFFECTS OF HOT WATER AND LACTIC ACID TREATMENT OF PORK CARCASS PRIOR TO COOLING ON MICROBIAL AND ULTIMATE PORK QUALITY

Sang-Hun Moon, Han-Sul Yang, Young-Hwa Hwang, Nak-Ju Sung, Gu-Boo Park and Seon-Tea Joo
Division of Applied Life Science, Gyeongsang National University, Jinju, Kyeongnam 660-701, Korea

Background

Prevention of microbial contamination during slaughtering and processing is one of the most critical safety issues of pork. Although the process carried out under ideal conditions, the pork from normal and healthy pigs could present opportunities for contamination with a variety of bacteria including some pathogens. Several intervention strategies have been developed to reduce bacterial numbers on pork carcass surface such as washing with hot water, chlorinated water, organic acids, alone and in combination. The combination of hot water and lactic acid treatment seemed to be the most effective for reducing microbial of beef (Gill and Landers, 2003), pork (Gordon and Bryan, 1995), chicken (Moon et al., 2004) and lamb (James et al., 2000). However, despite the effects of hot temperature organic acids on reducing pathogens, it would be expected to have some deleterious effects on meat quality. Especially pork quality could be affected by hot temperature treatment sensitively, but the information is limited.

Objectives

The effects of hot water and lactic acid treatment on microbial counts of eviscerated pig carcasses prior to cooling and ultimate pork quality at postmortem 24 hrs were investigated.

Materials and methods

Twenty pigs were slaughtered and split. Hot carcasses sides were inoculated with bacterial cocktail by pouring 500 ml of a peptone saline containing E. coli, Salmonella and Listeria. Inoculums were prepared from frozen (-20°C) stock cultures of *Escherichia coli* (ATCC #25922), *Salmonella typhimurium* (ATCC #14028) and *Listeria monocytogenes* (KCTC # 3569). Frozen cultures of *E. coli, S. typhimurium* and *L. monocytogenes* were thawed, and bacteria suspension was inoculated into separate of TSB. After 16 h of incubation at 37°C, suspended in the same volume of 1ml and then pooled together (1,000 ml of *E. coli,* 1,000 ml of *S. typhimurium* and 1,000ml of *L. monocytogenes*) to make a bacterial cocktail. The cocktail (For each specie in 3,000ml, 10^5 or 10^6 CFU/ml) was cooled to 4°C and used to pour upon carcasses. Carcasses were spray washed with hot water and 2% lactic acid at 80°C from a spray nozzle for 10, 20, 30 s, while for the cold spray treatment, the temperature was 15°C and the exposure time 30 s. After spray washing, sampling of the outside of carcasses for bacteriological examination was carried out by swab method. The swab sampling included four sites of the abdominal cavity and three sites of the back. After cooling of the carcasses for 24 hrs at cold room, pork loins were sampled to measure meat color and water-holding capacity. Meat color was measured by using a Minolta Chromameter CR-301, and water holding capacity was calculated by % drip loss (Joo et al., 1999). The data were analysed using statistical analysis systems (SAS. 1999). To evaluate the differences among treatments, data were analysed by analysis of variance and Duncun's multiple range test.

Results and discussion

As expected, total bacterial numbers were significantly reduced by spraying with hot water and 2% lactic acid, but not effectively reduced with spraying of cold lactic acid for 30 s (Table 1). Total plate count (TPC) showed about a 2.79 log unit reduction as a result of hot water spray while about a 1.57 log unit reduction was observed with spraying of cold lactic acid. TPC of pork carcass surface was completely removed by spray washing with 2% lactic acid at 80°C for 30 s. Moreover only 20 s treatment of 2% lactic acid at 80°C also effectively reduced all pathogens. This could be achieved by treatment with hot water for 30 s too. However, spray washing of 2% lactic acid at 15°C for 30 s did not completely eliminate *E. coli, S. typhimurium* and *L. monocytogenes*. Results suggested that a temperature of washing material was more effective in reducing the numbers of pathogens than a kind of washing material. Although spray washing for 30 s with hot temperature water and lactic acid completely eliminated microbial on the surface of carcasses,

pork loin showed undesirable color and water-holding capacity at 24 hrs postmortem (Table 2). The lightness values of pork loin treated hot water and lactic acid were significantly higher than those of cold treatments. Also drip loss % was significantly increased in loins from carcasses that spray washed with water and 2% lactic acid at 80°C for 30 s. After spray washing with hot water for 30 s, pork loins showed pale color, soft texture and exudative surface of meat. The PSE condition of pork loin was probably due to denaturation of proteins by hot temperature spray washing. However, pork loin treated with hot water for 20 s had a normal color and WHC. These results suggested that spray washing with 2% lactic acid at 80°C for 20 s would be the most effective for reducing bacterial numbers on the surface of pork carcass without deterioration of ultimate pork quality.

Conclusions

Spray washing of pork carcass with 2% lactic acid at 80°C for 20 s prior to cooling is the most effective way to reduce microbial including pathogens without any deterioration of pork quality in Korea.

LETHAL EFFECTS OF NON-DEHEATED (HOT) MUSTARD FLOUR ON *E. COLI* O157:H7 IN REFRIGERATED NITROGEN PACKAGED GROUND BEEF

Parthiban Muthukumarasamy, Jung H. Han and Richard A. Holley

Department of Food Science, Faculty of Agricultural and Food Sciences, University of Manitoba, Winnipeg, Manitoba, R3T 2N2, Canada.

Background

The incidence of *E. coli* O157:H7 which was first reported to cause hemorrhagic colitis and hemolytic uremic syndrome two decades ago (Riley et al. 1983) has been increasing year after year. Consumption of undercooked ground beef has been a common cause of *E. coli* O157:H7 outbreaks (hamburger disease) in North America. United States and Canada have the highest frequencies of foodborne illness caused by *E. coli* O157:H7 in the world. *E. coli* O157:H7 is a "zero-tolerated" pathogen in beef in the U.S., and as a result thousands of tons of ground beef are recalled every year for possible *E. coli* O157:H7 contamination. This has led to considerable financial loss for the meat industry. Canada is the single largest mustard exporter in the world and is one of the world's top five mustard producers. Mustard has been used as a spice or a condiment for centuries throughout the world. Mustard flours when deheated are used as emulsifiers, binders and bulking agents, but non-deheated mustard is used as a spice in seasonings and for flavouring in meat formulations, particularly in sausage and salami manufacture (Cui, 1997). Brown or oriental mustard (*Brassica juncea*) and yellow or white mustard (*Sinapis alba*) contain glucosinolates, which on enzymatic breakdown by myrosinase yield isothiocyanates, cyanides and thiocyanates (Tsao et al. 2002). The heat or flavour of the mustard is due to the presence of isothiocyanates and when used as binders the flour is treated to inactivate the myrosinase. Allyl isothiocyanate, one of the predominant breakdown products of glucosinolates, has been reported to have antimicrobial effects against bacteria including *E. coli* O157:H7 in ground beef, pre-cooked roast beef, alfalfa seeds, lettuce, and 'Asazuke' (a low salt vegetable) (Muthukumarasamy et al. 2003; Ward et al. 1998; Park et al. 2000; Lin et al. 2000; Ogawa et al. 2000). Although pure AIT from natural sources can be used as a food preservative in Japan, its use in food is restricted as a flavouring agent in North America. Moreover, use of pure AIT in food has limitations because of the strong pungent smell associated with volatile AIT which causes eye and nasal irritation and a burning sensation of the skin and tongue. Mustard flour, being a natural source of AIT, may be used as an alternative approach in food systems to eliminate *E. coli* O157:H7.

Objectives

The objective of the research was to study the lethality of mustard flour toward *E. coli* O157:H7 in refrigerated nitrogen packed ground beef. The effect of deheated mustard, which is incapable of producing isothiocyanates due to enzyme inactivation, was compared with non-deheated mustard to understand if isothiocyanates from the flour were responsible for lethal effects on *E. coli* O157:H7. The effect of pure allyl isothiocyanate, on *E. coli* O157:H7 was also studied.

Materials and methods

Five strains of *E. coli* O157:H7, 7128, 7110, 7236 (human isolates) and 7282 and 7283 (hamburger isolates) were kindly donated by Dr. R. Khakria, Laboratory Center for Disease Control, Ottawa, Canada. *E. coli* O157:H7 strains were maintained in tryptic soy broth at 37º C. Inside round beef roasts were obtained from a local supermarket and aseptically ground manually in a meat grinder (9.5 mm plate). The five strain cocktail of *E. coli* O157:H7 prepared in peptone water was inoculated in the meat to reach a level of 3 log CFU/g. Deheated and non-deheated mustard flour at 10 and 20% were added to the ground beef and re-ground to evenly mix the mustard flour. Twenty five grams of meat were placed in Deli*1 bags (Winpak, Winnipeg, Canada), a vacuum was generated, back flushed with nitrogen and the bags were sealed. Samples to study the effect of AIT were prepared by adding 1 ml of pure allyl isothiocyanate (Acros Organics, Geel, Belgium) and a commercial corn oil mixture (AIT: corn oil at a ratio of 7:3) to sterile filter paper inserts and one insert was placed in each bag containing 25g of *E. coli* O157:H7 - inoculated beef before packaging. The packaged ground beef was stored at 4º C. Triplicate samples for each treatment were analysed for *E. coli* O157:H7 and

total bacterial numbers from 0 to 18d at 3d intervals. Eleven grams of beef were mixed with 99ml of peptone water and stomached for 1 min. Serial dilutions were prepared in peptone water and plated with a spiral plater. Sorbitol MacConkey agar supplemented with cefixime-tellurite (CT-SMAC) and tryptic soy agar (TSA) were used for enumerating *E. coli* O157:H7 and total bacteria, respectively. The plates were incubated at 37º C aerobically for 24 and 48h for CT-SMAC and TSA, respectively. In order to determine if the *E. coli* O157:H7 cells were killed or injured as a result of mustard flour or AIT treatment, a resuscitation step on TSA (incubated at 37º C for 3h) was used followed by over-laying with CT-SMAC agar. Survivors on the TSA over-laid CT-SMAC plates indicated recovery of injured *E. coli* O157:H7 cells. All data were analysed by Statistical Analysis System (version 8.1) software. Analysis of variance by the General Linear models procedure and Duncan's multiple range tests were used to find significant differences ($P< 0.05$) among and between treatments.

Results and discussion

Bactericidal effects on *E. coli* O157:H7

The effect of AIT, deheated and non-deheated mustard flour on the viability of *E. coli* O157:H7 in ground beef stored under nitrogen at 4º C are shown in Fig 1. Non-deheated mustard at 20% was most effective in killing *E. coli* O157:H7 compared to deheated mustard at both 10 and 20% or AIT at ca. 1300 ppm. Non-deheated mustard at 20% completely eliminated *E. coli* O157:H7 at an initial level of 3 log CFU/g from ground beef by day 3, whereas AIT at ca. 1300 ppm and non-deheated mustard at 10% required 15 and 18 d respectively to reduce *E. coli* O157:H7 below detectable levels (40 CFU/g). Deheated mustard at both levels did not completely kill *E. coli* O157:H7 in ground beef stored under nitrogen at 4º C even after 18 days. On TSA over-laid with CT-SMAC plates, no recovery of injured cells occurred, indicating that *E. coli* O157:H7 were killed in treatments where no *E. coli* O157:H7 grew on CT-SMAC plates.

The results presented clearly show that non-deheated mustard flour at 20% had strong bactericidal effects against *E. coli* O157:H7 in ground beef stored under nitrogen at 4º C. Non-deheated mustard flour at 10% and AIT were able to completely eliminate *E. coli* O157:H7 but required significantly longer than 20% non-deheated mustard flour. The only difference between the two types of mustard flour used was the presence of active myrosinase in the non-deheated product. Lethal effects of the latter flour were attributed to myrosinase action, causing formation of isothiocyanates in the presence of moisture from the meat. Deheated mustard, with inactive myrosinase, was not significantly lethal to *E. coli* O157:H7. Allyl isothiocyanate is the main component of mustard that might be responsible for bactericidal effects (Isshiki et al. 1992). The average allyl isothiocyanate levels in mustard ranges from 7 to 13 mg/g. The results showed that non-deheated mustard flour at 20% was more effective than AIT (ca. 1300 ppm) in killing *E. coli* O157:H7. The increased lethality of mustard flour may be due to synergistic effects of AIT with other isothiocyanates present in mustard. The bactericidal activity of mustard flour may provide an opportunity for its use in meat and more widely in the food industry as a secondary preservative to control pathogenic microorganisms. This should provide added assurance of safer food for consumers.

Effect on total bacterial numbers

The effect of AIT, deheated and non-deheated mustard flour on the total bacterial numbers in ground beef stored under nitrogen at 4º C is shown in Fig 2. All treatments significantly delayed the growth of total aerobic mesophiles in ground beef stored at 4º C. In the untreated control the total bacterial count was 6.88 log CFU/g by 18d, indicating that the beef could be close to spoilage if untreated with any antimicrobials. Non-deheated mustard flour at 20% and AIT were able to maintain the total bacterial numbers at < 4 log CFU/g by the end of 18d.

Conclusions

Non-deheated mustard flour at 20% was more lethal than deheated flour to *E. coli* O157:H7 in ground beef. Non-deheated mustard flour may be used as a natural antimicrobial in ground beef to eliminate *E. coli* O157:H7 and has potential for similar use in other susceptible foods where mustard flavour is compatible. The use of mustard flour may not only increase the safety of ground beef but also extend its shelf life.

SHELF LIFE OF MEAT FROM PODOLIAN YOUNG BULLS IN RELATION TO THE AGEING METHOD

Napolitano, F.[1], Braghieri, A. [1], Pacelli, C. [1], Cifuni G.F. [1], Riviezzi, A. M. [1], Grasso, F. [2], Girolami, A. [1]

[1]Dip. Scienze delle Produzioni Animali, Università degli Studi della Basilicata, Via dell'Ateneo Lucano 10, 85100 Potenza, Italy [2]Dip. Scienze Zootecniche e Ispezione degli Alimenti, Via Università 133, 80055, Portici (NA), Italy

Background

During production, processing, distribution and storage, meat undergoes deterioration from chemical and microbial processes. Meat shelf life is an important parameter since consumers discriminate against meat cuts that have lost their fresh appearance and meat that becomes discoloured is often ground and marketed in reduced-value form. Lipid oxidation is one of the primary mechanism of quality deterioration in meat during display and it is directly related to the formation of precursors of oxymyoglobin oxidation and metmyoglobin (Insausti et al., 2001).
Ageing is an important factor influencing the final perception of meat quality and tenderness is the main parameter affected by this technological factor (Campo et al., 1999). This is particularly relevant for the improvement of meat properties of local breed such as Podolian, which is known to be tasty albeit though (Girolami et al., 1986). Previous works showed significant tenderness enhancement of Podolian meat extending maturation processes (Braghieri et al., 2002; Cifuni et al., 2004).

Objectives

Holding carcasses for prolonged time during ageing may produce chilling and technological losses. Ageing individually the various commercial cuts in vacuum packaging may represent a chance to improve tenderness avoiding this problem. On the other hand Lanari et al. (1989) found that beef aged in vacuum packaging may be darker in colour when removed from package due to the lack of oxygen. Shelf life could be also affected by the ageing method. This study aims to assess the effect of the ageing method (on the carcass or under vacuum packaging) on physical and sensory properties of Podolian meat. Meat shelf life under retail display in relation to the aging method was also evaluated.

Materials and methods

Eight Podolian young bulls, reared according to the traditional local practices (for the first 8 months at pasture and for the following 10 in loose housing conditions with free access to an outside paddock), were used. All the animals were slaughtered at 16÷18 months of age. Mean slaughter weight and dressing percentage were 237 kg and 53%, respectively. *Longissimus dorsi* (LD) and *Semitendinosus* (ST) muscles were removed from the right carcass side 48 h *postmortem*, vacuum-packaged and aged for 5 days at 4°C. The same muscles were taken from the left carcass side previously stored for 7 days at 4°C. Muscles were sliced (2.5 cm thickness), then placed on a polystyrene tray, wrapped in a polyvinylchloride film and displayed for five days at 2°C under 8 h illumination from cool white fluorescent lights (350 lux).
Lipid oxidation was determined by measuring 2-thiobarbituric acid reactive substances (TBARS), according to the method of Salih et al. (1987), at days 0, 2 and 4 and was expressed as mg malondialdehyde (MDA) produced per kg muscle.
Water loss was estimated by weighing the empty pack (Wp) and the pack with meat (Wp+m) on day 0. After storage the meat was removed from the pack and the weight of the pack plus the juice (Wp+j) was recorded. Water loss was expressed as a percentage of the initial weight of the meat (Insausti et al., 2001):

$$\% \text{ water loss: } \frac{(Wp+j) - (Wp)}{(Wp+m) - (Wp)} \times 100$$

CIE L*, a*, b* were measured at day 0, 1, 2, 3, 4 using a Minolta Chromameter (Minolta Co., Ltd, Osaka, Japan).
Microbial count was performed at day 0, 2 and 4 for total viable count (TVC) on Plate Count Agar (Difco) at 30°C for 72 h and *Lactobacillus* spp. on MRS Agar (Difco) at 37°C in anaerobic environment for 72 h.

Warner-Bratzler shear force was measured on LD and ST cores (1.27 cm diameter), cut parallel to the direction of the muscle fibres and sheared by an Instron Universal testing machine (model 1140), equipped with a Warner-Bratzler shearing device.
The sensory analysis (flavour and tenderness) was performed by a trained eight-member panel on LD and ST steaks grilled to an internal temperature of 75°C. Sensory values were normalised standardising each assessor by his standard deviation in order to reduce the effect of the different use of the scale (Cifuni et al., 2004). Data were subjected to analysis of variance for repeated measures with muscle, ageing technique and the interaction muscle x ageing method as repeated factors.

Results and discussion

The ageing method did not markedly affect colour parameters (Fig.1). Conversely other studies (e.g. Boakye and Mittal, 1996) observed that L index significantly increased in LD vacuum aged. In agreement with previous studies (Monin and Ouali, 1992; Torrescano et al., 2003), colour was significantly affected by muscle with higher L (36,32 ± 0,25 vs 36,32 ± 0,25; $P<0.001$) and lower a* (20,44 ± 0,18 vs 21,04 ± 0,18; $P<0.05$) values in ST compared with LD muscle. Muscle function is the most obvious factor accounting for colour differentiation between muscles according to the metabolic types. Intensity of meat colour depends on both the pigment level and surface structure (Monin and Ouali, 1992). Display time affected muscle colour (Fig.1). As also observed by Eikelenboom et al. (2000), for both muscles, redness a* value incresed after 1 day of display and subsequently decresed. The decrease in redness a* values may result from the gradual formation of metmyoglobin on the meat surface, because they have been reported to be negatively correlated (Insausti et al., 1999). It was noterworty that during the same time, there was an increase in TBARS value (Fig. 2). Previously, it was noted that a* redness was negatively correlated with lipid oxidation measured by TBARS values (Anton et al., 1993). According to Chan et al. (1997) the process of myglobin oxidation is a catlyst of lipid oxidation. Colour of fresh meat is a major factor affecting meat acceptability. In red meats, consumers relate the bright red colour to freshness, while discriminating against meat which has turned in brown (Zerby et al., 1999). Lipid oxidation, as indicated by MDA concentration, was not affected by the ageing method. One of the main factors limiting the quality and acceptability of meat products is lipid oxidation. This process leads to discolouration, drip losses, off-odour and off-flavour development and the production of potentially toxic compounds (Gray et al., 1996).
Lipid stability significantly varied between muscles, with higher MDA content in ST than in LD (0,072 ± 0,004 mg/kg meat vs. 0,048 ± 0,004 0,048 ± 0,004, respectively; $P<0.001$). The lower lipid stability observed in *Semitendinosus* muscle may be due to its higher polyunsaturated fatty acid content compared to *Longissimus dorsi* (Cifuni et al., 2004). However, for both muscles and during display the MDA content was well below the threshold value for rancidity of 1- 2 mg/kg of meat (Watts, 1962).
Microbial spoilage of food occurs when total aerobic counts reach 10^7 CFU/g (Nortje and Shaw, 1989). In the present work, TVC increased during display (Fig. 3), as previously reported by Zerby et al. (1999), but not to that level. Bacteria can produce colour changes in beef stored in air due to a reduction in the oxygen concentration at the surface tissue due to microbial respiration (Nortje and Shaw, 1989). TVC ($P<0.001$) and lactic bacteria ($P<0.01$) significantly differed in relation to ageing method with higher values in vacuum ageing method.
Water loss, an indicator of water holding capacity of muscle, may influence consumers choice, when purchasing packaged meat, as too much exudates around the meat is not appealing (Insausti et al., 2001). Drip loss may result from shrinkage of myofibrils *post mortem*, due to pH-fall, denaturation of myosin and formation of actomyosin at the onset of *rigor mortis* (Den Hertog-Meischke et al., 1997). In the present study neither ageing method nor muscle affected water loss (tab. 1).
Although Kannan et al. (2002) reported no effect of ageing method on WBS values of goat meat, in the present study meat aged under vacuum showed higher tenderness, as indicated by lower WBS value ($P<0.01$), compared with meat aged conventionally (tab. 1). No significant differences may be detected for sensory tenderness score between the two maturation method (tab. 1). As previously observed (Torrescano et al. 2003), shear force was significantly affected by muscle, with lower shear values muscle (2.00 ± 0.11 kg vs 2.63 ± 0.11 kg; $P<0.01$) and higher sensory tenderness score (5.90 ± 0.10 vs 5.62 ± 0.10; $P<0.05$) for LD compared with ST muscle. The ageing method and muscle had no effects on flavour of meat (tab. 1).

Conclusions

The ageing method did not markedly affect meat quality and shelf life. This result may encourage to employ vacuum packaging in the ageing of primal cuts from Podolian carcasses avoiding chilling and technological losses that generally occur in traditional maturation method.

OPTIMUM PROCESS CONDITIONS FOR SINGLE-SIDED PAN-FRYING OF HAMBURGERS FOR SAFETY

Dong Ou and Gauri S. Mittal*

School of Engineering, Unversity of Guelph, Guelph, Ontario, Canada N1G 2W1
*Corresponding author, Professor of Food Engineering, email:gmittal@uoguelph.ca, telephone: 1-519-824-4120, ext. 52431, fax: 1-519-836-0227

Background

Hamburger (meat patty) is one of the most popular foods in North America and also spread all over the world. However, such a simple food has ever led to numerous foodborne diseases. Hamburger disease is caused by *E. coli* O157:H7. FDA has recommended a minimum target cooking temperature of 68.3ºC with 16 s holding, for foodservice operations to enhance food safety (FDA 1999). However, it is difficult to implement these standards in a restaurant or at home due to the complexities and accuracy in measuring the internal temperatures, and the non-homogenous composition of the patties.

Objectives

To improve the quality of cooked patties while ensuring food safety, it is necessary to systematically study the influences of different cooking conditions, and optimize the single-sided pan-frying with turnings for frozen and unfrozen patties.

Modelling

During recent years, several models of patty cooking have been proposed (Ikediala *et al*. 1996; Chen *et al*., 1999; Zorrilla and Singh 2003; Pan *et al*. 2000). To develop the models, for pan-frying, heat was considered to be transferred to the patty surface by convection and conduction from the hot plate, and through the patty by conduction. Moisture and fat transfers were assumed to be due to the capillary flow due to patty shrinkage and pressure increase at increased temperature. The predicted temperature at each node in the patty was used to calculate the destruction or survival rate of microorganisms. The destruction rate of microorganism was represented by first-order kinetics and the decimal reduction time differential equation model. The simulation program was written in MATLAB-simulink and executed on a PC.

Materials and methods

The patties were bought as a batch. The frozen patties were individually packed in plastic bags to prevent moisture loss, and stored in a freezer at -8°C. To obtain unfrozen patties, the stored patties were thawed at a 4°C overnight. Patties were pan-fried using a combo health grill. A proportional controller through a solid state relay controlled frying temperature. Frying time was up to 10 min depending on patty initial temperature and pan temperature. For unfrozen patty, the first flipping (turning) was after 120 s, the second at 240 s and the third at 360 s with total time of 480 s. For frozen patty, these times were 240 s, 360 s, 480 s and 600 s, respectively. Water content was measured using AOAC (1984) method #24.002 with four replications. Fat content was measured using AOAC (1984) method #24.005, i.e. Soxhlet method. The temperature histories at the pan surface, and geometric centre and top and bottom layers of the selected patties were measured using high temperature rated copper-constantan thermocouple probes with diameter of 0.25 mm.

Results and discussion

Experimental validations: Predicted and experimental beef patty temperatures at 3 locations in a patty were compared (Fig. 1) and agreement is good. The temperature of the patty bottom rises quickly at early stage. The prediction errors for the bottom, centre, and top temperatures range from 2.33ºC to 5.28ºC. The errors for centre temperature predictions are smaller than those for bottom and top temperature predictions. Good

fit between the measured and predicted moisture contents (r^2 = 0.986, slope = 0.915, and intercept = 0.026 for the linear trendline) was observed. The root mean squared errors (*RMSE*) between experimental and predicted data were calculated. The prediction errors of average moisture contents for frozen and unfrozen patties were 0.1032 d.b. and 0.1695 d.b respectively. Good fit between the measured and predicted fat contents (r^2 = 0.989, slope = 1.023, and intercept = -0.029 for the linear trendline) was also observed. The fat content had a tendency to converge at equilibrium fat content gradually when increasing the cooking time or heating temperature. *RMSE* of fat contents for two cookings were 0.0778 and 0.0638 d.b.

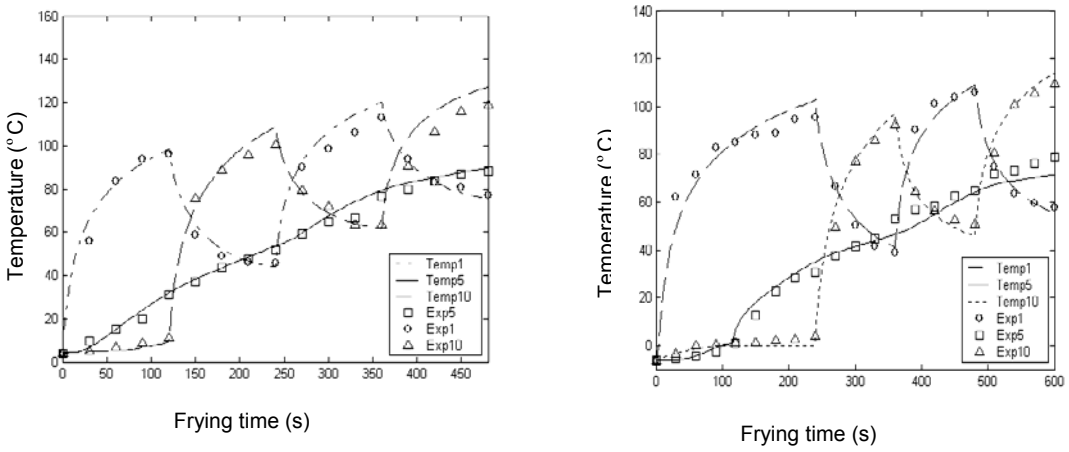

Fig. 1 Temperatures for unfrozen (left) and frozen (right) patties with overturned 3 times at 160°C pan temperature (Temp1, 5 and 10 are predicted temperatures of node1, 5 and 10, respectively. Exp1, 5 and 10 are measured temperatures of these nodes)

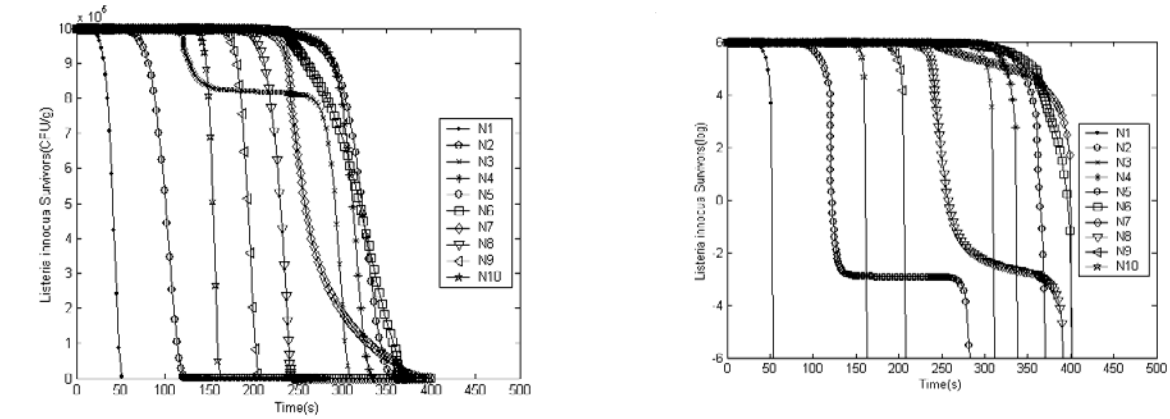

Fig. 2 Predicted *Listeria innocua* inactivation at different locations during pan-frying for frozen (left) and unfrozen (right) patties

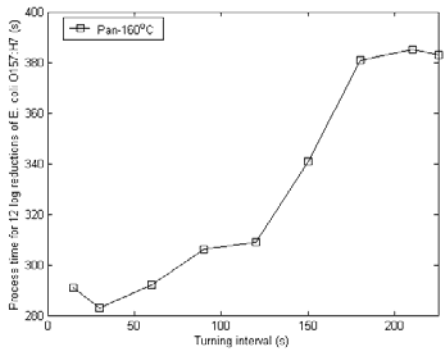
Effect of different turning intervals: The results show significant differences from 0.25 min to 3.75 min of turning intervals (Fig. 3). The maximum difference of process time was up to 102 s. When increasing the length of each interval, the time showed an ascending tendency and leveled off at about 3.5 min. The minimum time was 283 s at a turning interval of 0.5 min. Compared to the time at 1 min intervals, the difference was just 9 s. If the turning interval is too large, it could result in quality deterioration of the patty. Thus, for unfrozen patties, 1 min turning interval may be more practical.

Effect of initial temperatures (Tpi) of the patty: With increasing Tpi, the process time is reduced at a constant heating temperature (Fig. 4). When frying frozen patties, process time decreased slowly with the increase in Tpi at 160°C and 180°C pan temperatures. At 140°C pan temperature, the process time reduced faster. When the patties were thawed before frying (Tpi = 0 to 20°C), the time reduced gradually with the increase in Tpi. The process time for the unfrozen patty is considerably less than that for the frozen. At Tpi -20°C, the process time for 140°C pan temperature was almost twice as long than that for 180°C pan temperature.

Effect of patty thickness (Xpi): More time is needed to complete 12 log reductions of *E. coli* O157:H7 when increasing the Xpi. With decrease in the Xpi from 11 mm to 8 mm, the process time reduced considerably. At pan temperature of 140°C, the process time for an 11 mm thick patty was >3 times longer than that for 8 mm Xpi. A higher turn-over frequency is a means to reduce the process time for thicker patties. At 140°C and 160°C pan temperatures, increasing the number of overturns from 3 to 5 reduced the required process time by 1102 s and 200 s, respectively. At 180°C pan temperature, basically there was no difference between the process times for 3 and 5 overturns. This suggests that for low pan temperatures, increasing overturns effectively reduces the process time.



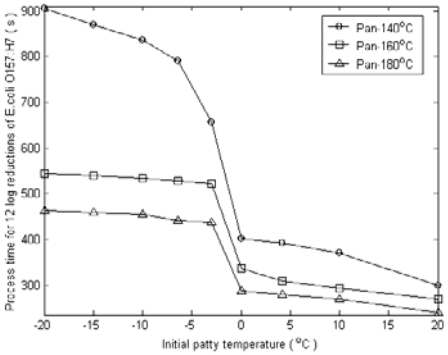


Fig. 3 Effect of different turning intervals on process time for 12 log inactivations of *E. coli* O157:H7 at 160°C pan temperature for (Tpi = 4.2°C) single-sided pan-frying

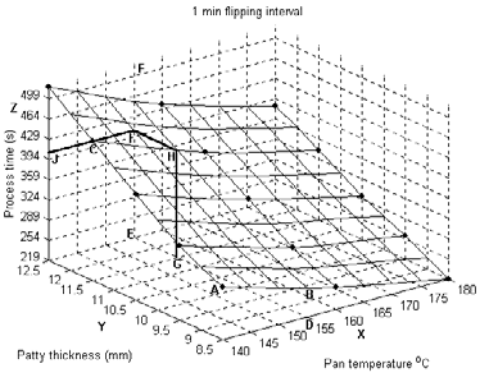
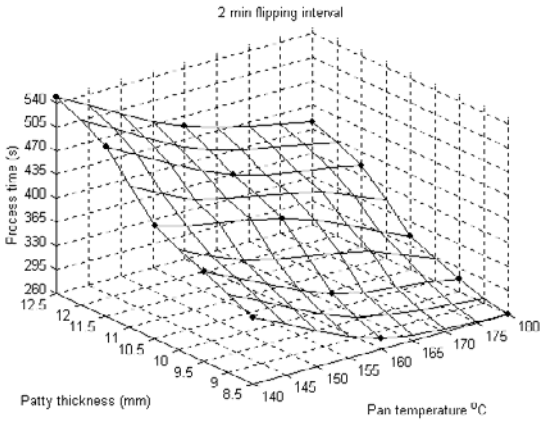
Fig. 4 (right) Process time at various initial patty temperatures and pan temperatures for with 3 overturns (Tpi < 0°C)

Effect of Various D Values of *E. coli* O157:H7: The heat resistance for each bacterium is affected by intrinsic and extrinsic factors, such as meat species, muscle types, product formulations, and other factors (Murphy *et al*., 2002). Increasing the fat content of hamburger increased the D values of microorganisms. More time was needed when increasing the D value of *E. coli* O157:H7. At 160°C and 180°C pan temperatures, the process time increased very slowly with increase in D. When comparing the results at 140°C pan temperature, the difference of the process time was considerable (182 s) with D value from 4840 s to 6280 s. Thus, a small variation of D value of *E. coli* O157:H7 has less effect on the process time at higher heating temperatures.

Three-dimensional plots for the process time: The three-dimensional plots present the relationship of pan temperature, patty size (thickness), and the process time for 12 log reductions of *E. coli* O157:H7 (Fig. 5).





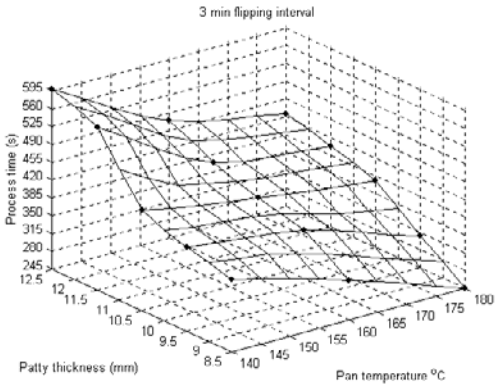


Fig. 5 Three-dimensional plots for single-sided pan-frying to determine process time

Conclusions

Good agreements were obtained between observed and simulated temperature profiles, and moisture and fat losses. The increase in heating temperature and initial patty temperature resulted in an increased patty centre temperature and higher rates of moisture and fat losses, but decreased the process time for 12 log reductions of *E. coli* O157:H7. The optimal turning interval of 1 min at 160ºC pan temperature was obtained. The process time for the unfrozen patty is considerably lower than that for the frozen to overcome the latent heat of fusion. With decrease in the patty thickness or increasing the number of overturns, the process time decreased considerably. A small variation of D value had less effect on process time at higher heating temperatures, but had significant difference for lower heating temperatures.

MICROBIOLOGICAL, CHEMICAL AND PHYSICAL CHANGES IN ITALIAN "LONZA"

Antonello Paparella[1], Clemencia Chaves López[1], Paola Pittia[2], Luca Di Berardo[1]

[1] *Dipartimento di Scienze degli Alimenti, Università degli Studi di Teramo, Via Spagna 1, 64023 Mosciano Stazione, Teramo, Italy*
[2] *Dipartimento di Scienze degli Alimenti, Università degli Studi di Udine,* Via Marangoni 97, 33100 Udine, Italy

Background

"Lonza" is a traditional Italian meat product, mainly produced in Central Italy, obtained by dry-curing of pork loin; this product is sometimes called "Lonzino". It was originally produced by peasants from heavy Italian pork during Winter, kept in dry rooms for dry-curing and maturation and consumed in summer and autumn. At present, chilled pork loins are usually sold as raw meat, and a minor part of production is used for curing. In modern factories, the production process starts by trimming pork loins in order to remove external fat, aponeurosis, and tendons. Soon after trimming, loins are seasoned with salt, flavoured and pickled at refrigeration temperature for one week. Then, loins are stuffed into cellulose casings, which are tied up and left to dry in dry-curing chambers, maintained at a relative humidity of 55 to 75 % and a temperature of 25°C to 18°C for about one week. Dry-cured loins are placed for maturation in chambers maintained at a relative humidity of 70 to 90 % and a temperature of about 14°C for 30-40 days. The present manufacturing process is considerably shorter than the original one, due to the lower fat content of raw materials.
Although Lonza is very appreciated in the European market, no data are available on the microbiological, chemical and physical changes which take place during the manufacturing process of this product.

Objectives

The aim of the present work is to point out the features of Italian Lonza, considering microbiological, chemical and physical changes throughout its manufacturing process. In order to obtain more details on the evolution of qualitative parameters, surface and core samples were collected and analysed.

Materials and methods

Sampling. Lonza samples were collected from two production cycles in the same factory. Sampling was carried out at different process times (days): 0 (raw pork loin), 1(start salting, after tumbling), 5 (salting), 8 (end salting), 8,5 (start dry-curing), 13 (dry-curing), 15 (end dry-curing), 20-22-27-29-33-35 and 45 (maturation). Analyses were performed on slices taken from the central portion of the product, collecting samples from the core (inner) and the surface (outer).
Microbiological analyses. Core and surface samples (10 g) were homogenized in a Stomacher lab-blender in 90 ml physiological solution. Decimal dilutions of the suspension were prepared in physiological solution, plated, and incubated as follows: mesophilic aerobic count (PCA, Oxoid: 30°C x 48 h), lactic acid bacteria (MRS Broth, Oxoid: 37°C x 72 h, anaerobiosis), micrococci (MSA, Oxoid: 37°C x 24 h), *Staphylococcus aureus* and coagulase-negative staphylococci (BPA + Egg Yolk Tellurite Emulsion, Oxoid: 37°C x 48 h), total yeasts and moulds (Sabouraud + 150 ppm chloramphenicol, Oxoid: 25°C x 48 h and 5 d, respectively).
Chemical and physical analyses. pH values were measured using a Mettler Toledo MP 220 pHmeter on aqueous dispersions (1:10) of the samples. Moisture was determined using the AOAC (1980) method. Water activity (a_w) was measured using a dew-point hygrometer Aqualab CX2 (Decagon Devices). Hunter L*, a*, b* values were determined by Minolta CM-508d colorimeter and chromaticity index (a*/b*) was calculated. Texture was evaluated using an Instron Universal Testing Machine mod. 5542, equipped with a 500 N load cell; penetration test was carried out by using a punch (diameter: 10 mm) at a cross-head speed of 0.83 mm s^{-1}. The maximum penetration force was considered as hardness index.

Results and discussion

Figure 1a shows the evolution of lactic acid bacteria (LAB) during the manufacturing process. After tumbling (24 hours), changes in LAB numbers were similar to those observed for mesophilic aerobic count (data not shown), but LAB increased more rapidly in core samples; this behaviour might be attributed to the stimulating effect of a lower redox potential inside the product. LAB count increased sharply throughout dry-curing, due to the inhibitory effect of the low a_w on competitive microbial populations. A slight decrease was observed in the second half of the maturation period (after 30 days), possibly due to the a_w decrease; similar results in surface and core samples were described by Vilar et al. (2000) in dry-cured lacón.

This salting effect is confirmed by the evolution of micrococci and coagulase-negative staphylococci (CNS), described in Figures 1b and 1c, respectively. Micrococci, and particularly CNS, are the microorganisms which are usually isolated in the greater proportion in dry-cured meat products (Carrascosa *et al.* 1992; García *et al.* 1995), due to their salt-tolerance, as well as to their resistance to low a_w and high osmotic pressure conditions. The salt effect on micrococci became evident during dry-curing, leading to 9 Log CFU g^{-1} in surface samples and 7 Log CFU g^{-1} in core samples throughout maturation. *Staphylococcus aureus* was not detected on the surface and inside the product during the manufacturing process.

In Figures 1d and 1e, the evolution of yeasts and moulds is shown. Yeasts numbers were generally higher in surface samples at the beginning of maturation (20 days). At the same time, temperature and relative humidity conditions during maturation contributed to increase the moulds count, up to 8.5 Log CFU g^{-1}. Moulds and yeasts have been reported as dominant organisms on the surface of different types of dry-cured ham throughout maturation (Nuñez et al 1996). In fact, it is known that they may contribute to ripening by means of their proteolytic and lipolytic activity.

Moisture and a_w (Table 1) decreased progressively during processing, as a consequence of air-drying and water-binding effect of salt on meat. As expected, these changes were more significant in the outer zone of the product. After salting, a deep decrease of pH occurred, possibly due to LAB growth, reaching the lowest value at the end of dry-curing. pH increase during maturation could be related to the activity of endogenous and microbial enzymes; this evolution is particularly evident in surface samples, where moulds are dominant (Figure 1e).

Lightness (L*) decreased throughout the process, whilst the chromaticity index (a*/b*) increased. These results could be attributed to both water loss and the progressive formation of meat pigments, in the presence of a source of nitric oxide, resulting in the typical and desidered color of dry-cured meat products.

Lastly, texture changes were observed in the product during the manufacturing period (Table 1). A marked decrease of hardness was detected in the samples taken after dry-curing, possibly related to the endogenous and microbial proteolytic activity (Parreno *et al.* 1994; Rodríguez *et al.* 1998). However, protein denaturation and oxydation, as well as water loss, caused a progressive hardness increase during maturation, more evident in the outer zone.

Conclusions

The prevalence of coagulase-negative staphylococci, micrococci, and lactic acid bacteria in the final product show a correct evolution of microbial populations during the manufacturing process of Italian Lonza. Final a_w and moisture were similar to those observed in other traditional dry-cured meat products. Colour and texture changed as a consequence of the processes occurring during maturation, greatly contributing to the product quality. The combination of salt and nitrites as preservatives, competitive lactic acid bacteria, a lowered pH and a_w, can be considered efficient hurdles, contributing to the quality of this traditional product, as well as to its microbiological and chemical stability.

MICROBIOLOGICAL CONDITIONS OF SHEEP CARCASSES FROM HIGH-CAPACITY SLAUGHTERHOUSE: A PRELIMINARY STUDY.

Pennisi, L. [1], Colavita, G. [2], Vergara, A. [1] and De Castelli, L. [3]

[1]Department of Food Science, Piazza Aldo Moro, 45, 64100 University of Teramo, Italy
[2]Dipartimento di Scienze e Tecnologie Agroalimentari, Campobasso, Italy
[3]Istituto Zooprofilattico del Piemonte e della Val D'Aosta. Torino, Italy

Background

A rigorous attention in the practice of slaughtering is, in meat production, of crucial importance in the prevention of the microbiological contamination of the carcasses aimed to assure both meat quality and safety of public health. In order to allow the risk assessment in question and the determination of the measures to be taken, the slaughtering process analysis must be completed by collecting specific control data of the slaughter house on the microbiological condition of the carcasses. The ovine slaughtering shows some features, compared to other species, that condition the initial level of carcasses contamination and of meat derived from them, such as the presence of critical process stages (removal of the fleece).
The Committee Decision 2001/47/ECC of 8 June 2001, "which lays down rules for regular controls on general hygienic conditions carried out by the operators in the factories, according to the EEC rule 64 433 on health conditions for the production and circulation of fresh meat and according to EEC rule 71 118 related to health problems in fresh meat exchanges of yard birds", established guidelines for microbiological controls in slaughter houses on the basis of HACCP methods.

Objectives

The purpose of this study has been the microbiological monitoring of adult ovine and lambs carcasses and of processing surface (Total Viable Count-TVC, *Enterobacteriaceae*-EC and detection of *Salmonella*, *E.Coli O157*, *Listeria monocytogenes*), in five high-capacity slaughterhouses of Abruzzo and Molise.

Materials and methods

In five high-capacity slaughterhouses (named 1,2,3,4,5), the processing hygienic conditions of 30 ovine carcasses (10 adult and 20 lambs) have been estimated.
In adult ovines, on each side of the carcass, samples have been collected with the swabbing method on the following sampling sites: flank, thorax lateral, brisket and breast, using a 100 cm^2 template.
The difference, regarding 2001/471/EEC Decision, is in testing in different way the fore side and back side. The four swabs of the fore side (brisket and breast), dipped in 50 ml of Maximum Recovery Diluent-MRD (Oxoid), have formed a single sample; and the procedure was the same for the back side (flank and thorax lateral).
For lambs the non-destructive method has been always used. There was one sampling site for each shoulder and thigh of both sides of every carcass, using template of 25 cm^2, as stated in 2001/471/EEC Decision.
In this case too the difference, related to the original 2001/471/EEC Decision, is in testing apart the fore side and the back side.
The four swabs of the fore side, dipped in 50 ml of MRD, were a single sample; and the procedure was the same for the back side. The samples, transported to laboratory in sterile way at the temperature of +4°C, have been immediately analyzed.
For the TVC and *Enterobacteriaceae*, the methods foreseen in the 2001/471/EEC Decision have been applied. The presence of the pathogenic microorganisms (*Salmonella, E.coli O157, Listeria monocytogenes*) has been analyzed by sponge-bag (PBI International).
Each sponge, rehydrated with 10 ml of MRD, has been scoured on the entire carcass and transported at refrigeration temperature to laboratory, adding 90 ml of the same diluent. After they have been homogenised with peristaltic Stomaker, pre-enrichment, enrichment and VIDAS screening have been carried out.
Salmonella: according to the official method AFNOR V08-052; AFNOR BIO 12/10-09/02.
Listeria monocytogenes: according to the official method AFNOR BIO 12/9-07/02.
E. coli O157: according to the official method AFNOR BIO 12/8-07100.

All suspected colonies from selective media were screened and identified by biochemical systems (API-Biomerieux).
Regarding surfaces, the samples have been performed after cleaning and sanitization operations and however immediately before operation starts. In case of visible dirt, cleaning should be considered as unacceptable without any further microbiological evaluation. For wet areas dry cotton swabs have been used. Samples have been collected with cotton swabs moistened with 1 ml of diluent, as reported in 2001/4717ECC Decision, from a surface area of 20 cm^2.
According to the Decision TVC and *Enterobacteriaceae* concentrations have been assessed.
The presence of *Salmonella*, *Listeria monocytogenes*and *E.coli O157* have been evaluated as previously reported.
Statistical analysis: colony count results were transformed into log values and depicted in box plots. The mean values, obtained by the set of samples coming from fore and back side, were analysed by the variance analysis (ANOVA) and regression analysis.

Results and discussion

The histogram reported in Fig. 1 and related to TVC values, shows the behaviour of mean values as a function of the two sampling sites.
The statistical analysis, carried out for TVC, shows that no statistical difference is visible among the different slaughterhouses, adult ovine and lambs and the mean values of surface and carcasses. The medium values of the fore side and back side instead, showed a positive coefficient of regression, but due to the low number of sample and presence of some anomalous data, the correlation coefficient is not very high (0,56).
The higher contaminated side was the back. In literature, it has been reported that bacterial count on carcasses processed according to the conventional dressing, show the back side as the most contaminated area, moreover the areas of highest contamination are the sites where cuts are made through the skin (Bell et al., 1993; Bell et al., 1996; Vanderlinde et al., 1999).
All of the TVC mean values are within the acceptable range of the 471/2001/ECC Decision (<3,5 log ufc/cm^2) like those described in literature on ovine carcasses, after sampling with non-destructive method (Gill et al., 1998; Vanderlinde et al., 1999; Duffy et al., 2001; Phillips et al., 2001; Hedges et al., 2002; Reid et al., 2002; Mazzette et al., 2003; Zweifel et al., 2003).
The TVC values were always higher than the other species, particularly equine and bovine (Vergara et al., 2002; Sarli et al., 2003; Splendiani et al., 2003; Reid et al., 2003). This results have been explained by the presence of the fleece, which is the most important factor of contamination. Hadley et al. (1997) have observed that carcasses derived from ovine with dirty fleeces have been shown to carry up to 1000 times more microorganisms than carcasses derived from visually cleaner animals. Moreover the lower values of TVC found in the bovine, are due to the fact that large areas of the beef carcass surface are not touched by workers and their equipments, whereas the surface of smaller sheep carcass is handled or touched by equipment during dressing (Gill et al., 1998).
The levels of *Enterobacteriaceae* was not detectable as already found in previous surveys (Colavita et al., 2003; Splendiani et al., 2003).
All the examined carcasses showed negative results regarding *Salmonella, Listeria monocytogenes* and *E.coli O157.*
Regarding surfaces (Fig. 2), in three of the five plants, although the optimal microbiological values of carcasses, the reported values over the terms of acceptability show difficulty in correct SSOPs management (sanitation standard operating procedures) carried out by workers.

Conclusions

Our findings show that the back side has a highest microbial contamination because its area is more manipulated during the dressing.
The lack of the correspondence between the mean values of carcasses and surfaces, evidences the necessity of a better management of sanitization operations. As the hygienic peculiarities of the working environment have a basic role in food industries, it could be useful that the plant is degraded in class A, for a single unacceptable finding.

INFLUENCE OF INJECTION, PACKAGING AND STORAGE CONDITIONS ON THE MICROBIAL AND COLOUR STABILITY OF BEEF AND BISON STEAKS

Pietrasik, Z., Dhanda, J.S., Pegg, R.B. and Shand, P.J.

University of Saskatchewan, Department of Applied Microbiology and Food Science, 51 Campus Drive, Saskatoon, SK, S7N 5A8, Canada

Background

Maintaining quality and appearance is essential during the distribution and merchandising of perishable food products like meat. The only criterion consumers have at the point of purchase when selecting meat cuts is visual appearance. To prevent product shrinkage and to delay the onset of its deterioration, optimum storage temperature and appropriate packaging are necessary for retail display. There are many packaging choices available; however, knowledge of the physical characteristics of the materials and systems in question, along with other factors that influence the keeping quality of meat, is essential when selecting the appropriate packaging. Vacuum (VP) and modified atmosphere packagings (MAP, *i.e.*, with one or more gases) are being used by the industry to design different conditions so as to maximize the shelf-life of meat and to promote desired product attributes. The most commonly used gases for packaging of meat are carbon dioxide (CO_2), nitrogen (N_2) and oxygen (O_2). The O_2 in the package headspace enhances meat colour and extends the stability of oxymyoglobin, while CO_2 restricts the growth of aerobic spoilage bacteria (Jeremiah, 2001).

Objectives

The objective of this study was to assess the influence of injection, packaging and storage conditions on the microbial, oxidative and colour stability of beef and bison steaks.

Materials and methods

Fresh beef and bison loins (*longissimus lumborum*, LL - 4 each) were procured from local sources. Each LL was divided into two sections. One section was injected with brine containing NaCl and sodium tripolyphosphate (0.5% and 0.3%, respectively in the finished product) to achieve 20% extension by weight, while the other section was kept as a non-injected control. Then, each loin section was divided into as many steaks (1" thick) as possible. These steaks were randomly allocated to storage atmospheres (MAP and VP), storage temperatures (-1 and +4°C) and storage interval subgroups (overnight, 1 and 2 weeks; and 1, 2 and 3 weeks for MAP and VP, respectively). The steaks (n=48) for VP treatment were individually packaged in ethylene/vinyl acetate copolymer polyvinylidene-chloride (PVDC) laminate bags. After making 2 holes through the over-wrap film for free exchange of gases, the steaks (48) for MAP were transferred to Cryovac B series bags, the headspace was evacuated, filled with a mixture of 70% O_2/30% CO_2 and then sealed. After removal from the main packaging following the designated storage intervals, pH, 2-thiobarbituric acid reactive substances (TBARS), purge during storage and total aerobic plate counts were determined. Colour (L*, a* and b*) was measured using a HunterLab Miniscan XE colorimeter. The change in colour was calculated for each L*, a* and b* values; *i.e.*, ΔL^* ($L_x^* - L_0^*$), Δa^* ($a_x^* - a_0^*$) and Δb^* ($b_x^* - b_0^*$), where L_0^*, a_0^*, b_0^* were at time zero and L_x^*, a_x^*, b_x^* were at time x. For each type of meat (beef and bison), data were analyzed as a split-plot with two replications. Storage temperatures of -1 and +4°C were the main plot treatment. Sub-plot treatments included a factorial combination of 2 injection treatments, and 6 packaging-storage treatments. Least-squares means were calculated for all main effects or interactions that were represented by a significant *F*-test.

Results and discussion

As expected, the pH of injected steaks was significantly ($p<0.05$) higher than non-injected samples (Table 1). The pH of beef steaks remained constant in MAP but decreased in the third week in VP. For injected bison, the pH decreased from 5.74 to 5.49 over time in vacuum-packed systems but did not change significantly ($p<0.05$) in the non-injected counterpart. At the higher storage temperature, pH of the meat decreased with time. Owing to a high O_2 concentration and subsequent increased lipid oxidation, MAP beef steaks stored for 1 or 2 weeks exhibited higher TBARS values compared to VP steaks. In bison meat, lipid

oxidation was also significantly influenced by different packaging treatments; however, their effect on TBARS was strongly dependant on injection and temperature of storage, as indicated by the packaging *x* injection and packaging *x* temperature interactions (p=0.000 and p=0.007, respectively). TBARS values for steaks stored under MAP for 1 week were higher than those stored under vacuum, while TBARS values for steaks stored under MAP-OV were the lowest (p<0.01). In the present study, the interactions between injection and temperature were probably due to the magnification of the TBARS differences among packaging treatments within non-injected steaks and those stored at the higher temperature. Both beef and bison showed significant injection *x* storage treatments interactions for purge lost during storage. Except for MAP steaks stored overnight, injected steaks had significantly lower fluid loss compared to non-injected samples. Regardless of the injection treatment, steaks stored under vacuum had significantly higher fluid loss in comparison to MAP treatments. The differences in purge among the storage treatments were greater in the non-injected than in the injected meat.

Storage temperature has a major influence on the microbial quality of meat products. As expected, microbial loads of steaks that had been injected and the ones stored at +4°C were higher than non-injected steaks and those stored at -1°C, respectively (Fig. 1). Modified atmospheres around steaks delayed the time to spoilage, which was evident from the data obtained on microbial load in the present study. Aerobic counts for steaks stored under MAP were lower than those stored under VP; nevertheless, counts from both packaging atmospheres were in the acceptable range. In the present study, a mixture of 70% O_2 and 30% CO_2 was employed. The CO_2 in the package atmosphere restricts the growth of aerobic spoilage bacteria, while the elevated O_2 concentration enhances meat colour and extends the stability of oxymyoglobin (Jeremiah, 2001). Aerobic counts increased gradually with storage, but generally colour deterioration occurred in advance of significant changes in aerobic plate counts.

In the present study, bison meat bloomed quickly with a dark red colour, but it tended to loose its brightness readily on storage compared to beef. As expected, steaks stored at the lower temperature (-1°C) held better colour than those stored at the higher temperature (+4°C) (Fig. 2). It has been reported that a low storage temperature promotes oxygen penetration into meat surfaces and increases the solubility of oxygen in tissue fluids, which increases the depth of the oxymyoglobin layer on meat surfaces (Hood, 1984). At the time of storage, non-injected beef steaks had higher a* values than injected ones. However, after 3 weeks of storage marination had no significant (p>0.05) affect on the colour of beef steaks. While for bison steaks, the change in a* values during storage due to brine injection was dependant on storage time and type of packaging. There was a positive influence on the colour of steaks under MAP treatment after overnight and 1 week of storage, whereas the colour of steaks deteriorated (*i.e.*, decreased a* values) significantly (p<0.05) after vacuum packaging irrespective of the storage time. These changes in a* values were more pronounced in injected than non-injected bison steaks (Fig. 3).

The largest increase in a* value of beef and bison steaks was observed during overnight storage under MAP. A slight improvement of the colour was also seen in beef steaks stored under MAP for 1 week. The a* value remained constant in beef steaks held under MAP for 2 weeks and under vacuum for 1 week but decreased significantly after 2 and 3 weeks of storage under VP. Bison steaks held under MAP for 1 week retained a bright red colour only in injected treatments and those stored at the lower temperature. Regardless of storage temperature and injection, bison steaks held under MAP for 2 weeks were totally discoloured, so rendered as unacceptable and were discarded from further assessments.

Conclusions

Beef LL steaks were able to retain their bright red colour longer than bison steaks. However, the deterioration in colour of bison steaks occurred in advance of significant changes in aerobic plate counts. Bison appears to develop higher TBARS on storage, and this might have an influence on the resulting rapid loss of redness with bison. Storage at -1°C provided greater colour stability and longer storage life for both beef and bison meat. MAP is an excellent option for short-term storage due to its positive effects on meat colour, but for longer storage, VP may be necessary. Storing meat under vacuum and then placing it under MAP just before retail display might be another option to increase shelf-life.

EFFECT OF MILD CHEMICAL AND PHYSICAL HURDLES ON THE SHELF LIFE OF VACUUM-PACKED PORTIONS OF ITALIAN MORTADELLA SAUSAGES

Pizza A.[1]*, Pedrielli R.[1], Quintavalla S.[2], Bergamaschi M.[1], Franceschini M.[1], Barbieri G.[1], Larini A.[1]

Experimental Station for the Food Preservation Industry, V.le Tanara, 31/A, 43100 Parma-Italy

[2]Department of Microbiology- Meat Products

Background

In a good manufacturing process of cooked meat products the curing and the cooking operations could be sufficient to guarantee their shelf life throughout the cool storage, nevertheless before the trade, the product is shared and packaged again causing a superficial re-contamination, which often compromises the microbiological safety (Pizza et al, 1981). Therefore these products need a mild treatment, limiting the chemico-physical damage: besides to the method already proposed by our laboratory to control this critical point (superficial pasteurisation of the samples at 70°-80°C for a few minutes), an interesting technique is the application of high isostatic pressures (HP): this "cold-pasteurisation" technique should limit heat-induced damages, with a better preservation of sensory and nutritional food characteristics. However, studies performed on meat showed that immediately after treatment, there occur oxidation phenomena (Cheftel and Culioli, 1997), above all colour changes (Carlez et al., 1995; Defaye and Ledward, 1995; Goutefongea et al, 1995; Cheftel, 1992) and an increase in lipid oxidation rate (Chea and Ledward, 1996).
In order to improve the stability to oxidation, the substrate can be enriched with natural ingredients having antioxidant activity, such as tomato powder and rosemary extract. In the first case the antioxidant activity of lycopene is due to an increase in the defences against the attack of singlet oxygen, to a decrease of the free radicals formed and to the inhibition of the oxidations induced by pro-oxidant metal ion (Lavelli et al., 2000; Lavelli et al, 1999; Oshima et al, 1996)). The second choice utilizes some substances, which are able to end the radical reactions and to block oxygen-reacting species (McCarthy et al., 2001).
In our Institute we confirmed the effect of tomato powder addition to traditional formulations on the shelf life of mortadella slices vacuum-packed in plastic trays and subjected to HP (Bergamaschi et al., 2002).
Moreover, the use of natural ingredients and HP could be a good tool in order to reduce or to eliminate from cooked meat processing an additive such as sodium nitrite, which is judged by consumer a risk factor for human health, even though its bacteriostatic (Castellani and Niven, 1955) and antioxidant activity are well-known (Morrissey, 1985).

Objectives

The aim of this work was to evaluate the single and combined effects of mild chemical and physical hurdles, based on both conventional and emerging technologies, on microbiological safety and oxidative stability of vacuum-packed portions of typical Italian mortadella sausages throughout the storage at 0°C.

Materials and methods

Experimental design

The experimental design is based on 4 formulations x 3 pasteurisation treatments arrangement in an unbalanced randomized block design: the results, grouped on the basis of chemical and physical treatments are reported as means and standard deviations, calculated at each storage step, by means of ANOVA analysis, SPSS 12.0 statistical package.
In a manufacturing firm four different mortadella formulations were prepared with the same raw meats, using the following curing agents: a) with 150ppm of sodium nitrite (mix **0**); b) without sodium nitrite (mix **1**); c) without sodium nitrite and with tomato powder (mix **2**); d) without sodium nitrite and with rosemary extra ct (mix **3**). All products were portioned and vacuum-packed in multilayer plastic trays, therefore they were divided into three lots: the first did not undergo any treatment after packaging (standard, **STD**), the second was treated by dipping in hot water (80°C) for four minutes (**T**), and the third was subjected to the action of isostatic high pressure at a level of 600 MPa for five min at 15°C by means of a ABBQFP6-Sweden

pilot plant, available in our Institute (**HP**). All the samples were thermostated at 0°C and at discrete storage times, they were controlled for bacteriological, chemical and sensorial characteristics.

Microbiological analyses

The following bacteriological analyses were carried out on all samples: total aerobic count after incubation at 30°C for 72h in TS Agar; lactic acid bacteria after incubation at 30°C for 48h in MRS Agar.
A load of $5*10^6$ cfu/g was considered as being the threshold value for sample spoilage.

Chemical and sensorial analyses

The analyses were carried out on the ground lean component of the products. The pH was measured by means of a HI 9321 MICROPROCESSOR pH-meter (HANNA INSTRUMENTS) on the minced sample. The oxidative state of the lipid component of the samples was evaluated by measuring thiobarbituric acid reacting substances (TBARS) according to the method of Tarladgis and Watt (1981), adapted to meat. The D- and L-lactic acids were measured by means of an enzymatic kit (cod 1112821 BOEHRINGER, Mannheim, Germany) on the extract of 5g of sample according to the official SSICA method. Just after the opening of the packaging, the perception of off-flavour was evaluated by a 7-8 members experienced panel, using the following scores: 0=extremely poor, 1=poor, 2=satisfactory, 3=fair, 4=good, 5=very good.

Results and discussion

Table 1 shows that all samples mainly were spoiled by lactic acid bacteria (LAB), moreover bacterial growth was not significantly different among the formulations, except for mix 0, in which the values of sodium nitrite additions and the residue (5-6 ppm) were sufficient to significantly inhibit total aerobic flora outgrowth.
After 15-20 days for **STD** samples, LAB concentration quickly reached high values (10^6-10^7 cfu/g), while the shelf-life of **T** and **HP** samples could be prolonged to two months (Figure 1). **HP** treatment was more effective than **T** treatment and sodium nitrite-HP combination better warranted the microbiological safety of product for all the period of observation.
Since no sugar was added in the mix, LAB grew by using other metabolic ways, throughout the storage of all samples, the D-lactic acid values not changing: consequently, the pH values didn't drop significantly (Figure 2); moreover the sum of L- and D-lactic acid remained constant, since L-form was changed into D- isomer.
The formulations had a different oxidative stability (Figure 3): in fact, throughout the storage, the TBARS concentrations were below 0.2 ppm of malonaldehyde (MDA) in all samples with sodium nitrite (mix **0**), while these values quickly increased in the absence of sodium nitrite. The rosemary extract had a greater antioxidant activity than tomato powder, but, on the whole, the results were not satisfactory, since these ingredients individually didn't allow a good preservation of the product. This confirms that sodium nitrite couldn't be entirely replaced, without changing the typical sensorial characteristics of this product belonging to the ancient Italian tradition: even at these low concentrations of natural ingredients, the panelists underlined a roast fragrance in samples with rosemary extract and an agreeable pink colour in samples with tomato powder.
The **STD** samples were slightly more oxidized than **HP** and **T** samples, with values not significantly different ($p<0.01$). The flavour was well preserved by sodium nitrite in **HP** samples and less in **T** products; moreover it quickly dropped in samples in function of both chemical and physical hurdles (Figure 4).

Conclusions

Both the thermal treatment (T) and high isostatic pressure (HP) reduce the initial microbial load and stabilize the samples, throughout the storage, but HP is more effective than T treatment. Consequently the HP samples slowly spoil and the flavour keeps good for a longer time. Moreover these physical hurdles don't preserve the product against the oxidation.
The chemical hurdles have no effect on microbial stability, except for sodium nitrite addition that also reduces the oxidation of the samples; the rosemary extract has a slight antioxidant effect, while even low concentrations of tomato powder demonstrate a slight antioxidant effect in the case of abuse storage (not published data). Consequently traditional formulations can be revised by decreasing the initial concentration of nitrite through mild thermal or pressure based hurdles and the addition of moderate concentrations of not conventional natural ingredients. No thermal resistant or pressure resistant outgrowth has been observed, if the storage temperature is strictly controlled.

A PROPOSAL ON SETTING PERFORMANCE OBJECTIVES FOR CAMPYLOBACTER AND EHEC IN MEAT INDUSTRY

Rahkio, M. and Kärkkäinen, T.
Finnish Meat Research Institute, P.O. Box 56, FIN 13101 Hämeenlinna, Finland

Background

Food Safety Objective (FSO) is the maximum level of a hazard, which still provides an appropriate level of protection in a food at the time of consumption. Governmental risk managers should evaluate the need for an FSO for a certain hazard and food combination. However, risk managers in food industry usually encounter the challenging task to implement these FSOs to HACCP (Hazard Analysis, Critical Control Points) - and GHP (Good Hygiene Practice)-plans so that FSOs are really met. A practical tool in this work, Performance Objective (PO) is the maximum level of a hazard in any specified food at a specified time of production before the consumption in order to ensure the achievement of an FSO. In the Proposed Draft by Codex Alimentarius (2004) on Microbiological risk management it is suggested that PO could be less stringent than the FSO for those food items, which are supposed to be cooked by the consumer. Nevertheless, if these food items can be a source of cross-contamination the PO and FSO could be the very same according to the Codex Alimentarius proposal (2004).

In year 2002 the National Public Health Institute in Finland reported 3738 cases of campylobacteriosis and 17 cases of EHEC infections (Enterohaemorrhagic E.coli O 157:H7) (KTL 2003). In most of these cases the connection with the causative food item was missing. According to Finnish strategy for zoonosis (MMM 2004) the progress of risk assessment for both Campylobacter and EHEC are among the national priorities in Finland. The parameters used are the number of reported human cases for Campylobacter and EHEC as well as the number of EHEC –isolates in cattle and the prevalence of Campylobacter in poultry. The aim is to lower the number of reported human cases and to decrease Campylobacter among poultry and to keep the existing low number of EHEC isolates in cattle.

There is a great seasonal variation of Campylobacter in Finnish poultry. About 10% of the herds are infected with Campylobacteria during summer months. From November to May infected herds are uncommon. According to Lahti et al. (2001) EHEC was isolated from 1,3 % of the 1448 bovine faeces samples taken at Finnish slaughterhouses in year 1997. In 2003 EHEC was isolated from 0,4% of the samples (EELA 2004).

Objectives

The purpose of this paper is to propose a model that could be used in establishing performance objectives for meat industry.

Materials and methods

There is a simple mathematical model, which illustrates the relationship between maximum level of a microbiological hazard in food, (Food Safety Objective, FSO), the initial level of the hazard in food (H_0), the reduction of hazard during process ($\sum R$) and the total increase in the level of hazard during distribution and the shelf-life ($\sum I$). In this model; $H_0 - \sum R + \sum I \leq FSO$, $H_0 \leq FSO + \sum R - \sum I$ the parameters are expressed in $\log_{10}$ units. (Stewart et al. 2003).

The model is practical for food items, which are ready-to eat and the reduction of hazard during process ($\sum R$) means the effect of heating or cooking. However campylobacter and EHEC are hazards in non-heated meat products, which are expected to be cooked at home.

Results and discussion

Campylobacter and poultry

The setting of Performance objective, PO is accomplished in two steps by estimating the initial safety level and by comparing this estimate to known initial levels of Campylobacter in food.

I Estimation of the safety level by identified tolerable intake

The Food Safety Objectives should be based on real risk assessment. Since there are no official Microbiological Food Safety Objectives for Campylobacter in poultry, the safety level of Campylobacter in poultry is estimated according to the identification on minimum infective dose.

The amount of Campylobacteria in a portion of cooked poultry should not exceed its tolerable intake. When the known infective dose is 500 cfu (NFA 2003) and it is considered as the tolerable intake, a 100 g portion of cooked poultry should not contain more than 500 campylobacterial cells. Thus the level of hazard should not exceed 5 cfu/g (0,7 $\log_{10}$). However, the safety level is estimated to be one thousandth of the tolerable intake, that is 0,005 cfu/g (-2,3 $\log_{10}$).

The model $H_0 - \Sigma R + \Sigma I \leq FSO$ is used for the situation at home kitchen. Supposing the temperature has been below 32°C during transportation and storage and no growth has taken place neither during the transportation nor during the storage at home kitchen, thus the H_0 for the home kitchen is the performance objective, PO for the industry. The reduction of hazard during home cooking is estimated to be as low as 3,5D, ($\Sigma R = 3,5$). The estimate of the safety level –2,3 $\log_{10}$ is used in this model instead of the FSO. ΣI is zero.

$H_0 \leq FSO + \Sigma R - \Sigma I$, when FSO = safety level = -2,3; $\Sigma R = 3,5$: $\Sigma I = 0$; $H_0 = PO$

$PO \leq$ safety level $+ \Sigma R - \Sigma I$

$\Leftrightarrow$

$PO \leq -2,3 + 3,5-0$

$\Leftrightarrow$

$PO \leq 1,2$

The performance objective of 1,2 $\log_{10}$ means that the level of Campylobacteria in 1 g of raw poultry could be 15 cfu/g before cooking at home. This level of hazard is the initial level of hazard before cooking and it is also the level of hazard, which is not supposed to be exceeded at the end of the industrial processing of raw poultry.

II Comparing the performance objective to the identified levels of Campylobacteria in poultry.

According to the Finnish National Food Agency (2003) in 1999 Campylobacter was found in 4,1% of the analysed poultry samples and the levels of Campylobacter were less than 90 MPN/kg, excluding two samples, which had levels of 200 MPN and 10500MPN/kg. If these results obtained by most probable number method are considered comparable to figures of cfu/g, it can be concluded that the highest levels of Campylobacter in poultry are 0,2cfu/g (-0,7 $\log_{10}$) and 10,5 cfu/g (1,02 $\log_{10}$). According to this published information on levels of Campylobacter, the PO of 1,2 $\log_{10}$ is not exceeded in the industry.

The levels of Campylobacter in poultry vary from country to country and between establishments as well. When comparing results, the analysing method used must be paid attention to. According to Stern and Robach (2003) the level of Campylobacter in broiler carcasses was 3.03 $\log_{10}$ (2,10-4.59) per postchilled carcass. Studies were made by rinsing method.

EHEC and food

When setting the Performance objective, PO is accomplished in two steps by estimating the safety initial level and by comparing this estimation to known initial levels of EHEC in food.

I Estimation of the safety level by identified tolerable intake

The Food Safety Objectives should be based on real risk assessment. Since there are no official Microbiological Food Safety Objectives for EHEC, the safety level of EHEC is estimated according to the knowledge on minimum infective dose.

The amount of EHEC in a portion of food like beef should not exceed the tolerable intake. According to the National Food Agency, the known infective dose is only a few cells. If the figure of 5 cfu is considered as the tolerable intake, dose of 100 g should not contain more EHEC cells than 5. Thus the level of hazard should not exceed 0,05 cfu/g (-1,3 $\log_{10}$). However, the safety level is estimated to be one thousandth of the tolerable intake, that is 0,00005 cfu/g (-4,3 $\log_{10}$).

The model $H_0 - \sum R + \sum I \leq FSO$ is used for the situation at home kitchen. The growth of EHEC is dependent on the temperature and is characteristic for the food. Supposing the temperature during transportation from industry to the retail shop has been less than 10 degree C, no growth has taken place. The growth during transportation from retail shop and during home storage can be estimated by predictive modelling programme (USDA PMP6). Supposing the transportation temperature is 18 degree C, the time is 2 h, the pH of the food is 6,9 and water activity 0,997, the growth during transportation that can be estimated is 0,13 $\log_{10}$. The growth during storage can be estimated by the same way. If this storage time is of 3 days at 10 degree C, the growth during storage is 1,11 $\log_{10}$ and $\sum I_0$ is 1,24 $\log_{10}$.

The initial level H_0 for the home kitchen is the performance objective PO and the $\sum I_0$.

$H_0 \leq MFSO + \Sigma R - \Sigma I$, when FSO = safety level = -4,3; ΣR =3,5: ΣI = 0; $H_0 = PO + \sum I_0$

$PO + \sum I_0 \leq$ safety level + $\Sigma R - \Sigma I$

$\Leftrightarrow$

$PO + 1{,}24 \leq -4{,}3 + 3{,}5$

$\Leftrightarrow$

$PO \leq -4{,}3 + 3{,}5 - 1{,}24$

$\Leftrightarrow$

$PO \leq -2{,}04$

The performance objective of –2,04 $\log_{10}$ means that 1 g of food could have EHEC level of 0,0092 cfu/g at the end of the processing in the industry level. The in proper storage of food at 10 ° C for 3 days at home is included in the estimation.

II Comparing the performance objective to known levels of EHEC

It's very rare to know the number of EHEC-bacteria in a food. Therefore reliable comparisons between estimated PO and real levels are not possible.

The estimated performance objectives are linked to the effect of home cooking. If the reduction effect of cooking at home is not taken into consideration at all, ΣR is zero and the performance objectives according the model would be much more stringent.

Conclusions

According to the model used in this paper, the estimated performance objective of 1,2 $\log_{10}$ for the Campylobacteria in poultry is not exceeded in the industry. If poultry meat is heated and cross-contamination is avoided at home kitchen, poultry should not be a risk and a source of Campylobacter infections.

However, a lot of research is needed before more exact estimations can be given. More information on the actual levels of Campylobacteria in poultry is needed and quantitative methods should be favoured instead of qualitative analysis. Instead of estimation of safety level used in this paper, proper national Food Safety Objective, FSO should be assessed for Campylobacteria in poultry.

The performance objective of –2,04 $\log_{10}$ for EHEC in food is estimated in this paper. However the quantitative information of EHEC levels does not exit and the practical achievement of this theoretical performance objective is not evaluated.

Both estimated performance objectives are dependent on the effect of cooking at home.

QUANTITATIVE RISK ASSESSMENT OF PATHOGENIC *YERSINIA* AND *LISTERIA MONOCYTOGENES* CONTAMINATION PROCESS ALONG PRODUCTION STAGES OF ORGANIC AND TRADITIONAL PORK MEAT

J. Ranta[1], K.-M. Siekkinen[1], R. Laukkanen[2], P. Ortiz[2], H. Korkeala[2], R. Maijala[1]

[1]Department of Risk Assessment , National Veterinary and Food Research Institute, EELA, P.O.Box 45, FIN-00581 Helsinki, Finland [2]Department of Food and Environmental Hygiene, Faculty of Veterinary Medicine, P.O.Box 57, FIN-00014 Helsinki University, Finland

Background

Consumers are becoming increasingly aware of the quality of meat and meat products as well as animal welfare and production issues. Consequently, interest on organic production where animals have lower animal density and possibilities for expressing normal behaviour has grown. In general, consumers also expect products from this kind of system to be of a higher microbiological quality compared to products from conventional production systems. Unfortunately, only limited amount of information on differences of microbiological food safety risks in organic and conventional farming is available (Muukka *et al*. 2003, Williams & Hammitt 2001). In order to obtain a reliable data for public discussions as well as for farmers planning to start the organic production, a study was launched for pig production. Examples of quantitative risk assessments can be found e.g. in Coleman *et al*. 2003, Hartnett *et al.* 2001, Rasmussen *et al.* 2001 and Nauta *et al.* 2000.

Objectives

The goal of this study is to create a risk assessment model in order to assess risks in different parts of the pork production chain for three microbiological pathogens (*Yersinia enterocolitica*, *Yersinia pseudotuberculosis* and *Listeria monocytogenes*) in organic vs. conventional production systems (CAC/GL-30 1999).

Materials and methods

Three groups of pig farms were chosen for the study:

- 5 organic farms,
- 5 conventional farms with similar production capacity as organic farms, and
- 5 conventional large meat producing farms

In every farm, pigs are sampled at farm level as well as in slaughterhouses. In addition, product samples from organic and conventionally produced meat will be taken. In addition to that, other relevant data on production farms, risk factors, behaviour of these three pathogens in environment, meat production volumes etc. are gathered for the risk assessment model. The model will cover the chain from animals intended for slaughter up to the meat cuts sent for retail level.

The infection status of a pig is analysed at two points by microbiological testing: at the farm from living pigs and after slaughter. While the first measurement is a single faecal test, the second measurement consists of several different tests taken at the slaughterhouse. The two tests are taken from the same individuals which allows detailed studies of the change in infection status over production chain.

A probability model is constructed to describe the probability of infection at the first testing and the transition probability from this initial infection status to the second infection status at the slaughterhouse. This model can further extended to describe the third measurement which is taken from meat cut samples. However, the third measurement no longer represents individual specific data. The model then describes the population level only, i.e. the probability of certain meat sample result given the prevalence in certain pig population at the slaughter stage testing. The model can either describe the apparent prevalence at all observation points in two different production systems (Figure 1), or it can be used to estimate the true prevalence by accounting for the test sensitivity for each type of test. It can also be used to simulate the effect of possible interventions, if needed (Gelman *et al.* 2004, Clough *et al.* 2003, Cox 2002, Congdon 2001)

Preliminary results and discussion

The results can be used as point estimates or as Bayesian probability distributions of likely parameter values, given data. The joint distribution can be exploited when simulating the production process for making predictions under the current situation and under alternative scenarios concerning changes in the production (proportion of organic vs. conventional can change, small farms quit, all farms will be of the highest/lowest risk index group, etc.) We have already do simple experiment with limited amount of data, so the process is still going on. It will be possible to start final model simulation runs and compare both production systems when all of the data collection is finish. Simulation runs and reporting the result of the model will be done by the end of the year 2005.

Acknowledgments

EFFECT OF MODIFIED ATMOSPHERES PACKAGING ON THE HYGIENIC AND ORGANOLEPTIC QUALITY OF "CECINA DE LEON" KEPT FOR EXTENDED STORAGE

Rubio, B.; Molinero, C.; Martínez, B., González-Fernández, C. and García-Cachán, M.D.

Estación Tecnológica de la Carne. Instituto Tecnológico Agrario de Castilla y León. C/ Filiberto Villalobos s/n. 37770 Guijuelo (Salamanca). Spain

Background

Spanish "Cecina" is a salted, dried, and smoked beef meat product manufactured traditionally in the province of Leon (north-western Spain). The preparation method is similar to that used in dry-cured ham manufacture. The final product has a typical red colour, smoked flavour and a characteristic slight salty taste.
During the last years many conservation procedures have been developed, such as vacuum packaging, packaging in CO_2/N_2 atmosphere, etc., in order to increase the shelf-life period of meat products to guarantee its sanitary and organoleptic quality. However, no studies have been carried out on packaging of "Cecina de Leon".

Objectives

The aim of the present study was to investigate the shelf life of commercial "Cecina de Leon" packaged in CO_2/N_2 atmosphere and vacuum under refrigeration for an extended storage period.

Materials and methods

Samples. The study was carried out on 12 pieces of "Cecina de Leon" provided by Protected Geographical Indication (PGI) "Cecina de Leon". Each piece was divided in 5 portions: one portion was used for initial analyses and the other portions were packaged.
Packaging and storage. The "Cecina" portions were individually packaged either: (a) in plastic bags (polyamide/polyethylene) which were subjected to vacuum (VP) and sealed using a packer TECNOS.CVP mod: A-300 or (b) in polystyrene rigid trays which, after gassing with a mixture of 20/80% CO_2/N_2 (MAP), were closed by heat-sealing with a packer TECNOVAC mod: Linvac 400 with a high barrier film. Packages had a headspace volume ratio of 1:1. The gas content of each pack was controlled using a Servomex model 1450 B3 gas analyzer. The packages were stored at 6ºC. Four packs of each treatment were opened for subsequent analysis after 15, 30, 60, 90, 150 and 210 days of storage. The entire experiment was replicated twice.
Microbiological analysis: 10 g of each sample were taken aseptically and were homogenised with 90 ml of tryptone water for 2 min in a PK 400 Masticator. Serial decimal dilutions were made in sterile tryptone water and plated onto growth in duplicate. The samples were analysed for aerobic mesophilic bacteria (Plate Count Agar (Scharlau, Spain) at 30 ºC for 72 h), psychrotrophic bacteria (Plate Count Agar (Scharlau, Spain) at 7 ºC for 10 days), anaerobic bacteria (Schaedler Agar (Scharlau, Spain) at 37 ºC for 48 h), enterobacteria (Violet Red Bile Glucose Agar (VRBGA, Scharlau, Spain) at 37 ºC for 24h), enterococci (Slanetz Bartley Agar (Scharlau, Spain) at 37 ºC for 24 h), pseudomonas (Pseudomonad Agar (Oxoid, Spain) supplemented with Cetrimide, Fucidine and Cephaloridine (CFC, Oxoid, Spain) at 30 ºC for 48 h), lactic acid bacteria (LAB) (MRS Agar (Scharlau, Spain) at 30 ºC 72 h), micrococci (MSA (Scharlau, Spain) at 37 ºC for 48 h), yeasts and molds (Agar OGYEA (Oxoid, Spain) supplemented with Oxytetracicline (Oxoid, Spain) at 25 ºC for 5 days).
Physicochemical analysis: Water activity (a_w) was measured by CX2 AQUA LAB equipment. The pH values were determined by puncture with a pH meter equipped with a glass electrode. Objective measurement of colour was performed at the surface of "Cecina" portions using a reflectance spectrophotometer (Minolta CM-2002). Colour coordinates were determined in the CIE-LAB system and the results were expressed as lightness (L*), redness (a*) and yellowness (b*). Instrumental Texture Profile Analysis (TPA) (Breene, 1975) was performed with a TA-XT2 Texture Analyzer (Stable Micro Systems Ltd.). Six cubes of "Cecina" (1x1x1 cm) were compressed twice with a cylindred probe of 1 cm in diameter, at 1 mm/min speed and the

level of compression was 60% of the thickness of the sample (1 cm). The test was accomplished always at room temperature and the parameters determined was: hardness, springiness, cohesiveness and chewiness.
Sensory evaluation was carried out on "Cecina" slices after each storage time by an experienced 8-member sensory panel. The sensory attributes (colour, odour, flavour, hardness, juiciness and overall acceptance) were scored using 5-points scales, 5 denoted extremely high and 1 denoted extremely low.
Statistical analysis of data was carried out by one-way analysis of variance, and means were separated by Tukey- honest significant difference test at 5% level (Statistica software package).

Results and discussion

Figure 1 shows results of the microbiological analysis, except enterobacteria and enterococci counts, which were always $<10^2$ cfu/g. Aerobic mesophilics and anaerobes counts were similar to psychrotrophs counts. Psychrotrophs numbers in VP remained constant for up to 210 days. However, a significant increase ($p<0.05$) was noted in MAP after 210 days of storage ($>10^7$ cfu/g). Among the undesiderable microbial strains, Pseudomonas were subjected to a significant growth inhibition under 20/80% CO_2/N_2. This fading is caused by the bacteriostatic effect of CO_2. The typical microflora of "Cecina" (LAB, yeasts and molds and micrococci) remained constant for up to 210 days in VP but a significant increase ($p<0.05$) was noted at the end of storage in MAP.

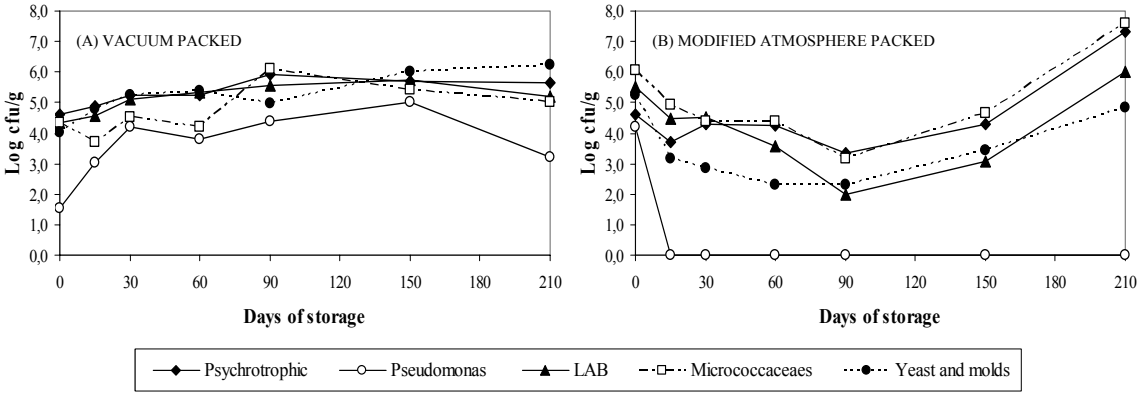

Figure 1: Evolution of microbiological parameters of "Cecina" packed under vacuum (A) and under 20/80% CO_2/ N_2 (B) during storage.

Regarding pH and a_w values, these parameters remained constant during storage. No differences in pH and a_w were found from VP and MAP samples. The pH values in all samples were in the range 5.8-6.1 and the a_w values were typical of the intermediate moisture foods (0.878-0.903).
Results of colour measurement are shown in Figure 2. No differences ($p>0.05$) in lightness (L*) and yellowness (b*) values were found between treatments at any given storage times. With regard to redness (a*), which has been used as an indicator of colour stability in meat and meat products, a pronounced initial fading was seen within the first 15 days for VP samples and within the second month for MAP samples. Presence of white film on surface of "Cecina" portions is a probable explication for discolouration. The later appearance of white film in MAP samples can be attributed to presence CO_2. Arnau *et al*., (1988) found that CO_2 delayed white film formation in Iberian ham packed in modified atmosphere

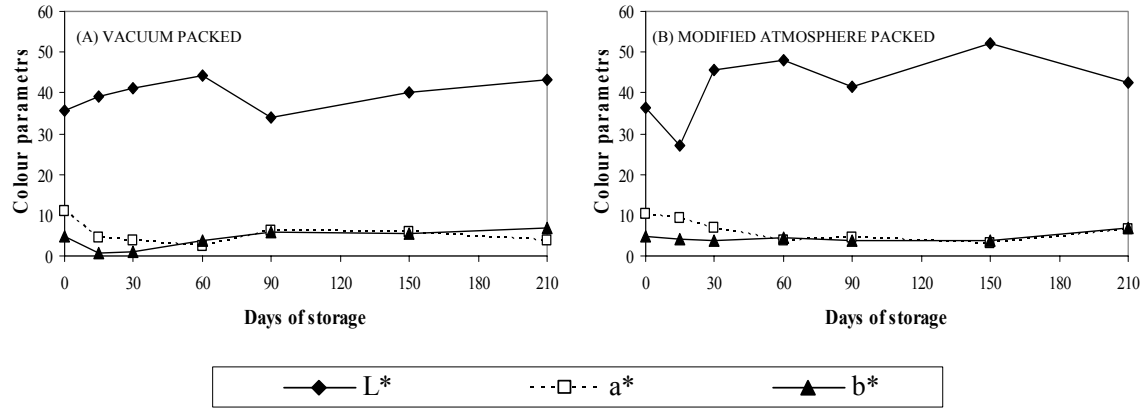

Figure 2: Evolution of colour parameters of "Cecina" packed under vacuum (A) and 20/80% CO_2/N_2 (B) during storage.

In relation to the texture parameters, no differences ($p>0.05$) were found between MAP and VP samples during the studied period. Values (means ± SD) found for different parameters were: hardness=2413.7±486.2 g; springiness=0.368±0.036 mm; cohesiveness=0.395±0.017; chewiness=375.09±111.76 g mm. Taking into account the normal variability found for these parameters, all values were considered normal for this type of product (García et al., 2004).

Table 1: Sensory parameters (mean ± S.D.) of "Cecina" slices packaged under different conditions during storage.

Parameter	Packaging	0 days	15 days	30 days	60 days	90 days	150 days	210 days

Means with different small letters indicate significant differences between storage times (Tukey test: $p<0.05$).
Means with different capital letters indicate significant differences between packaged treatments (Tukey test: $p<0.05$).
* Values below 3 means that "Cecina" was not accepted.

Table 1 shows the results of the sensory evaluation of "Cecina". According to panellists, MAP samples were slightly less acceptable (3.1) than VP samples (3.8) at the end of storage. As panellists evaluated odour, flavour and hardness in MAP samples below 3, it could be considered that colour and juiciness were the main factors which influenced the panellist in the evaluation of overall acceptance. This agrees with the conclusion of Ruiz *et. al.* (2002) who reported a relationship between juiciness and acceptance in Iberian ham. The sensory evaluation of colour did not confirm the instrumental results since sensory analysis was carried out on "Cecina" slices instead of portions.

Conclusions

On the basis of the results reported, in microbiological and sensory terms the shelf life of chilled vacuum packed "Cecina" in the conditions given in this study is 210 days, and the shelf life of chilled modified atmosphere packed (20/80% CO_2/N_2) "Cecina" is 150 days (based mainly on microbiological counts).

SENSORY AND MICROBIOLOGICAL PROPERTIES OF DRIED HAMS TREATED WITH HIGH HYDROSTATIC PRESSURE (HP)

Saccani G., Parolari G., Tanzi E. and Barbuti S.
Experimental Station for the Food Processing Industry, Parma- Italy

Background

Expansion of ready to eat (RTE) foods in the last decade has urged the need to ensure microbial safety while maintaining sensory and nutritional qualities. Among innovative mild technologies high hydrostatic processing (HP) is a promising technique for the treatment of those products that are not heat treated, such as dried hams and sausages.

Objectives

Aim of the present study was to evaluate the effect of HP treatment on the sensory and physical (instrumental colour assessment) properties of dry cured hams. The study was conducted after a preliminary investigation indicated the best conditions (pressure, time) enabling inactivation of *Listeria monocytogenes* (LM).

Materials and methods

HP equipment

HP treatments were performed by a pilot plant developed by Avure Technologies (Vasteras – Sweden). It consisted of a vertical vessel with a total capacity of 35 litres and enabling a T range of 4-90°C and max pressure of 600 MPa.

All HP treatments were performed at 600 MPa with different holding times (3, 6 and 9 minutes) at 25 °C.

Survival of Listeria monocytogenes in HP treated hams

The trials were carried out on ham slices (14 month of maturing, a_w=0.92) inoculated with *Listeria monocytogenes*, then vacuum-packed and finally treated at 600 MPa for three holding times: 3, 6 and 9 minutes (3 independent treatments). Microbial analyses were carried out at 24 hours after treatment.

1. *Inoculum preparation and inoculation procedure*

   The inoculum was prepared from a mixture of strains (Scott A and LM38, LM39, LM51 and LM134) previously isolated from meat products. The samples (N=140) were slices of dried hams (a_w= 0.92) of 25 g weight. They were partly inoculated (N= 100) at a concentration of about 10^4 cfu/g , while the remaining 40 slices were used as control. All slices were vacuum packaged for HP treatment.

2. *Microbiological analysis*

   a. *Detection of Listeria monocytogenes.* In order to determine the presence/absence of LM in 25 g of product, the ISO 11290-1 method was applied both as such and by using the ALOA (Biolife) medium (37° C for 24/48 hours) for isolation and differentiation of Listeria colonies. To quantify the contamination level (n. of Listeria/g), direct plate as count (ISO 11290-2) and/or the MPN as proposed by USDA were used. In both methods, the ALOA medium (Biolife) was used.

   b. *Total aerobic microbial count.* Triptone soy agar was used as medium (OXOID) and count was determined after incubation at 30°C for 72 hours determined.

Sensory evaluation

Descriptive attribute analysis of hams after HP treatment was conducted by a 8-member trained panel. Descriptors were rated on an intensity scale ranging 0-9. Descriptors were uniformity and intensity of colour, matured taste, salty taste, off-flavour, fibrousness on chewing, firmness.

Results and discussion

Effect of HP treatment of Listeria monocytogenes survival.

Surviving data after treatments are reported in table 1 as positive packages and surviving Listeria cells. Increasing the treatment duration (from 3 to 9 minutes) decreased viable LM cells. After 3 minutes at 600

MPa, all packages were found positive; after 6 minutes 9 out of 25 packages were positive and after 9 minutes LM was present only in one package. Results are consistent with those of other researchers who reported inactivation of fresh meat and dry-cured ham of 4-5 log cycles and 2-3 cycles respectively (1-4).
HP effects on typical microflora of dry-cured hams were also evaluated (fig.1). Microflora was reduced at all treatment times (mainly Staphylococcus strains), with 2.6, 4 and 4.5 decimal reductions after 3, 6 and 9 treatment times, respectively.
It is known that the effect of HP treatment on bacterial inactivation is influenced by several factors such as microbial morphological and structural characteristics (Gram positives more resistant than Gram negatives, cocci more resistant than rods) and physico-chemical properties of food-matrix (5). Our findings indicate that HP had more effect on LM than on typical microflora of dry-cured ham.

Sensory quality assessment of HP-treated dried hams: effects of maturing time and storage after treatment.
A trained sensory panel was asked to judge dry cured hams of different maturing age (14 and 18 months) after HP treatment. Mean scores of sensory attributes are reported in table 2, showing that colour, salty taste and firmness were mainly affected. Colour intensity decrease was less evident at 18 months, with HP treatment not significant ($P<0.05$) compared with treated samples. The matured taste did not change significantly after treatment, whereas salty taste was more intense in treated samples for both classes of age, with a marked increase in the less matured ones. Major changes in lean meat structure were also reported in terms of increased fibrousness on chewing and firmness (resistance to compression). Data indicate that sensory properties were less affected in the more aged hams, which was likely due to the relative lower impact of pressure on more dehydrated meat; this conclusion is in agreement with similar observations from other Authors working on meat substrates and other than dried hams (6).
Lighness (L*) increased after HP treatment, whereas redness (a*) decreased and yellow (b*) increased significantly (table 3). Therefore the a*/b* ratio was lower in all treated samples while the *hue* index, being inversely correlated with redness, increased. These changes were consistent with the sensory test data (table 2), suggesting that discoloration occurred as result of treatment.
In order to assess whether cold storage of HP treated hams were susceptible to change of sensory quality traits, hams were analysed at different times during one month of storage at 4°C. Results are graphically reported in fig.2 for sensory colour intensity, showing an increase of scores after 7 days of storage. It is concluded that cold storage of hams after treatment is a means to reduce the impairing effect of pressure on meat colour affecting dried hams immediately after the HP processing.

Conclusions

High hyperbaric pressure treatment allows reduction of *Listeria monocytogenes* to negligible levels in dry cured ham. Treatment affects colour (discoloration) and saltiness (enhanced perception) in such a way that changes are inversely related to the age of the ham.

MANUFACTURING PROCESS DEVELOPMENT ON A READY TO HEAT AND EAT PORTUGUESE TRADITIONAL PRODUCT: "MARANHOS"

Salavessa, J. J.[1] and Barreto, A. S.[2]

[1]Escola Superior Agrária, Instituto Politécnico de Castelo Branco, 6000-500 Castelo Branco, Portugal
[2]CIISA - Faculdade de Medicina Veterinária, Universidade Técnica de Lisboa, 1300-477 Lisboa, Portugal

Background

Cooked meat products are generally marketed after having been heat-processed within the production facility. The application of heat to these products as a finishing production step, and before they are sliced and/or packaged, is necessary to make them easily digestible, to inactivate enzymes (e.g. lipasas) and microorganisms, and to give them a specific colour, taste and consistency (Hammer, 1991). In recent years there has been a tremendous growth in the chilled food market, with a wide variety of products available to the consumer through retail and catering outlets (HMSO, 1993). Safety is the prime consideration and food manufacturers must ensure that products pose a minimum hazard to the consumer. The safety required has to be achieved both by preventing the growth of pathogens during production and by reducing the remaining contamination to the lowest possible level (Barbuti & Parolari, 2002).

"Maranhos" is a goat meat sausage, traditionally home-made in Beira Baixa, a region in the centre of Portugal, where it is a very popular dish. It is a product with low price raw materials, easily perishable, with a reasonable composition and energetic value and low salt content. Although no pathogenic flora is usually present in the product, research on and counts of hygienic indexes are higher than desirable. Therefore, the microbiological quality of the product is low (Salavessa & Barreto, 2003).

Objectives

Research on manufacture of this type of product has been extremely limited, therefore this work aims to study the effect of pre-cooking on both the chemical and microbiological characteristics of "Maranhos".

Materials and methods

Three batches of this meat product were prepared in three different times, according to a traditional recipe and technological procedures used by a local manufacturer. "Maranhos" were prepared from raw ground adult goat meat mixed with rice and seasoned with salt, peppermint (*Mentha* sp.) and white wine. All the ingredients were then stuffed into natural casings, small bags especially made from the goat gastric compartments, and boiled for 75 minutes in a pan.
The water temperature and the temperature in the slowest heating point (SHP) of the product were measured during the cooking process with a CTF9008 Precision Digital Thermometer & F_0- Value Computer, ELLAB.
Samples of four uncooked and four cooked "Maranhos" were collected from each batch and immediately transported under cooling conditions to the laboratory.
Moisture content was determined by dissection until constant weight at 105ºC (Martins & Patarata, 1993). Ashes were determined by weighing the mineral residue after incineration at 550-600ºC (Martins & Patarata, 1993). Fat content was determined by the Soxhlet method (Martins & Patarata, 1993). Protein content was determined by the Kjeldhal method (Martins & Patarata, 1993). Carbohydrate content was estimated by exclusion of moisture, ashes, fat and protein contents. Energetic value was determined according to the classical conversion factors of Atwater (Martins & Patarata, 1993). pH was measured with a pH-meter HI9023-HANNA INSTRUMENTS. Water activity (a_w) was measured with the ROTRONIC HYGROSKOP DT, with the measure cell WA-14TH at 25ºC of constant temperature. Salt content was determined by the current method (NP-1845, 1982). Free fatty acids (FFA) were measured by extraction by chloroform and titration with 0.1N sodium hydroxide using phenolphthalein (Person, 1970). Peroxide value (PV) was determined by extraction by chloroform and titration with 0.01N sodium tiossulphat using starch as an indicator (Hungarian Standards, 1973). Tiobarbituric acid (TBA) was determined by spectrophotometer UV/Visible PHARMACIA BIOTEC Ultrospec®2000 with λ=538 nm (Martins & Patarata, 1993). Total basic volatile nitrogen (TVN) was determined by Conway cells method (Martins & Patarata, 1993).

For the microbiological analysis a 25 g sample of each sausage was aseptically transferred to a sterile plastic bag and pummelled in a stomacher LAB BLENDER-400 with 225 ml of buffered peptone water (DIFCO). Decimal dilutions of suspension were prepared using triptone salt solution (SCHARLAU) and plated in duplicate on different growth media. The following media and incubation conditions were used: total aerobic in Plate Count Agar (SCHARLAU) at 30ºC for 2 days; total psicrophiles counts in Plate Count agar (SCHARLAU) at 7ºC for 10 days; total anaerobes count in Anaerobic Agar acc. to Brewer (MERCK) inside an anaerobic jar at 7ºC for 10 days; total termophiles counts in Plate Count agar (SCHARLAU) at 42ºC for 2 days; moulds and yeasts counts in Cooke Rose Bengal agar with clorophenicol (OXOID) at 25ºC for 5 days; *Enterobacteriacea* counts in Violet Red Bile agar (OXOID) at 37ºC for 2 days; lactic acid bacteria counts on Man Rogosa Sharpe agar (OXOID) at 30ºC for 3 days; *E. coli* research with Kovacs reagent in Briliant Green broth (SCHARLAU) and Peptone water (DIFCO) at 45ºC for 2 days; *Clostrdium* sulphite reducers spoors research in Sulfadyzine Polimyxine Sulphite agar (MERCK) at 45ºC for 2 days; *S. aureus* research by the cuagulase test after isolation of suspicious colonies in Baird Parker agar (OXOID) and then Brain Heart Infusion (DIFCO) at 37ºC for 1day; *Salmonella* research by biochemical test API 20E (BIOMÉRIEUX) after isolation of suspicious colonies; and *Listeria monocytogenes* research by biochemical test API *Listeria* (BIOMÉRIEUX) after isolation of suspicious colonies.

Means of uncooked and cooked product were subjected to one-way ANOVA analysis of Statgraphics v. 7.0.

Results and discussion

Heat treatment is a critical operation, which takes part in most manufacturing processes of meat products, that controls not only microrganism growth but also affects taste, flavour, colour and texture of end products, allowing for sensorial features required by consumers (Botelho *et.al.,* 2003). The evolution of temperature values in SHP during the cooking process of the product is shown on the time/temperature chart (Fig. 1), the product reached temperatures above 90 °C for a range of time longer than 10 minutes, which are expected to cause a 6 log reduction of all vegetative pathogens present including spores of psychrotrophic *Clostridium botulinum*. However, heat resistant spores and pre-formed toxins may persist. That is, the heated product should be cooled as quickly as possible through temperatures that minimize the risk of spore germination and outgrowth. The cooling time will vary from product to product, but as a guideline, it should not exceed 4 hours (HMSO, 1993). Tables 1, 2, 3 and 4 summarise the results as mean, minimum and maximum values, standard deviation (SD), coefficient of percentage variation (CV%) and treatment significance (P) on the physicochemical and microbiological analyses.

Mean values for chemical composition of the uncooked product were the following: moisture 59.30%, protein 12.33%, fat 10.36%, carbohydrates 16.22% and ashes 1.79% and the mean energetic value was 871.25 kj/100g. Mean values for chemical composition of the cooked product were the following: moisture 60.58%, protein 14.08%, fat 7.50%, carbohydrates 16.50% and ashes 1.35% and the mean energetic value was 797.00 kj/100g. The differences observed between uncooked and cooked product in protein, fat and ash contents were very significant ($p<0.01$). The decrease in fat content could be explained by fat losses that occur during the cooking process, with a consequent increase in protein content in the centesimal composition of the cooked product. Fat melts at 37-40ºC, free fat may therefore escape from a product mixture at quite low temperatures unless held in an effective matrix (Ranken, 2000).

No significant differences between uncooked and cooked product were observed in the degradation indexes analysed. Mean values for uncooked and cooked product were: for FFA 3.67% and 3.85% as oleic acid, for PV 15.87 and 13.27 mequiv/kg of extracted fat, for TBA 0.28 and 0.37 mg of malonaldehyde/kg of analysed product and for TVN 25.91 and 21.81 mg/100g.

pH and a_w mean values were of 5.90 and 0.937 in the uncooked product and of 6.22 and 0.939 in the cooked product, which means that in both cases “Maranhos” is an easily perishable meat product. The differences observed in the pH value, which increased slightly after cooking, were very significant. A slight increase in the pH value is expected to happen when sodium salts are added to meat products because of their slight alkaline nature (Wirth, 1992). Highly significant differences in salt content were observed with a decrease from 1.07% in the uncooked product to 0.74% in the cooked one. These differences are due to salt diffusion into the water used to boil the product.

Highly significant differences were found in all the microbiological counts, and very significant differences for the *Enterobacteriacea* counts. The mean value for the aerobic plate count in the uncooked product was of 7.06 $\log_{10}$ cfu/g and after cooking the value decreased to 3.94 $\log_{10}$ cfu/g. Termophiles also reduced the accounts from an initial 4.34 to 2.93 $\log_{10}$ cfu/g, psicrophiles reduced from 7.05 to 2.93 $\log_{10}$ cfu/g, anaerobes reduced from 6.35 to 2.22 $\log_{10}$ cfu/g, moulds and yeasts reduced respectively from 2.24 and 4.92 to 1.11 and 2.24 $\log_{10}$ cfu/g, *Enterobacteriacea* reduces from 5.34 to 3.66 $\log_{10}$ cfu/g and the number of lactic acid bacteria reduced from 5.04 to 2.32 $\log_{10}$ cfu/g. *Staphylococcus aures* coagulase positive was present up to 0.1g in the cooked product. Research on the cooked product for *E.coli* and *Clostridium* sulphite reducers' spoors (absent in 1 g), and for *Salmonella* and *Listeria monocytogenes* (absent in 25 g) was always negative.

Conclusions

The ingredients hygienic quality is low therefore the raw product is heavily contaminated with vegetative microorganisms. Sometimes pathogens can be present. The shelf life of the raw product is very short and, therefore, it can be considered a dangerous product because it may be a source of cross contamination to other foods.

The heat processing of the product improves its hygienic standards and eliminates vegetative pathogens but not all spore forms. However, it cannot be overestimated because there is risk of recontamination during assembly that may present a food safety hazard. On the other hand, the heat treatment is probably too long, which results in fat losses and production yields.

Shelf life of the heat-processed product will depend on the control of all the above-mentioned factors. The growth of pathogenic flora can be controlled by product formulation, packaging systems and chill storage conditions. Modifications based on technology and combined preservative factors should be researched in order to develop a hurdle technology capable of preventing microbiological and chemical spoilage as well as the risk of food borne diseases to the consumer.

Background

In manufacture of dry fermented sausages, the drying/ripening stage is of decisive importance to the final product sensory properties. During this process, the occurrence of complex physicochemical, biochemical and microbial phenomena affect proteins and lipids, modifying their structural integrity and physical characteristics (Gray & Pearson, 1984; Melgar *et al*., 1990). Different formulations are adopted according to cultural traditions of the geographical regions where they are produced but generally lipids represent the major fraction. The specificity of the flavour is then greatly dependent on the intrinsic composition of raw materials and on the hydrolytic and oxidative changes operated on that substrate. This is influenced by a wide range of factors namely, the relationships of environmental temperature/relative humidity/ventilation, type of ingredients/spices and duration of ripening.

Objectives

The present study was undergone to evaluate the chemical composition of "Painho de Portalegre", a traditional dry fermented sausage, and the variations occurred during the ripening period.

Materials and methods

Preparation of Painho de Portalegre and sampling – Chilled chunks of pork lean and fat were ground to obtain mincing sizes of about 2 cm (hole plate grinder), mixed together (Sample 1) and added of paprika paste, NaCl and garlic paste. After a holding period of 3 days at 0-2˚C (sample 2), the mixture was stuffed in natural casings (rectal portion of pig intestine) and transferred to a traditional drying/smoking house (firewood burning inside) until an a_w value of 0.88-0.85 was reached. Depending on the prevalent atmospheric conditions, this period varied between 30 to 40 days. Samples 3, 4, 5, 6 and 7 were taken after 6, 15, 20, 30 and 40 days of the ripening process. After processing the product was transferred to a room temperature environment where they were stored up to day 60 and then packaged under vacuum (BB4L plastic bags) up to 180 days. During the storage period samples 8, 9 and 10 were taken at days 55, 120 and 180.

Physicochemical analysis – pH was determined using a Metrohm 654 pH meter, according to the method described in NP 3441 (1990). Water activity evaluation was carried out with Rotronic Hygrolab using a probe AwVC-DIO. Moisture was determined using the method described in NP 1614 (2002). Total lipids were extracted by the procedure of Folch *et al* (1957). Protein was determined through total nitrogen using the Kjeldahl method. Sodium chloride content was determined following the procedure described in NP 1845 (1982).

Determination of free fatty acids – Lipids were extracted from Paínho samples with chloroform/methanol (2:1) according to the method of Folch (1957). FFA were purified from neutral lipids using an anionic exchange resin (Amberlyst A-26). An aliquot of 500 mg of lipids was dissolved in 30 ml of a mixture of acetone/methanol (2/1) as described by Alasnier *et al.* (2000) and Needs. The mixture with the lipid fraction was mixed with 750 mg of the exchange resin, was added with 1 ml of the internal standard solution (20µl of heptanoic acid/ml acetone/methanol) and shaken for 60 min. The resin was washed five times with 5 ml of acetone/methanol mixture for removing of neutral lipids. After drying for 1 h at ambient temperature, the resin with adsorbed FFA was placed in a reaction vial for FFA methylation with BF_3 in methanol (14%) as described by

Partidário (1998). The methyl esters were separated and quantified by gas chromatographic analysis, on a TRACE GC, series 2000 instrument (Thermo Quest, USA), using a DB-23 (50% cyanopropyl-

methylpolysiloxane) fused silica column (60 m long, 0,25 mm i.d., 0,25µm film thickness), supplied by J&W Scientific, Folsom, USA.
For the determination of fatty acid composition of triacylglycerols, extracted lipids were dissolved in isooctane and transesterified with a methanolic solution of KOH (0,1N). Methyl esters were separated and quantified as just described.

Results and discussion

Table 1 shows the mean, standard deviation, maximum, and minimum values found out for some general parameters, which are important to the characterisation of centesimal composition of "Painho de Portalegre". For a similar water availability (mean a_w=0.87), this traditional dry fermented sausage presented some variation in protein/fat relationship among producers, from a minimum of 0.30 up to a maximum value of 0.62. Sodium chloride content, an important factor influencing the ripening process evolution, in particular the rate and extension of the lipid autoxidation process, also showed variations of about 2%, between 3% and 5% approximately. The continuing decrease of pH, which likely affects the preservation ability, the physical aspect and the taste characteristics of the product, is closely associated to microbial development along the processing stages. The degree of variation verified in this study is enough expressive to differentiate the final products into acid (pH< 5.0) or moderately acid (pH>5.5).

Results for the fatty acids composition of pork fat used in "Painho de Portalegre" production showed a saturated/unsaturated fatty acids relationship lower than the usual profile referred for this type of product (Ordónez *et al*., 1999) (Table 2). This difference (0.48 vs 0.69) is basically due to the lower presence of C16 (-4.2%) and C18 (-4.6%) elements and a significantly higher concentration of oleic acid (+9.4%) and could be ascribable to the rearing and feeding procedures applied to the animal production system.
Raw material analysis showed already important amounts of FFA, reaching about 707 mg/100g of fat (Table 2). Among these compounds, C18:1 (9), C16 and C18 predominated, with values of 276.5 mg, 144.7 mg and 112.9 mg/100g of fat, respectively, keeping that order all over the ripening process. Linoleic acid appeared in 4th place with 80.6 mg/100g fat, and was the only detected polyunsaturated fatty acid. All the other elements appeared at much lower concentrations. At this early processing stage, MUFA slightly predominate over SFA, making a SFA/MUFA relationship of 0.93. During the standing of spiced raw materials in the refrigerator (flavour up taking and natural flora selection purposes) FFA formation was just slightly increased (+5.7%). However, a remarkable change occurred in the FFA profile, due a the significant rise in SFA (497.5 mg vs 301.9 mg) and, on the contrary, a sound reduction in MUFA and PUFA concentration, approximately –40% in both classes. As a consequence, the SFA/MUFA relationship more than doubled (0.93 vs 2.44). The evolution of C16/C16:1 and C18/C18:1 quotients clearly shows that the relative extension of that saturation mechanism affected mostly the former (6x vs 1,6x). However the possible impact over the product sensory quality coming from oxidation of oleic fatty acid
should also be emphasised due to its much higher concentration in the raw material prior the chilling holding stage (303 mg- C18:1 (9)+(11) vs 18.6 mg-C16:1 (7)+(9)).

During the development of the fermentation which occurs at least during the first 6 days of the drying/smoking process (Sample 3), intrinsic and microbial lipolysis phenomena proceeded continuously up to day 180 (Sample 10), and was traduced on a 4 fold increase of the FFA level (1053 mg vs 4187 mg). Apart the initial phase where SFA content was still superior to MUFA (SFA/MUFA=1.3), the unsaturation level of the FFA profile gradually increased up reaching a SFA/MUFA relationship of 0.63 (55 days of ripening-S8). This is in agreement with the results reported by Chasco *et al*., (1993) for identical dry fermented sausages.

The conditions under which the processing stages take place are thought to be extremely important to the definition of the eating quality of the final product and to its stability over the storage period. Despite the formation of straight chain aldehydes butanal, pentanal and hexanal by a mechanism other than lipid peroxidation should not be ruled out, a significant correlation between their concentration, namely that of hexanal, and the rancid alteration of lipids has been observed (Shahidi *et al*., 1986).

From an extended study made on Paínho de Portalegre (results submitted for publication elsewhere) it could be observed that hexanal was never identified in all evaluated ripening periods (Table 3).

Table 3- Relative percentages % r.p. of volatile aldehydes detected along the drying/ripening stages.

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10
2-Metylpropanal	-	3.73	0.0	0.0	1.63	1.36	0.0	0.0	0.0	0.0
Butanal	-	0.0	0.0	0.0	0.0	0.0	0.39	0.0	0.69	0.48
2-Metylbutanal	-	0.0	0.0	0.0	0.0	0.20	0.15	0.19	0.62	1.65
Pentanal	-	3.45	0.0	0.3	0.39	0.0	0.15	0.0	0.82	0.0
2-Metylpentanal	-	0.0	0.94	0.0	0.0	0.27	0.17	0.0	0.0	0.0
Hexanal	-	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0

Pentanal and 2-metylpentanal predominated at the early phases of processing (spiced raw materials stored at a chilling room - 3.45%r.p.) and during fermentation (first 6 days on drying/smoking house -0.94%r.p.), but its concentration decreased during on going stages to less than 0.5%. The presence of butanal was only noted from day 40 of ripening in minor concentrations (0.39%, 0.69% and 0.48% at day 40, 120 and 180 of storage ripening period, respectively). The detection of 2-metylpropanal in S2, with a value of 3.7%r.p., is probably a consequence of the utilization of linoleic acid by microbial agents (Grosch, 1987) and could explain the drop observed for this fatty acid in the free form at this processing stage (80.6mg to 45.2mg).

Conclusions

Painho de Portalegre is characterized by a strong lipolysis during the processing and storage ripening period, over 180 days, traduced by an expressive liberation of fatty acids, which is more pronounced in the period of greater microbial development (first 15 days of drying/smoking stage). Excepting the earlier processing period in which saturated fatty acids predominated, MUFA is the most important class of compounds. The reduced production of straight chain aldehydes, namely hexanal, can be an indicator of good lipid stability, associated to the natural ingredients used on spicing and the intense/long smoking phase.

PREDICTING THE RISK OF HIDE CROSS-CONTAMINATION IN THE CATTLE LAIRAGE DURING HOLDING PRIOR TO SLAUGHTER

A. Small & S. Buncic

Division of Farm Animal Science, Department of Clinical Veterinary Science, University of Bristol, Langford, Bristol, BS40 5DU, UK

Background

Foodborne pathogens carried asymptomatically in the intestines of cattle can be found on the hides of these animals [1], and pose a significant risk of contamination of the subsequent carcass during the slaughter and dressing procedure[2]. Similarly, spoilage organisms present on the hide can be transferred to the carcass during harvest [3]. Although only a small proportion of animals arriving at the abattoir may be contaminated with significant pathogens, extensive cross-contamination can occur during the holding period [4]. Understanding of the factors affecting the rate of transfer of micro-organisms between animals could assist in developing a risk-based strategy to minimise the spread of foodborne pathogens during the pre-slaughter phase, thus minimising the risk of contamination of carcasses processed in the abattoir.

Objectives

This study aims to evaluate some factors affecting cross-contamination during the holding period prior to slaughter in the commercial cattle abattoir.

Materials and methods

91 groups of cattle were observed continuously throughout the holding period at a large commercial beef processing plant in the Southwest of England. One focal animal in each group was selected and each incident of contact between that animal and either the vertical structures of the holding pen or another animal within the group was recorded, in five-minute blocks throughout the holding period, a minimum of 30 minutes. Group size ranged from 1 to 18 animals, held in pens of 24 m^2 to 30 m^2, giving space allowances ranging from 1.88 m^2 to 26 m^2 per animal. The result sets were grouped into low ($\leq$ 2.5 m^2 per animal), medium (2.5 $\leq$ 5 m^2 per animal) and high (>5 m^2 per animal) stocking density and the number of contacts over time analysed by ANOVA using MINITAB Statistical Software.

Results and discussion

Over the 30-minute holding period, at all stocking densities, total number of contacts affecting the focal animal in each 5-minute block declined. At all stocking densities, the numbers of contacts with the vertical structures of the pen did not significantly decline over time, and there was no significant difference in the numbers of wall contacts occurring per time block between each stocking density. At medium and high stocking densities there was a significant difference between animal activity in the first ten minutes of holding and in the subsequent period, by comparing average contacts per animal per minute (ACAM) (Table 1). There was also a significant difference in ACAM over all time periods between stocking densities, animals at low stocking density experiencing fewer animal-to-animal contact incidents than animals at medium stocking densities, which in turn experience fewer animal-to-animal contact incidents than animals at high stocking densities. The relationship between ACAM over a 30-minute period ($ACAM_{30}$) and space allowance was not linear, whilst plotting $ACAM_{30}$ against $\log_{10}$ space allowance showed two distinct lines of best fit, one associated with medium to high stocking density, the other associated with low stocking density. Linear regression analysis of the line of best fit associated with low stocking density identified that to achieve no animal-to-animal contacts, each animal would require a space allowance of 17.22 m^2, whereas linear regression analysis of the line of best fit associated with medium to high stocking densities suggested that a space allowance of 4.22 m^2 would lead to no animal-to-animal contacts.

Conclusions

It is likely that each physical contact of animals with lairage's structures and other animals results in some extent of transfer of microbial contamination, if one of hides/contact surfaces is contaminated. During the holding period at the lairage, contact between a beef animal and the structure of the holding pen is inevitable. Furthermore, micro-organisms remaining on the pen walls when one group of animals is removed are likely to be transferred to animals' hides in subsequent groups of cattle. Contact between animals does increase with restricted space allowance, but to eliminate the risk of animal-to-animal transfer of micro-organisms, each animal would require a substantial amount of space. Animal interactions at low stocking densities differs from that at medium to high stocking densities, those at lower densities maintaining a level of interaction over the entire lairage holding period, whilst animals at medium to high stocking densities appear to settle down after the initial ten-minute period, reducing interactions. Use of ACAM factors could assist in predicting the risk of hide cross-contamination during the holding period, by estimating the numbers of contacts that would occur in a group of animals at a particular stocking density, over a set period of time. As the hide contamination is a key factor for carcass contamination, this would be the first step in risk-assessment-based identification and development of best strategies to improve meat safety through controls of hide contamination.

Background

Nham, traditional Thai fermented pork, is normally consumed without cooking and considered as a ready-to-eat food after 3-4 days of spontaneous fermentation. The reports on occurrence of the most common contaminant strain of *Salmonella anatum* in the product [1, 2, 3] are therefore a serious public health concern. Since the advantage of using lactic starter cultures was reported to have a positive effect on the microbiological quality and safety of various fermented products [4, 5], thus, the use of lactic starter cultures to control *S. anatum* in Nham was studied [1, 6]. The selection of the most potent bacteriocin-producing lactic acid bacteria (LAB) from the spontaneous fermentation of this thai fermented meat product had been studied [7, 8]. The strain of TISTR 536, which was first isolated from Nham [9] and kept as LAB culture collection at Thailand Institute of Scientific and Technological Research (TISTR), was later studied for bacteriocins production and reported as a bacteriocin-producing strain [8]. The strain exerted the best antimicrobial spectra of their produces on various indicators, which included the opportunistic food pathogens of *Listeria monocytogenes* and *Enterococcus faecalis* [8]. This strain exhibited no effect on *Staphylococcus carnosus,* which may enhance adverse effects on colour and aroma of Nham.

Objectives

According to the report on antagonistic substances produced from LAB strain TISTR 536 [8], thus, this report was conducted to identify the strain of TISTR 536 by using 16S rDNA sequence analyses and commercial kit carbohydrate fermentation patterns of API 50 CHL. In addition, identification of bacteriocins produced from this strain was also reported in the study.

Materials and methods

Bacterial strains and culture media : Bacteriocin-producing strain of TISTR 536 obtained from Bangkok MIRCENS in lyophilized form was used in this study. Before experimental use, the culture was cultivated twice in de Man Rogasa Sharp (MRS) broth [10] and incubated at 30^{o} C for 20-24 hours.
Escherichia coli JM 109 was used as host cell for PCR cloning and sequencing analysis. The strain was propagated in LB medium containing 50 µg/ml of ampicillin at 37^{o} C [11].

Identification of TISTR 536 : Carbohydrate fermentation patterns for the isolated strain of TISTR 536 were determined by using API CHL 50 test (bioMorieux Vitek, Inc., Hazelwood, Mo.) and 16S rRNA sequence analyses were performed by using the following methods :
Partial phenotypic characterization of the strain was performed by firstly preparing overnight cultured of TISTR 536 in MRS broth. 2 ml of the overnight cultured was harvested by centrifugation. The cells were then resuspended in 80 µl of TE buffer (50 mM Tris, 50 mM EDTA, pH 8). Lysis was initiated by the addition of 5 mg/ml lysozyme. After incubation at 37^{o} C for 30 min, the mixture was further provided with MagExtracter-Genome (TOYOBO) as specified by manufacturer. 16S rDNA gene was applied from genomic DNA using primer 1101A (5'- AACGAGCGMRACCC–3') and 1407B 5'-GACGGGCGGTGTGTRC –3') based on primers described by Kawamura, *et al*. Reaction [50 µl contained 50 mM KCl, 10 mM Tris-HCl pH 8.3, 1.5 mM $MgCl_2$ and 0.1% Triton X-100, TOYOBO Co. Ltd.), 200 µmol of each deoxynucleotide triphosphate (TOYOBO Co. Ltd.), 20 pmol of primer and 1 U of Taq polymerase (TOYOBO Co. Ltd.)] was set up in a tube containing 200 ng of template DNA and genomic DNA amplification was then performed using Astec program temp control system PC-800. The program was

3 min at 94° C for 1 cycle followed by 30 cycles of 94° C at 30 sec, 55° C at 30 sec and 72° C at 1 min. The additional step for extending incomplete products was performed at 72° C for 5 min. PCR product was TA cloned and transformed into E. *coli* JM109. Selected white colonies were picked and transferred into 20 µl of PCR solution for confirming the insert using M13 forward and reverse primers (5'-GAGTGGGAACTAGAATAAGCGCGTA–3' and 5'–TTTCACACAGGAAGCTAT GAC –3' respectively). Plasmid DNA of selected transformants was isolated using MagExtracter-Plasmid (TOYOBO). The sequence was determined by using Thermo Sequenase fluorescent-labeled primer cycle sequencing kit (Pharmacia Biotech) with an automatic sequencer (ALF express, Pharmacia Biotech). The results from the sequencing analysis were analyzed using catalogued sequences in GenBank with the BLAST tool at National Center for Biotechnology Information (NCBI).

Determination of the concentration of antimicrobial produced from TISTR 536 : The study was conducted by inoculating 1 % an overnight culture of the selected potent LAB strains and culturing for 24 hours at 30° C. The culture of TISTR 536 were then centrifuged at 2,700 x g for 10 minutes. The supernatant from the culture was adjusted to pH 7.0 with 5.0 N NaOH and then filter-sterilized with 0.20 µm pore-size polysulfone (Cica, Tokyo). The cell-free supernatant was determined for antagonistic activity by using spot on lown method [12, 13] against the indicator strains (Table 1). The titer expressed in activity units/ml (AU/ml) was defined as the highest dilution factor of bacteriocin preparation that still caused a clearly visible zone of inhibition in the indicator lawn.

Bacteriocins purification : The cell-free supernatant of 2 liters culture incubated at 30° C of TISTR 536 was purified by a four step procedures as described by Ennahar *et al.* (1999) [12]. The final sample containing the purified bacteriocins was dried by Speed-Vac rotary evaporator (Savant Instruments) and stored at –20°C.

Mass spectrometric : The molecular masses of purified bacteriocins were determined using a Accu TOF spectrometer, model JMS-T100LC (Agilent Technologies, Germany).

PCR analysis and DNA sequencing of bacteriocin from TISTR 536 : The total DNA of TISTR 536 was isolated by using the method described by Anderson and McKay [14]. Pediocin PA-1 primer designed and synthesized (Hokkaido System Science Co. Ltd., Hokkaido, Japan) for PCR amplification are Pedi-1F (5' –GAGTGGGAACTAGAATAAGCGCGT A –3') and Pedi-1R (5' –TTACTCTTATTCATAAAATCACCCC –3'). DNA analyses and sequence alignments were carried out using the BLAST program [15].

Results and Discussion

Identification of TISTR 536 : Microscopic results of TISTR 536 revealed that this strain was gram-positve, coccus-shape bacteria and existed in pairs and tetrads. Based on the microscopic results and the rapid API carbohydrate fermentation patterns (Table 2) implied that the microorganism was 92.4 % identical to *Pediococcus pentosaceus*. By the complete DNA sequence analysis, the results showed the 100% of identity related to *P. pentosaceus*. Thus, this was confirmed that LAB strain TISTR 536 is classified as *P. pentosaceus*.

Determination of the concentration of antimicrobial produced from TISTR 536 : The confirmation of antagonistic produced from TISTR 536 was reexamined with 20 indicator strains using MRS cell-free cultured supernatant spot on lawn (Table 3). The results revealed that the LAB strain TISTR 536 could produce bactericidal substances to inhibit various bacterial indicators and exhibited most effect on *Kocuria varians*, *Lactobacillus plantarum* (ATCC 14917T), *L. sakei* subsp. *sakei*, *Listeria innocua* and *Lis. monocytogenes.*

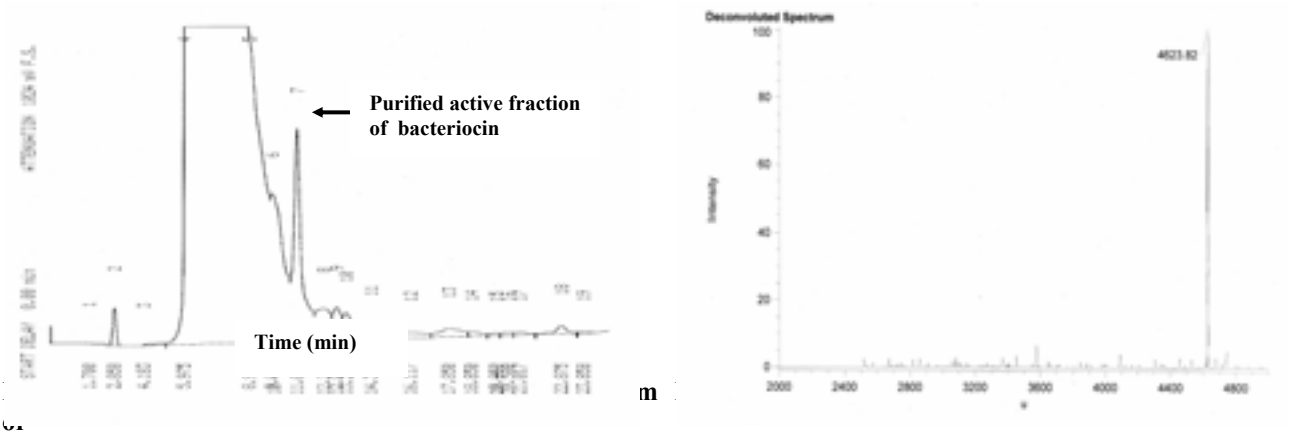
Bacteriocin purification and Molecular mass determination : The bacteriocins from TISTR 536 were purified after subjecting to C_2/C_{18} reverse-phase (PepRPC HR 5/5, Amersham Pharmacia Biotech) chromatography. The active fraction of purified bacteriocin (Fig. 1) were then analyzed by ion spray mass spectrometry. The results (Fig. 2) implied that the molecular mass of this bacteriocin was related to pediocin PA-1 (4,623.82 Da) produced from *P. acidilactici* PAC1.0 [16] and *L. plantarum* WHE 92 [17].



TISTR 536 after subjected to C_2/C_{18} reverse-phase HPLC

bacteriocin from TISTR 536

PCR analysis and DNA sequencing of bacteriocin from TISTR 536 : In order to prove that the bacteriocin produced by strain TISTR 536 was pediocin PA-1, PCR analysis using the known sequences of the pediocin structural gene was performed. The expected 300 bp fragment containing the structural gene of pediocin PA-1 of TISTR 536 was amplified and then sequenced. The results (Fig. 3) indicated that the sequences were 100% identical to that of pediocin PA-1.

MICROBIOLOGICAL SAFETY IN SUCCEDANEUM ITALIAN SALAMI

Terra, N. N., Fries, L. L. M., Terra, A., Peña, C. V. M., Terra, L. M. and Milani, L.

Departamento de Tecnologia e Ciência dos Alimentos – CCR – Universidade Federal de Santa Maria – 97105-900 - Santa Maria – RS – Brazil - e-mail: nelcindo@terra.com.br

Background

The Italian salami is characterized by being a fermented sausage that takes thirty days for its production, where in the first seven days the fermentation occurs and in the others twenty-three days there is the formation of its characteristic flavor (Fernández *et al* 2001 and Demeyer *et al,* 1996). The substitution of starter cultures in Italian salami production by the addition of encapsulated organic acids followed by cooking will assure a microbiological safety product and reduce the time of its production (Terra, 1998 and Lizaso *et al* 1999).

Objectives

The objective of this work was to produce differentiated Italian salami by substituting the starter cultures by the addition of encapsulated organic acids followed by cooking. This fact will make possible to produce similar Italian salami in a shorter time and without the need of ripening house.

Materials and methods

To the elaboration of a succedaneum Italian salami, three treatments were used as follow: Treatment 1 - control, Treatment 2 - received 500g of MEATSHURE encapsulated citric acid and treatment 3 – received 400g of MEATSHURE encapsulated lactic acid. The pork meat was cut in a 16 mm disk and the bovine meat was cut in a 3 mm disk. After grinding salt, cure meat mixture and others ingredients were added to the basic mass (Terra, 1998). Starting from the basic mass, the three treatments were separated, where T1 is the basic mass (control), T2 and T3 had the addition of encapsulated organic acids as above. The treatments were equally stuffed in fibrous case (40 mm), previously put in a 2% lactic acid solution, identified and cooked in the incubator. The encapsulated citric acid (MEATSHURE TM 341) is composed by 50% of citric acid and 48 - 52% of vegetable oil partially hydrogenated. The encapsulated lactic acid (MEATSHURE TM 509) is composed by 30% of lactic acid, 48 - 52% of calcium lactate and 48 - 52% of partially hydrogenated of cotton and soybean oils. The proportion of encapsulated organic acids added to the treatment of the succedaneum Italian salami was 1% of citric acid and 0,82% of lactic acid. Total mesophilic aerobic microorganisms, coagulase positive *Staphylococcus* and *Escherichia coli* determinations were done.

Results and discussion

The succedaneum Italian salami was done in 24 hours. The experimental results demonstrated the reduction of meat initial pH (6,1) to 5,3 in the treatment with encapsulated lactic acid and 5,1 in the treatment with encapsulated citric acid. The initial microbiological counts before the acids addition and the cooking was 10^6 UFC·g^{-1} for the mesophilic aerobic bacteria, 10^3 UFC·g^{-1} for *E. coli* and coagulase positive *Staphylococcus*. The Italian salami treated with encapsulated organic acids followed by cooking presented a significant microbiological reduction. The salamis treated with lactic acid showed 10^3 UFC·g^{-1} for mesophilic aerobic microorganisms, 10^2 UFC·g^{-1} for *Staphylococcus* and 10^1 UFC·g^{-1} for *E. coli* (Figure 1). In the salami treated with citric acid presented less than 10^1 UFC·g^{-1} counts for all tested microorganisms (Figure 2). In none of the salamis treated with encapsulated acids followed by cooking was observed the presence of coagulase positive *Staphylococcus*. The addition of encapsulated organic acids in the salami partially substituted the action of starter cultures, acidifying the mass and consequently making a safe product for the costumer. The reduction of microbial contamination followed the pH reduction in the treated samples presented a larger microbiological safety for the succedaneum Italian salami.

Conclusions

The production of acidified and cooked Italian salami demonstrated to be an option for microbiological safe products with low cost and reduced time of production.

ENRICHMENT OF THE ITALIAN SALAMI WITH INSOLUBLE WHEAT FIBER

Terra, N. N., Terra, A.. M., Peña, C. V. M., Terra, L. M., Milani, L. and Fries, L. L. M.,

Departamento de Tecnologia e Ciência dos Alimentos – CCR – Universidade Federal de Santa Maria – 97105-900 - Santa Maria – RS – Brazil - e-mail: nelcindo@terra.com.br

Background

Since the old times, the Italian salami is known as a sausage of thick mass, fermented and ripened (Lizaso et al, 1999). The fat content of the salamis results in a consumption obstacle for this product by people who show cardiovascular and nutritional problems. The salami's fat is partly responsible for the sensorial characteristics of the product, when the tissue enzymes and bacterial lipolysis takes place. The drastic reduction of salami's fat would implicate in sensorial alterations, which are capable to turn the product unacceptable by the consumer, such as the aroma and flavor alterations (Demeyer et al, 1996). The fiber addition in the salami production without reducing the fat content could be a way of improving the nutritional value without altering the sensorial characteristics of this meat product.

Objectives

The objective of this work was to evaluate the effect of the addition of insoluble wheat fiber to the Italian salami, on its acceptability by a non-trained panel and the pH, moisture, fat content and water activity changes.

Materials and methods

For this experiment the Italian salami was elaborated using three treatments as following: Treatment 1: control, without the addition of starter culture nor the insoluble wheat fiber; Treatment 2: only the addition of starter culture and the Treatment 3: the addition of the starter culture as well as the insoluble wheat fiber. All the treatments were obtained by grinding the pork and bovine meats and adding salt, cure salts, seasonings and antioxidant. The stuffing was done using a natural casing (Terra, 1998). The starter culture used was a combination of *Lactobacillus plantarum* and *Staphylococcus xylosus*. Each treatment had 18 samples. Moisture, fat content, pH and water activity were determined (Terra & Brum, 1988). The sensorial analysis was accomplished by 15 non-trained judges. The analyzed sensorial parameters were appearance, color, odor, flavor and texture.

Results and discussion

The insoluble wheat fiber addition in the Italian salami reduced the moisture in the treatment 3 (Table 1), reducing the water activity (a_w) of the product. The reduction of a_w (Table 1) caused by pH drop reduces the water availability for biochemical and physical-chemical reactions, which are necessary for the growth and the multiplication of microorganisms and the possible toxins formation (Jay, 1994). The reduction of the pH values is responsible for the water liberation from the product, for the formation of sensorial characteristics of the salami and for the aid the homofermentative acid lactic bacteria to overcome the contaminant flora through the competitive antagonism. The fat content was important for endogenous and bacterial lipases, because they are the main responsible enzymes for the liberation of free fatty acids during ripening, with preferential release of poly-unsaturated fatty acids (Demeyer *et al*, 1996). The importance of lipolysis for lipid oxidation and thus, flavour promoting effect is often assumed. All the treatments were approved with grades superior than 5.0 (Table 2). The starter culture in the treatments T2 and T3 contributed for the acceptability of the product, and the insoluble fiber of wheat did not significantly differ ($p<0.05$) in the acidification and flavoring.

Table 1. The pH, moisture, fat and water activity values of the Italian salami treated with insoluble wheat fiber in the presence or absence of *Lactobacillus plantarum* and *Staphylococcus xylosus*

	Determinations			
Treatments	**pH**	**M(%)**	**F(%)**	**Aw**
T1	4.8	32.1	32.7	0.9
T2	5.2	39.4	31.6	0.86
T3	5.1	37.9	32.1	0.82
Mean	5.03	36.46	32.10	0.88

T1= control
T2= Italian salami treated with *Lactobacillus plantarum* and *Staphylococcus* ***xylosus***
T3= Italian salami treated with *Lactobacillus plantarum* and *Staphylococcus xylosus* and insoluble wheat fiber
M= moisture **F**= fat **Aw**= water activity

Table 2. Sensorial characteristics of the Italian salami treated with insoluble wheat fiber in the presence or absence of *Lactobacillus plantarum* and *Staphylococcus xylosus*

	Sensorial properties				
Treatments	**Appearence***	**Color***	**Odor***	**Flavor***	**Texture***
T1	7.8	7,9	7.0	6.0	6.0
T2	8.0	8.5	8.2	8.5	8.1
T3	6.9	6.5	6.3	6.9	6.5
Mean	7.56	7.9	7.0	6.0	6.0

T1= control
T2= Italian salami treated with *Lactobacillus plantarum* and *Staphylococcus xylosus*
T3= Italian salami treated with *Lactobacillus plantarum* and *Staphylococcus xylosus* and insoluble wheat fiber
*The values correspond as: > 5.0 = acceptable; < 5.0= unacceptable

Conclusions

The insoluble wheat fiber addition can enrich a product without altering the sensorial characteristics. The insoluble wheat fiber added to a fermented sausage is a new meat product and it is a healthier option for the consumer.

Background

The high quality and the safety of fresh meat products are important features to be conserved during the production, the distribution and the storage.
During the last years, several studies were carried out in order to reduce the spoilage bacteria and, consequently, to extend the shelf-life of the products. Djenane *et al*. (2002) showed small but significant inhibition of the growth of psychrotrophic microorganisms with the application of rosemary extract on the surface of beef steaks, although Sanchez-Escalant *et al*. (2001) demonstrated a lack of effect of the antioxidants on microbial growth. Zhagh *et al*. (1996) reported that the storage of beef in presence of lactic acid reduces the initial number of spoilage bacteria. Moreover, the modified atmosphere packaging (MAP) is well known as a method for extending the shelf-life of meat products (Luno *et al*., 2000; Djenane *et al*., 2002; Jajasingh *et al*., 2001).
In a recent study, Djenane *et al.* (2003) showed that either lactic acid bacteria and *B. termosphacta* are significantly inhibited in beef steaks packaged in CO_2 40% and the shelf-life of these products, previously treated with lactic acid and a mixture of natural antioxidants, could be extended. Even though, the use of modified atmosphere with high CO_2 and low O_2 levels could cause meat bleaching (Ledward, 1970; 1984).
Jayasingh *et al*. (2001) reported that the colour stability of ground beef, packaged with CO 0.5%, was strongly improved. However, the consumers require safe and natural products (Hugas *et al.*, 2002) without additives such as preservatives and antioxidants and without the use of toxic gasses.
In this perspective, the present study aimed to compare three different gas mixtures. The screened MAP were obtained with low CO_2 and high O_2 concentration (MAP1), high CO_2 and O_2 concentration (MAP2), or high CO_2 and low O_2 concentration (MAP3).

Objectives

The aim of this study was to investigate the effect of different modified atmosphere packaging on the shelf-life of fresh meat products in order to harmonise the safety with the sensorial quality of the products.

Materials and methods

Use of modified atmosphere packaging. A mix of triturated pork lean, fat (10%), NaCl (2.5%) and black pepper (0.15%) was used to fill casing. After filling, the products were divided into four batches. The first (MAP1) was packaged in modified atmosphere containing CO_2 20%, O_2 70% and N_2 10%; the second (MAP2) was packaged in modified atmosphere containing CO_2 40% and O_2 60%; the 3rd (MAP3) was packaged in modified atmosphere containing CO_2 40%, O_2 30% and N_2 30%; the last batch was used as a Control (C) and packaged without gas mixtures. Each batch was stored at +4 °C for 12 day.
pH measurement. Potentiometric measurement of pH was made at 0, 3, 6 and 12 days of storage by inserting a pin electrode of a pH-meter (Crison 2001) directly into each sample. The results were expressed as the mean of four determinations performed on different parts of the samples.
Colour determination. Colour was measured on sausages at 0, 3, 6, and 12 days of storage, using the Hunter L*, a*, b* system (CIE, 1978) with a reflectance spectrophotometer (Minolta CR300b).
Microbial analyses. Total and faecal coliforms were counted on VRBLA after incubation for 48 h at 37 °C and 44 °C respectively.
Total mesophylic bacteria were counted on Plate Count Agar (Oxoid) after incubation at 28°C for 48 h.

Brochothrix thermosphacta was enumerated on STA Agar base (Oxoid) with STA selective supplement (Oxoid) after incubation at 37°C for 48 h.
Pseudomonas spp. were counted on Pseudomonas Agar (Oxoid) with SR102E supplement (Oxoid) after incubation at 22°C for 24 h.
Water holding capacity, cooking loss and shear force analyses. Water holding capacity (WHC) was measured with the procedure described by Monetti (1997), and values were expressed as meat expulsed water. For cooking loss determination, sausages were weighed and cooked at 177 °C in a convection oven to an internal temperature of 74 °C. The temperature was measured with thermocouple probe inserted into the center of the sample. After cooling at room temperature, sausages were weighed, and cooking loss was determined as percentage reduction of weight.
For Warner-Bratzler shear force determination cooked sausages were cooled, wrapped in freezer paper and held overnight at 4 °C before WB shear values were obtained on four 1.27 cm-diameter cores. Each core was sheared three times at a crosshead speed of 230 mm/min. Average shear values for each sample were calculated on the basis of 12 measurements.

Results and discussion

The packaging without modified atmospheres caused an increase in undesirable microorganisms producing alterations. In fact, the samples from batch C showed an appreciable increase in psycrotrophic microorganisms, such as *Pseudomonas* spp., able to degrade the proteins producing off-flavours and free amines.
B. thermosphacta is described by several Authors (Grau, 1980; Nissen *et al*., 1996) as an important and undesirable microorganism in the fresh meat products. This species occurs constantly in the samples packaged without modified atmospheres and in the present work showed an increase in counts during the storage time in the Control samples. In this batch an increase of all the other microbial groups was also observed.
In this research we observed that CO_2 produces an appreciable action on microbial growth in batches stored in modified atmosphere, as previously demonstrated by other Authors (Djenane *et al*., 2003), but the effect and the entity of the antimicrobial activity are both due to the CO_2 concentration and to the presence of other gasses. In fact, the batches treated with a modified atmosphere of CO_2 20% (MAP1) showed microbial counts very similar to those of the Control batch (without modified atmosphere).
CO_2 40% determined the best results on the assayed fresh sausages but this CO_2 percentage showed different effects on microbial growth when combined with different O_2 concentrations: the mixture CO_2 40% and O_2 60% (MAP2) caused a sensitive inhibitory effect on microbial growth but no effect was revealed in the samples packaged with CO_2 40% and O_2 30% (MAP3). In fact this combination evidenced a lack of effect on microbial counts and the samples showed an increase of the altering microorganism, even though their levels were slightly lower when compared to those of MAP1 and of the Control batch. Concentration of CO_2 20% (MAP1) didn't seem to cause any inhibitory effect on the spoilage bacteria.
These results confirmed that microorganisms are CO_2-sensible in presence of a high O_2 concentration while they are not CO_2-sensible in a low O_2 concentration (Mano *et al*., 2000).
The gas composition of the MAP2 determined also a positive effect on the definition and maintenance of the red colour, the most important parameter for the consumer's choice. In the samples from MAP2 the high O_2 concentration permitted the presence of myoglobine in oxidative state, which is responsible for the red colour, and at the same time, the high CO_2 concentration assured the safety of the product. The above phenomena have not been recorded in the samples from the other batches.
In conclusion, the gas mixture of MAP2 determined a good inhibitory effect on the microorganisms, assuring the prevention of alterative factors, and positively affecting some rheological parameters.
In fact, greater WHC showed by those sausages determined less cooking loss, while the treatment didn't modify the juiciness. In addition, sausages from MAP2 showed a more reduced shear value.

Conclusions

By the results obtained from microbiological, physical and rheological analyses it was possible to understand the playing role of the different atmosphere compositions on the microbial evolution and on the quality of sausages during the storage. In particular the use of techniques that modify in a very significant way the microbial growth in fresh sausages allowed us to assure the preservation of the most important quality parameters and the extension of the shelf-life.

Background

The production of naturally fermented sausages in the Mediterranean countries and the southern part of Central Europe has a very long tradition. In the second half of the 20th century, sausage production has been gradually industrialized and a very large assortment of fermented sausages has been developed. Aiming at maintaining the traditional sensorial quality of dry sausages and to assure their safety, although produced in industrial scale, it is important to develop and use protective cultures, after selection of strains isolated from naturally fermented products. A prerequisite for this research is to identify the main differences in the traditional production of fermented sausages, in various countries, and to study the evolution of physicochemical and sensorial characteristics of the sausages, during natural fermentation and ripening.

Key words: fermented sausages, physicochemical features, sensorial characteristics

Objectives

The main task of the research was to investigate the physicochemical features (pH, a_w and NaCl content) and the sensory characteristics of certain naturally fermented sausages, as produced traditionally in different countries (Greece, Serbia and Montenegro, Bosnia and Herzegovina, Croatia, Hungary and Italy). At the beginning, sausage composition was defined and then, during the processes of fermentation and ripening, the physicochemical and sensorial characteristics were investigated.

Materials and methods

For the purpose of the investigations, typical traditional sausages were produced in local meat processing plants, without using starter cultures. Sausages composition is presented in the table 1. The specifications applied in the preparation stage (final size of meat and fat pieces and used casings) as well as the critical technological parameters (i.e. temperature, relative humidity and duration) in the subsequent stages of traditional production (i.e. draining of stuffed sausages, smoking, fermentation, ripening and drying), are presented in table 2.

Three batches of sausages were used for the experiments, carried out within a 3 month period. Samples were taken from each batch at 0, 2, 4, 7, 14 and 28 days after formulation. Every sampling day, 3 sausages were transported to the laboratories and subjected to physicochemical analysis (moisture, NaCl, nitrite and nitrate content, pH and a_w). Standard methods were used for the analysis.

At the end of each process, sausage samples were subjected to sensory analysis. A panel of 10 persons was created in each country. In a 10 degrees scale, the panelists had to grade the produced sausages for coherence, smell, acidity, tenderness, flavor, after taste and overall impression. The differences in the sensory scores were further evaluated using a statistical program.

Results and discussion

Sausage composition, dimensions as well as fermentation-ripening processes varied among the different countries. Serbian, Hungarian and Italian sausages are produced by pork meat, only. The Bosnian sausages are produced by beef meat only, while the Croatian and Greek producers use mixed pork and beef meat. Other ingredients are sugars, salt, fat and spices (it might be simply black pepper for Italian sausages, garlic and paprika for Serbian sausages or spice mixture). The size of sausages varied between 28 and 50 mm in

diameter. Smoking was applied for the sausages produced in Serbia, Bosnia and Croatia, partial smoking in Hungary and Greece, while in Italy no smoking was performed. Ripening of the sausages was carried out under controlled conditions of temperature and relative humidity. In general, temperature higher than 12°C and relative humidity 60-80%, were the conditions of ripening in all countries, except for Serbia where ripening temperature was at 5-12°C. Sausages were considered ready for consumption on the 28th day, which was also considered the final time point of experiments. It should be noted that for the Croatian sausages, ripening times were usually shorter, but for purposes of harmonization with the rest of the partners, experiments were carried out beyond the average time of release to the market.

In sausages examined in Greece the most intensive decrease of pH (table 3) was observed during the fermentation and ripening procedure (6.25 to 4.90). The lowest starting pH (5.47) was detected in sausages produced in Serbia and Montenegro, but its decrease during processing was very slow (final pH was 5.27). In sausages produced by beef meat (Bosnia and Herzegovina), decreasing of pH had the most correct flow (from 6.15 to 4.86). The Croatian, Bosnian and Italian sausages showed a pH decrease till 7th day, and a slow increase in the rest 21 days of production. In sausages investigated in Hungary pH changes had the similar flow, but at a little higher level than the sausages from Serbia and Montenegro. Generally, final pH values were between 4.86 and 5.66. The most acid sausages were produced in Bosnia and Herzegovina (4.86) and Greece (4.90) and the most basic in Italy (5.66).

Salt content (table 4), just after the preparation (day 0), was between 1.51% (Croatia) and 2.52% (Italy). Proportionally to starting content and degree of moisture losses, an increase of NaCl content was observed. At the final product, the highest concentration of salt was determined in Hungarian sausages (4.71%).

Significant differences were observed in a_w values (table 5). After 28 days, a_w values in sausages investigated in Bosnia and Herzegovina, Croatia and Italy were higher than 0.90, while the lowest a_w values in the final product were found in sausages prepared in Greece, Serbia and Montenegro.

Sensorial characteristics of sausages (Figure 1), processed in the traditional way, were evaluated very high (overall impression was above 70), except products examined in Croatia. Differences between investigated sausages in other countries and Croatia were probably due to the prolongation of the usual process. Sensorial characteristics of sausages, in all 6 countries, showed that they were of very high quality with characteristic smell, flavor and coherence.

Conclusions

There are differences among the produced fermented sausages in the 6 countries, as far as composition, size and fermentation-ripening process. Physicochemical changes that occurred during ripening, can be summarized as follows for all countries:

1. Decrease of pH (final value between 4.86 and 5.66; sausages produced in Bosnia, Herzegovina and Greece are the most acid, and in Italy the most basic);
2. Decrease of a_w (final values between 0.78 and 0.94; Greek sausages had significantly lower a_w compared with the ones from other countries);
3. Increase of NaCl content (final values between 2.29 in Croatian sausages and 4.71 in the Hungarian ones).
4. The sensory analysis of the final products showed an overall acceptability of the products, above 70% for all partners, except for Croatia, due to the extension of the regular ripening time.

Acknowledgment

This research has been carried out under the umbrella of the “SAFETYSAUSAGE” project, which is funded by the E.C. within the framework of the INCO-DEV program (Contract No ICA4-CT-2002-10037). The authors gratefully acknowledge the Hungarian Meat Research Institute, the Agricultural University of Athens and the University of Udine for their physicochemical and organoleptic results, BEKKA SA, “OVAKO” Meat Industry and HUNNIA Meat Processing and Service Ltd for the production of sausages and Dr. Rantsios for his overall advice and support.

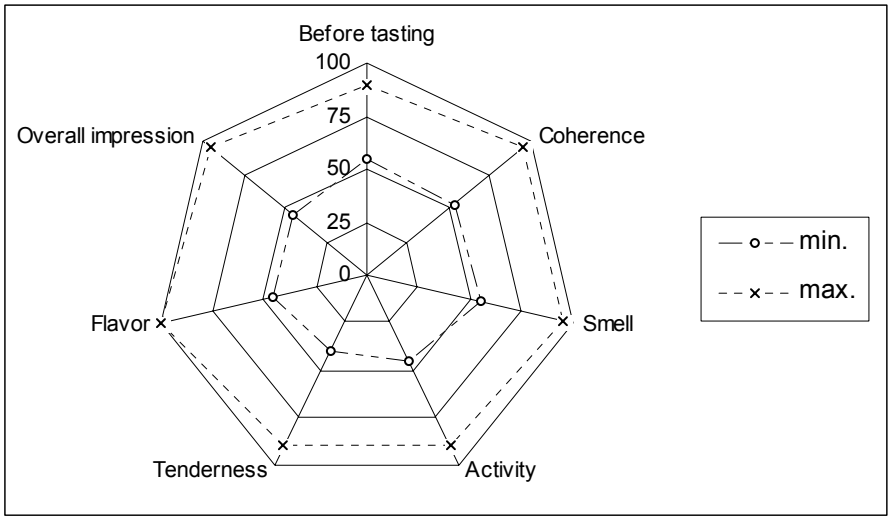
Sensorial analysis of final product

Figure 1



COMPARISON OF SENSORY AND ANALYTICAL PROPERTIES OF DRY SAUSAGE PRODUCED WITH DIFFERENT PROCESSING PROCEDURES

Kathrin Ulmer and Albert Fischer

University of Hohenheim, Institute of Food Technology, Department of Meat Technology, D-70599 Stuttgart, Germany

Background

Traditional processing of typical German dry sausage followed by ripening in drying chambers takes a long time (up to 20 days), requires huge storeroom capacity, is energy intensive and often results in low production rates. A faster method of producing dry sausage would allow considerable energy savings while raising the production rate. This could have interesting applications in the meat industry.
The concept of adding a certain amount of dried fermented meat in production of dry sausage would not only shorten the ripening time, but also raise the question if there are differences between the final products in terms of organoleptic characteristics such as odor and taste.
In earlier investigations, a number of volatile organic compounds released from dry sausage were analyzed by gas chromatography/mass spectrometry [1, 2, 3, 4]. In dry sausage, identified volatile constituents are mainly derived from added spices (pepper, garlic etc.) and as a result of light and oxygen induced lipid oxidation as well as enzymatical degradation of carbohydrates, proteins and lipids.
Also, sensory properties determined by test panels were reviewed for correlation with more objective and reproducible analytical methods such as GC/MS and electronic nose [5].

Objectives

The objective of this study was to develop a novel method to shorten the ripening time of dry sausage by adding a certain amount of dried fermented meat. In comparison with a traditional German dry sausage product, the overall properties such as odor and taste were determined by sensory evaluation and correlation with GC/MS and electronic nose results have been investigated.

Materials and methods

Production of dried fermented meat: Preparation of meat: Refrigerated lean pork (estimated fat content of 10%) was coarsely cut into pieces. 2.8% nitrite curing salt, 1.2% mixture of spices, 0.3% dextrose and a 0.05% starter cultures compound (containing *L. sakei* + *Staph. carnosus*) (Bitec, Germany) were added. All ingredients were mixed in a blender and minced through an 8 mm plate. Fermentation: The meat was fermented in vacuum-packed bags at 24°C for at least 40 hours depending on the change of the pH value (below pH 5.0). Drying: The meat was air-dried at 50°C. The drying process was completed when the weight was reduced by 60%. The dried fermented meat was chopped again on high speed in the cutter, packed in bags and stored frozen at -18°C.
Production of dry sausage (batch 1, control): Traditional dry sausages were prepared according to the following weight based formula: 30% lean frozen pork (estimated fat content of 10%), 30% 3 mm minced beef (estimated fat content of 8%), 30% frozen pork back fat (estimated fat content of 90%) and 10% 3 mm minced lean pork. Additives and spices were added per kilogram: 28 g nitrite curing salt, 12 g mixture of spices and 0.5 g of a starter cultures compound (containing *L. sakei* + *Staph. carnosus*) (Bitec, Germany). The mass was stuffed into 65 mm diameter fiber-reinforced cellulose casings (Nalo Fibrous, Kalle, Germany).
Production of dry sausage with dried fermented meat (batch 2): Dry sausages were prepared according to the following weight based formula: 5% lean frozen pork, 30% 3 mm minced beef, 30% frozen pork back fat, 10% 3 mm minced pork and 10% dried fermented meat. Additives and spices were added per kilogram (except dried fermented meat): 28 g nitrite curing salt, 12 g mixture of spices, 1 g sodium diphosphate and 0.5 g of a starter cultures compound (containing *L. sakei* + *Staph. carnosus*) (Bitec, Germany). The lack of freezing capacity during chopping makes it necessary to add liquid N_2 periodically. The mass was stuffed into 60 mm diameter fiber-reinforced cellulose casings (Nalo Fibrous, Kalle, Germany).

Ripening: The sausages were placed in a drying chamber under the following conditions: 2 days at 24°C, 88 – 92% relative humidity (RH); 2 days at 20°C, 85 – 88% RH; 3 days at 18°C, 82 – 86% RH and finally the dry sausages were ripened another day (control 8 days) at 14°C, 75 – 85% RH until a weight loss of 25% and another 22 days (control 29 days) at 14°C, 75 – 85% RH until a weight loss of 35% was reached. The sausages were smoked after 2, 3 and 5 days using friction smoke for 30 min each time.
pH measurement: The course of pH while ripening was measured using a spear tip electrode (Schott, Germany). The electrode was calibrated with two buffer solutions of pH 4.000 and 7.000.
Weight loss: The sausages were weighed once a day (Universal pro 32/34 F, Sartorius, Germany) until a weight loss of 25% and 35% was reached.
Sensory evaluation: A sensory panel determined the odor and taste of the dry sausages after a weight loss of 25% and 35% was reached.
Gas chromatography/mass spectrometry: In a 500 ml gas tight glass jar, 50 g of homogenized sample was equilibrated for 30 min at 42°C in a water bath. Then, each sample was purged for 15 min with 200 ml 99,995% pure N_2/min using an automatic sampling device (GS 301, Desaga, Germany). The extracted volatiles were trapped onto 225 mg of Carbotrap 349 (Perkin-Elmer, Germany) in a stainless steel thermodesorption tube. Each sample was analyzed in triplicates. The Carbotrap tubes were thermally desorbed at 300°C in a thermal desorber (ATD 400, Perkin-Elmer, Germany). The compounds were separated in a gas chromatograph (GC 6890, Agilent, Germany) equipped with a DB-5 low polar column and identified using a mass spectrometer (MSD 5973, Agilent, Germany). The temperature was programmed at 40°C for 3 min, from 40°C to 230°C at 7°C/min and to 260°C at 12°C/min and then held at 260°C for 15 min. The mass spectra were recorded in electronic impact mode at 70 eV, from 30 to 250 m/z. Identification of compounds was based on mass spectra from a library database (NBS 75K, Agilent, Germany).
Electronic nose: In a 22 ml headspace vial sealed with a silicon/PTFE septum, 10 g of homogenized sample was equilibrated for 30 min at 50°C in a headspace autosampler (HSS 7694, Agilent, Germany). Each sample was analyzed four times. An aliquot of 3 ml headspace was transferred with the carrier gas to a chemical sensor system based on 4 different metal oxide semiconductor (MOS) gas sensors (VOCmeter-Hybrid, AppliedSensor, Germany). The evaluation by means of a principal component analysis (PCA) was performed using a commercial software package (Argus, AppliedSensor, Germany).

Results and discussion

In the following, different characteristics such as weight loss and pH value between the batches were investigated. A fundamental advantage of batch 2 is the shortening of ripening time. Figure 1 shows the weight loss during ripening. In comparison with the control, the batch with dried fermented meat reaches a weight loss of 25% and 35% after 8 and 30 days, respectively, whereas the control loses the corresponding weights not before 15 and 44 days, respectively. As can be seen, batch 2 already has a 15% weight loss at the beginning of the ripening process. This can be explained by the fact that moisture has been removed from the fermented meat during drying.
After adding the starter cultures to the meat mixture a course in the pH value over the ripening period was obtained (Figure 2). In comparison, the traditional product and the new technology started at different pH values but met after 2 days. The traditional product began at a higher pH level with a steeper decrease within the first day. The batch produced with dried fermented meat started at pH 5.7 and decreased more slowly the first day. This can be explained by the fact that the water activity of this batch was lower than the traditional one and for this reason the starter cultures needed a longer period to grow and to produce lactic acid.
The determination of the odor after a weight loss of 25% and 35% by a sensory panel resulted in no difference at all between the two batches. On the contrary, the taste differed clearly. Batch 1 showed a typical distinct fermented flavor which has been developed during the longer ripening time.
The headspace GC/MS analyses of batch 1 and 2 at the beginning of the ripening process, at 25% and 35% of weight loss are thought to result from a combination of added spices, oxidation processes and microbial activities. Figure 3 represents a typical headspace gas chromatogram of a dry sausage sample. The individual compounds identified by mass spectrometry are shown in Table 1. Between the batches there were hardly any qualitative but more quantitative differences regarding individual volatile compounds. Regarding the hexanal values, both batches show an increase over ripening time (Figure 4), where batch 2 starts at a comparatively high value which might be induced by adding dried fermented meat.
Figure 5 presents a PCA plot of batch 1 and 2 at different ripening stages resulting from electronic nose measurements. Here, all volatile compounds present in the headspace are measured as a sum parameter using

4 MOS sensors with different selectivities to give a specific aroma fingerprint for each individual sample. It can be seen that there is a clear difference between the samples at the beginning and at the end of the ripening time, but hardly any differences between the ripened samples or individual batches. This is in correlation with the odor results obtained by the sensory panel.

Conclusions

The aim of this study was to show that the use of dried fermented meat in the production of dry sausage can shorten the ripening time by about one week. However, this new processing procedure leads to a less intense dry sausage taste. Furthermore, the investigations have shown that analytical tools such as headspace GC/MS and electronic nose can be used to provide more objective and reproducible results, but with the limitation that only the human being can specifically describe taste and odor impressions.

Background

The interest in meat hygiene has increased in recent years, mainly due to the current crisis suffered by the meat sector. These emergencies have alerted the European Union (EU) to perform an extensive normative for controlling hygienic-sanitary quality of meat "from the farm to the fork", therefore including slaughtering and dressing procedures in this slogan. The European regulatory authorities have set up the microbiological assessment of carcasses before chilling in the abattoirs (Directive EC/471/2001). However, carcass quality during chilled storage has only been recommended by the ICMSF, but not by EU requirements. On the other hand, in the products with undisputed prestige that have attained their own official label, such as Manchego Spanish Breed Lamb, it is necessary for their organoleptic quality also to be accompanied by optimum microbiological quality during the pre-sale period.

Objectives

The aim of this work was to evaluate the effects on microbiological development of carcass lamb chilled at 4ºC of the next factors: size of the abattoir (number of animals slaughtered per week), the sampling site (flank, neck and rump), and the time of storage (at 24 h and 6 days post-slaughter which is the maximum time permitted for sale in "Manchego Lamb Denomination of Origin").

Materials and methods

In June, forty lambs of the Manchega breed were slaughtered at 25 kg live weight using standard commercial procedures. The slaughter was carried out in two commercial abattoirs of different size (located in the same city): a small abattoir and a big abattoir, (less than 2000 and more than 8000 animals slaughtered per week respectively, including pigs, lambs and beef). In each abattoir 20 lambs were slaughtered and the carcasses remained at 4ºC for 6 days post-slaughter in a chilling room. None of the carcass exhibited 24-h pH values higher than 5,7.

In all carcasses, the sampling (according to EC Decision 471/2001) was carried out by swabbing areas of 100 cm^2 in three different sites of carcass (rump, flank and neck), and at 1 and 6 days post-slaughter. Samples were stored at 4ºC in sterile tubes containing 10 ml of peptone water until examination, after no more than 3 hours.

Each sample was homogenised for 60 seconds, and additional serial 10-fold dilutions of homogenates were made in peptone water and were inoculated in Petri dishes for enumerations of: Mesophiles, pouring on Plate Count Agar (Scharlau Chemie, Barcelona, Spain) at 32°C for 2 days; psychrotrophs, pouring on PCA at 7ºC for 10 days; enterobacteria, using pour plates of Violet Red Bile Dextrose agar (Scharlau Chemie, Barcelona, Spain) and incubated at 32°C for 48 h; and Yeasts and Moulds, were determined on Rosa Bengala agar (Scharlau Chemie, Barcelona, Spain) incubated at 25ºC for 3 days. All microbial counts were expressed as base –10 logarithms of colony forming units per cm^2 of surface area (log CFU cm^{-2}).

Effects of abattoir, time of storage, sampling site and their interactions, on each microbial group was determined using a general lineal model (GLM). Factors and interactions that did not achieve significance were excluded from the analysis to increase the degrees of freedom of the residuals. Differences between sites of carcass in each abattoir were examined using a analysis of variance (ANOVA). When the differences among sites were significant ($p< 0.05$), Tukey's test was carried out to check the differences between pairs of groups. The effect of time of storage in refrigeration for each site was analysed using ANOVA at a significance level of $P< 0.05$. The correlation between pairs of microbial groups were examined using a simple correlation. Data were analysed using the SAS (1998) statistical package.

Results and discussion

GLM shows that the number of microorganisms found on carcasses varied significantly between abattoirs, sampling sites and time of storage (Table 1). In general for all microbial groups we found significant interactions between these factors. Other works (Sumner et al., 2002) reported that there were little difference in the mean values of aerobic viable count of the carcasses produced in abattoirs and very small plants.

After 1 day post-mortem in both, small and big abattoir (Table 2 and 3, respectively), the highest microbial recovery were observed on the flank ($P < 0.05$). After 6 days post-slaughter in the small abattoir the differences among sites only remained for enterobacteria ($P < 0.05$), and the lowest recovery was in the rump. However after this time in the big abattoir there were significant differences among sites for all microorganisms groups analysed.

In general, all microbial groups increased with time in both abattoirs. But in the small abattoir significant differences were not found in mesophiles neither psychrotrophs in flank site with time.

The correlations between the microbial groups assayed achieved significance in the four groups. Thus, mesophiles showed a positive correlation with psychrotrophs ($R= 0.881$, $P < 0.01$), enterobacteria ($R= 0.641$, $P < 0.01$), and yeasts and moulds ($R= 0.711$, $P < 0.01$); psychrotrophs were positively correlated with enterobacteria ($R= 0.674$, $P < 0.01$), and yeasts and moulds ($R= 0.702$, $P < 0.01$); and enterobacteria with yeasts and moulds ($R= 0.626$, $P < 0.01$).

The mean of mesophiles per cm^2 in this work ranges from 1.37 to 4.91 log, whereas the means counts of psychrotrophs varied from 0.85 to 3.91 log. According to these results, it could be concluded that the slaughtering practices in both abattoirs were acceptable. Moreover, the counts after 6 days of chilled storage are in agreement with the current EU requirements for ovine carcasses immediately after slaughter. Both, mesophiles and psychrotrophs were recovered from 95% of samples analysed in both abattoirs after 1 day at counts inferior than 3.5 log CFU/cm^2. After 6 days only 17.8% and 15.6% of samples recovered for mesophiles and psychrotrophs, respectively, showed counts superior than this level.

Our results are in the range found by other authors in a similar period of time. Along this line, Sumner *et al.* (2002) found that 364 chilled lamb carcasses from 17 Australian abattoirs had a mean value of aerobic viable counts of 2.59 log CFU/cm^2. In three Swiss abattoirs the median counts for aerobic total counts ranged from 2.5 to 3.8 log CFU/cm^2 (Zweifel and Stephan, 2003). Other studies showed mean values of mesophiles on chilled carcasses which ranged from 3 to 5 log CFU/cm^2 (Prieto et al., 1991; Vanderlinde et al., 1999; Duffy et al., 2001).

Enterobacteria values were less than 1 log CFU/cm^2 in 90% of samples after 1 day of storage. This group was only presented in 50% of samples at this time. After 6 days the 75% of samples showed count inferior than 2 log CFU/cm^2 . The EU requirements establishes count above 2.5 log CFU/cm^2 as unacceptable for this microbial group in carcasses before chilling.

The results also showed a low occurrence of yeasts and moulds. In 75% of samples analysed overnight this microbial group was not recovered. Counts were inferior to 3 log CFU/cm^2 in 95% of the samples stored for 6 days. These results suggest that yeasts and moulds contamination is apparently not a problem.

Conclusions

In general, the microbial counts for the four microbial groups analysed were higher in the big abattoir. In both abattoirs the mean values in the flank were higher than in the rump and in the neck. After six days post-slaughter there was an increase in all microbial groups analysed, however these levels were similar to those observed in other European or non abattoirs. According to these results, it could be concluded that the slaughtering practices in both abattoirs were good and the counts fell within the recommendations of International Commission on Microbiological Specifications for Foods (ICMSF).

Background

Reducing the contamination level of beef carcasses with enteric pathogens such as *E.coli* O157:H7 (VTEC), by means of implementing preventive measures in the slaughterhouse, is regarded to be important. Cost-effectiveness analysis is a valuable tool to evaluate the existing preventive measures. For a reliable cost-effectiveness analysis, beside calculation of the costs for each intervention, a good insight into the benefits is needed. According to the definition of Food Safety Objectives (FSOs), any reduction in the frequency and/or concentration level of a microbiological hazard in a food product can be treated as an appropriate benefit for a certain intervention (Havelaar et al. 2004). Microbial decontamination methods are the commonly used preventive measures against the bacterial hazards in slaughtering plants. In the majority of studies in this field, scientists have been mostly interested on reduction in the number of bacterial Colony Forming Units (CFUs) on the surface of the meat, using interventions after experimentally contamination. Due to the essences and objectives of these types of studies, the effects of interventions, in terms of reduction in frequency of the contaminated beef units, will not be reported. Moreover, only few studies have been done to investigate the effectiveness (in terms of reduction in prevalence) of the intervention methods in the slaughtering process in real practice.
To fill this gap one can consider two approaches: 1) putting the interventions into practice in a slaughterhouse and observing the effects or 2) using computer simulations and performing sensitivity analysis. The first approach is not feasible to apply, because it is costly and disruptive (van der Gaag, 2003). Computer simulation is an attractive alternative to the implementation of explorative control strategies.

Objectives

The aim of the study presented in this paper is to build an epidemiological framework to investigate the effectiveness of different intervention methods along the beef slaughter line, in terms of reducing the frequency of contaminated beef quarters with VTEC. The result of this study will be used as a part of inputs needed for the cost-effectiveness analysis, which will be the next step in our research. Decision makers in the beef slaughtering industry are the potential users of the results.

Materials and methods

The general model described in this paper was build on a Microsoft Excel spread sheet using @Risk add-in software. In our model 500 cattle enter a typical Dutch industrial slaughterhouse on a daily basis. Two main sources of VTEC in/on the body of cattle on the farm can be recognized: 1-In the gastrointestinal tract (GI) and 2- On the hide (Heuvelink, 2001). Animals entering to the slaughterhouse can be grouped in the four groups, based on their GI tract and hide status: 1- [GI^+ H^+] 2- [GI^+ H^-] 3- [GI^- H^+] 4- [GI^- H^-].

Slaughter process

The following stages have been included in the model: *de-hiding*, *evisceration*, *splitting*, *fat/tail removing*, *trimming* (as a decontamination method), *washing with cold water* (for cooling down purpose) and *chilling*. Because the main possible interventions on the slaughter line are applied before the de-boning and fabrication stages, the beef carcass quarters (hind-quarters and fore-quarters), which are produced after the chilling stage, have been considered as the end product in our model. For each of the mentioned stages, a main risky event for VTEC transmission was identified from the literature: Direct contact of carcass surface with the hide of anus area for the de-hiding stage, rupture of the GI tract for the evisceration stage, contamination of splitter saw for the splitting stage, contact with contaminated knife for the fat trimming stage, spreading the bacteria from the hind-quarter to the fore-quarter for the washing stage and carcass-to-carcass contact for the chilling stage.

The output of the model is a distribution of the number of VTEC contaminated quarters of the beef carcasses, produced in one day at the end of *chilling* stage. Therefore, the prevalence of contaminated quarters in this model refers to the number of contaminated quarters out of 2000 produced quarters.

Stochastic Process of the model

Monte Carlo simulation with 10,000 iterations was implemented. One iteration of the model represents one day production of the slaughterhouse. As, during each slaughtering stage, two possible outcomes (contaminated versus not-contaminated) can be recognized, the *Binomial process* was chosen as the stochastic process of the model (Vose, 2000). In this model, quarters contaminated with no bacteria (zero CFU) are defined as negative, irrespective to the detection level of the routine bacteriological tests. In opposite, quarters with even one CFU contamination on their surface are treated as positive.

Three different stochastic processes are distinguished that determine the contamination status of a quarter in a stage. These processes are modelled as from equations 1 to 6. Let N denote the total number of quarters entering stage, $S_{(j)}^{+}$ the number of positive quarters after modelling the stochastic process by either $(j=1)$ the main risk factor or $(j=2)$ the environment or $(j=3)$ decontamination processes. $S_{(j)}^{-}$ is thus the number of negative quarters after each stochastic process. Considering Pr and Pe as probabilities of changing the status of a quarter from negative to positive due to the risky event or/and environment , and denoting Pd for changing the status from positive to negative by decontaminations, three levels of the model are written as:

1- Contamination due to the Risky Event of the stage

$$S_{(1)}^{+} = \text{Binomial}\ (S_{(0)}^{-};\ Pr) + S_{(0)}^{+} \qquad (1)$$

$$S_{(1)}^{-} = N - S_{(1)}^{+} \qquad (2)$$

2- Contamination by the Environment of the stage

$$S_{(2)}^{+} = \text{Binomial}\ (S_{(1)}^{-};\ Pe) + S_{(1)}^{+} \qquad (3)$$

$$S_{(2)}^{-} = N - S_{(2)}^{+} \qquad (4)$$

3- Decontamination

$$S_{(3)}^{-} = \text{Binomial}\ (S_{(2)}^{+};\ Pd) + S_{(2)}^{-} \qquad (5)$$

$$S_{(3)}^{+} = N - S_{(3)}^{-} \qquad (6)$$

The yearly prevalence of VTEC infection of dairy cattle (0.0096) in the Netherlands, infected in the GI, was used in the model to determine the number of infected cattle entering into the slaughtering line (Nauta, 2001). The other mentioned probabilities have been estimated based on available data found in the literature and experts opinion, which the list of these references is available with the authors.

Interventions

Interventions can reduce transmission probabilities of VTEC in certain stages of the slaughtering process. They also can reduce the transmission probability from the environment to the carcass and can change the contamination status of the quarters itself. Interventions can be categorized in three groups: *a*- cleaning and hygienic interventions; *b*- decontamination methods (and combinations); *c*- other interventions (e.g. replacing a stage by another or stopping a risky event).

We mainly focused on the decontamination methods and tried to compare their effectiveness, when they are used individually or in combination with other interventions. A linear relation between the reduction of CFUs and the reduction factor for the changing status probability (from positive to negative) was assumed. Using the data reported by Phebus et al (1997) for the level of reduction in number of CFUs in experimental studies, and mentioned linear relation, the level of reduction on changing the status probability for the five important decontamination methods were determined (the estimated reduction factors are given as: 0.0 for no intervention; 0.12 for hot water wash (H); 0.43 for lactic acid rinsing; 0.5 for trim (T); 0.51 for steam-vacuum (V); 0.57 for steam-pasteurization (S) and 0.99 for irradiation). Irradiation has been known as the most effective decontamination method by reducing the numbers of CFUs of VTEC by 10^6 CFU/cm^2 (Molins, 2001). Therefore irradiation was chosen for the upper bound of reduction factor. The default situation, where no intervention is applied, represents the lower bound. In total 18 interventions (including combinations) were examined in our model.

Results and discussion

Table 1 shows the baseline output of the model as well as the effects of implementing the interventions on the output. In the baseline situation, on average 18 contaminated beef quarters are produced in a working day. The distribution of the number of contaminated quarters in the baseline situation shows that in 95 % of the working days, the number of contaminated quarters is less than 33 quarters. Besides that, in 5% of the working days less than 6 contaminated quarters are produced. As it is expected, irradiation shows the highest effectiveness. In opposite hot water wash has the lowest effectiveness to reduce the frequency of contamination.

To make a comparison with the baseline situation, the distributions of two interventions, one from the middle of the table 1 (TW) and one from the top (VWLS) are illustrated in figure 1A. Applying TW and VWLS, the 95th percentiles values reduce to 18 and 6 quarters. In general a combination of interventions gives a better effect.

A comparison between our results and the study of Phebus et al (1997) shows an almost similar ranking order (table 1). However some differences exist. In the mentioned research, hot water washing of the carcasses after trimming (TW), had the first place of their list and applying only hot water wash was the least effective method to reduce the number of CFus/cm^2 of the meat surface. The most important difference is that, the combined intervention TWLS showed the most promising results in our study whereas, it's in the fifth place in their list. A possible reason for this is that in the laboratory trimming, freshly sanitized instruments are used and great control to prevent cross contamination is applied.

In a higher prevalence scenario (0.05), illustrated in figure 1B, the mean number of contaminated quarters will increase up to 95 quarters per day (125 quarters for 95 percentile). The TW and VWLS can reduce the mean number to 45 and 18 quarters, with 95 percentile as 68 and 20 respectively. This implies that the prevalence of infections at the farm is important and application of interventions at the slaughterhouse in such a situation would play a crucial role to keep the frequency of contaminated product in the acceptable level.

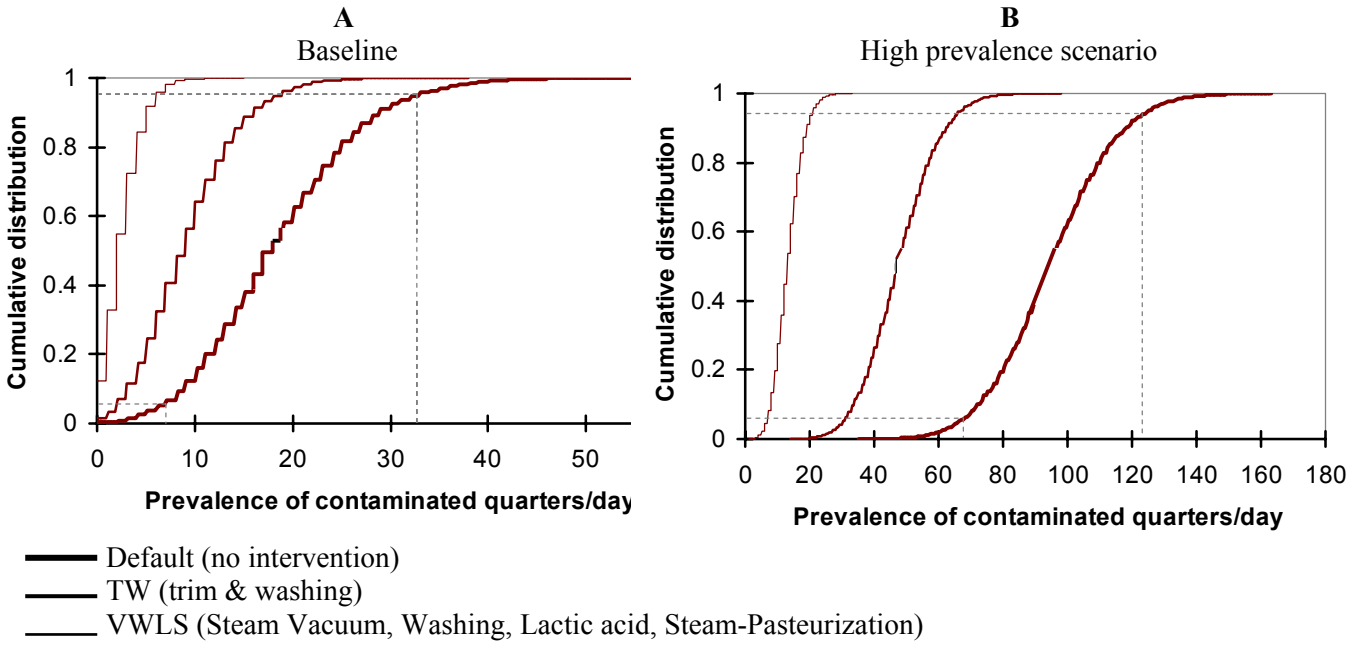

Figure 1 Distribution function for the number of contaminated beef quarters per day in with and without intervention situations. Graph A: baseline results, using yearly prevalence of GI infection for incoming animals to the slaughterhouse. Graph B: higher prevalence scenario (0.05).

Table 1 Baseline output of the model and the effects of interventions.

Interventions	Stage	Mean	5th & 95th percentiles	Rank order in this study	Rank order in Phebus's study
Irradiation	washing	00.22	0 – 1	1	na*
VWLS	de-hide/evisc/wash/split	02.58	0 – 6	2	2
TWLS	de-hide/evisc/wash/split	02.57	0 – 6	2	5
VWS	evisc/split/wash	04.16	1 – 9	3	6
TWS	de-hide/evisc/wash	05.00	1 – 11	4	3
TWS	de-hide/evisc/split	05.14	1 – 11	4	3

Trim (T)	de-hiding	10.38	3 – 20	8	9
Steam Vacuum (V)	evisceration	10.20	3 – 20	8	8
Trim (T)	splitting	10.46	3 – 20	8	9
Steam Vacuum (V)	splitting	10.40	3 – 20	9	8
Acid Lactic (L)	washing	11.36	3 – 21	10	na
Move chest opening**	de-hiding	15.34	5 – 28	11	na
Hot water wash (W)	washing	16.33	6 – 29	12	na
Hot water wash (W)	splitting	16.67	9 – 29	12	10
Baseline (without)		**18.42**	**6 – 33**	-	-

*na: These interventions either have not been considered in study of Phebus (1997) or have been applied in other sequence.
** Brisket region is opened in the de-hiding stage in our visited slaughterhouse.

Conclusions

Firstly, the results of this study show that, the use of computer simulation to evaluate the effectiveness of interventions along the slaughter line is a promising approach.
Secondly, the combinations of decontamination methods have more positive effect on reduction of frequency of contaminated quarters than individual interventions.
Thirdly, in a high prevalence scenario, application of interventions in the slaughterhouse plays a crucial role to keep the frequency of contaminated product in the acceptable level.
The forth and the last conclusion of this study is that, changing the place of the individual interventions in the slaughtering line has not a significant effect on the frequency of contamination. However the effectiveness of interventions is slightly increasing toward the end of the slaughter line.

THE EFFECTS OF NITRITE AND TRADITIONAL COOKING PROCESS ON THE SURVIVAL OF *CLOSTRIDIUM SPOROGENES* AND AUTOXIDATION IN KAVURMA, A TRADITIONAL TURKISH FRIED MEAT PRODUCT

Yetim, H.[1], Kayacier, A.[1], Gungor, Z.[2] and Ockerman, H.W.[3]

Background

Kavurma is a traditionally deep fried (coarsely ground) meat product and produced to extend the shelf life of the product for 6-9 months. In the past, this technology was used only to conserve meat, but currently it is preferred as a processed meat variety; although, some people living in many places in Turkey and the Middle-East are still processing kavurma for preservation purposes. In traditional processing, the meat from beef or mutton is ground (approximately 4x5x6 cm) and mixed with 2.0 to 5.0 % salt, and then fried or cooked in animal fat using a double sided steam cauldron. After the cooking process, it is kept in almost anaerobic condition which is provided by solidified animal fat in the container. Recently, it has also become available in vacuum-packaged forms produced in modern meat processing plants and sold in department stores and markets (Vural and Oztan, 1989; Anon., 1996; Gungor, 2000; Yetim *et al*., 2003). The popularity of ready-to-eat foods is increasing in the world because of changing life styles, and kavurma is also considered as a ready-to-eat meat product since it is generally consumed without further processing or cooking. The technological and hygienic insufficiencies during the production of kavurma may cause quality deteriorations in the product as well as a health risk associated with microorganisms.

Deteriorations occurring in kavurma are generally due to microorganisms. Although, it is heat treated, it may contain a small microbial load. Microorganisms surviving during the heat treatment of kavurma may proliferate if the product is stored under inappropriate conditions. When the microorganisms present in kavurma are pathogenic or toxic, there is a potential health risk to the consumers. For example, clostridia are considered important bacterial group in the heat treated meat products, because of their facultative anaerobic and spore forming nature; *C. botulinum* produces a deadly toxin which causes botulism.

Research on kavurma is very limited in the literature. A study on kavurma sold on local markets indicated that some thermophiles, subtilis-mesenticus bacteria and micrococci were commonly present in kavurma samples (Inal, 1992). Additionally, Sarigol (1978) determined the microbial load in kavurma stored under different conditions and reported that lipolytic and proteolytic microorganisms, yeast, mold and staphylococci were present in home type and industrial type of kavurma. Vural and Oztan (1989) investigated the effects of α - tocopherol and potassium sorbate on the enhancement of shelf life of kavurma, and determined that control and antioxidant added samples initially contained less than 10 bacteria/g while samples with antimicrobial agent had no microorganisms. They observed that total viable microorganism of the control sample continuously increased during 6-month of storage. Another study conducted for the determination of microbiological, physical and chemical qualities of kavurma sold in Bursa (Turkey) market revealed that a potential health risk might be evident resulting from the consumption of kavurma when the procuct is not hygienically produced or it is stored under improper conditions (Tiryakioglu and Yucel, 1995). On the other hand, Cetin (2000) reported some pathogenic microorganisms, such as *Salmonella*, *Morganella*, *Yersinia* or *Klebsiella* in the kavurma samples obtained from local stores in Erzurum. He pointed out that the kavurma samples containing these pathogens may pose a probable public health risk. Yetim et al. (2003) investigated the formation of nitrosamines in kavurma prepared with nitrite addition and concluded that there was no detectable amount of nitrosamine compounds in the kavurma samples.

Objectives

The objective of this study was to determine the influence of nitrite addition and the traditional cooking process of kavurma on the survival and proliferation characteristics of *C. sporogenes,* representing the *C. botulinum*, and their effects on rancidity which was evaluated by TBA, FFA values and peroxide number.

Materials and methods.

Traditional Kavurma was manufactured as described by Gokalp et al. (1994). In this study, 4 types of kavurma were prepared as illustrated in Table 1). 1) Control, 2) 100 ppm nitrite, 3) *C. sporogenes* and 4) Nitrite + *C. sporogenes* containing samples. A steam jacketed cauldron was used for kavurma processing and the internal temperature of the meat-fat mixture was approximately 98°C during cooking that took approximately 1.5 hours. Kavurma samples were filled into sterile fibrose casings and sliced and vacuum packaged under aseptic conditions before storage. All the samples were kept for 6 months under refrigerated (4±1°C) conditions.

Table 1. Kavurma samples prepared in experiment,

Sample	Kavurma Types
1	Control (contains only meat and fat)
2	Nitrite added sample (100 ppm)*
3	*C. sporogenes* inoculated sample (10^6 cfu/g)**
4	Nitrite + *C. sporogenes* (100 ppm + 10^6 cfu/g)

* : $NaNO_2$ was dissolved in distilled water and added into beef stew before cooking,
**: *C. sporogenes,* strain no: 413; the bacteria was obtained from Pendik Veterinary Control and Research Institute (Istanbul, Turkey) and proliferated in Cooked meat medium (Difco) before inoculation.

For the analysis, 25 g of Kavurma samples were homogenized using a Waring blender at 6000 rpm in 225 of ml sterile serum physiological salt solution for microbiological analysis. *C. sporogenes* count in the samples was determined by the pour plate technique using Heart infusion agar (Oxoid). Plated samples with anaerobic kit (Oxoid) in anaerobic jars (Anaerocult, Oxoid) were incubated at 37 ^oC for 48 hr. Typical *C. sporogenes* colonies were counted after the incubation period (Anon, 1994). The TBA, Peroxide and FFA values of samples were determined using the methods described by Gokalp *et al*., (1993).
The collected data was subjected to ANOVA, and means were separated using the Duncan's Multiple Range Test.

Results and discussion

C. sporogenes counts
The number of *C. sporogenes* in the control and nitrite added samples were less than <1 log CFU/g. It was 3.08 log CFU/g for *C. sporogenes* inoculated and 2.99 log CFU/g for nitrite + *C. sporogenes* containing samples. Analysis of variance results revealed that nitrite addition and *C. sporogenes* inoculation had a significant effect ($p<0.05$) on the count of *C. sporogenes*. For example, if only *C. sporogenes* inoculated samples were considered, it was observed that clostridium count was slightly lower in the samples prepared with the addition of nitrite. Duncan test indicated that there was a statistically significant difference in terms of the number of *C. sporogenes* between those two samples (Table 2). Before the processing, 6 log CFU/g microorganisms were inoculated into the kavurma sample during production, and that number was decreased about 3 log CFU/g unit with the cooking processes. The results indicated that *C. sporogenes* were not completely eliminated during the heat treatment of kavurma production and survived the storage period. It was observed that the storage time significantly affected the number of *C. sporogenes* in kavurma (Table 3). *C. sporogenes* inoculated samples initially contained 3.27 log CFU/g organism which was reduced to 2.89 log CFU/g after six months of the storage. For the nitrite + *C. sporogenes* sample; the initial count was 3.21 log CFU/g, and the count was 2.73 log CFU/g after six months.

Table 2. Duncan results (averaged over storage time) for the effect of nitrite addition on *C. sporogenes* count and oxidation parameters of the kavurma samples

Sample Type	*C. sporogenes**	TBA	Peroxide Number	FFA Value
1	$<1^c$	1.96^a	6.07^a	0.879^b
2	$<1^c$	0.43^b	4.04^c	1.036^a
3	3.08^a	1.44^a	5.38^b	0.817^b
4	2.99^b	0.25^b	3.84^d	0.981^a

Table 3. Duncan results for the effect of storage time on *C. sporogenes* count and oxidation parameters of kavurma

Storage Time (month)	*C. sporogenes**	TBA	Peroxide Number	FFA Value
0	1.97 [a]	0.80[b]	4.04[c]	0.79[b]
1.5	1.93 [a]	0.81[b]	4.69[b]	0.86[b]
3	1.82 [b]	1.03[b]	5.14[a]	0.99[a]
6	1.76 [c]	1.43[a]	5.46[a]	1.07[a]

*log CFU /g sample, TBA: mg malonaldehyde/kg fat, Peroxide number: meq O_2/kg fat, FFA: mg KOH/g fat,
[a-c] : Different letters in a column are significantly different ($p<0.05$).

It was reported in the literature (Hamilton, 1990) that the spores of *C. botulinum* did not germinate in the medium with low water activity (<0.95). Similarly, the water activity of kavurma produced in this study was less than 0.95 (the data was not reported) which may have caused no increase in the number of viable *C. sporogenes* during storage. Storage temperature of kavurma samples was 4 °C which could be another factor for the reduction or not germination of *C. sporogenes* during storage. It could also be noted that the *C. sporogenes* count was lower for the samples prepared with nitrite addition as indicated in the literature by many researchers that nitrite has an antimicrobial effect against clostridia. It was stated that the antimicrobial effect of nitrite is due to prevention of growth of bacteria rather than directly killing them (Ockerman, 1983, Cassens, 1995).

TBA value

TBA value of the samples changed in the range of 0.125 – 2.56 mg malonaldehyde/kg sample. Kaya and Gokalp (1995) stated that TBA value would be a proper indicator for determination of rancidity in kavurma. ANOVA results indicated that the addition of nitrite and nitirite + *C. sporogenes* into samples had a significant effect ($p < 0.01$) on TBA values (Table 2). It was determined by Duncan test that nitrite added kavurma (samples 2 and 4) had significantly lower TBA values compared to non-nitrite samples (1 and 3). This occurrence was probably caused by antioxidant effect of nitrite. It is known that nitrite inhibits the formation of oxidative rancidity in meat products. Oxidized Fe^{+++} present in meat catalyzes the oxidation of fat but if the meat is cured with nitrite, reaction of NO with myoglobin reduces the heme molecule to Fe^{++} state which has no effect on the oxidation of fat. It was determined that TBA value significantly increased with time during storage (Table 3). The TBA value of the samples after 6 months of storage was higher than those of the samples at any other storage time. Vural and Oztan (1989) reported that initial TBA values of the control and with 30 ppm tocopherol added kavurma samples were 1.65 and 2.10, respectively. They determined that TBA values increased during storage, and after 6 months TBA value of control group increased to 2.32 while that of antioxidant added sample reached to 1.80 mg malonaldehyde/kg fat.

Peroxide number

The peroxide number of kavurma samples ranged between 3.21and 7.10 (meq O_2/kg). The statistical analysis revealed that the addition of nitrite had a significant effect ($P<0.01$) on the peroxide number of kavurma (Table 2). It was found that sample 2 and 4 (nitrite containing samples) had significantly lower peroxide values than that of non-nitrite containing samples, 1 and 3. The change in peroxide number of sample with storage time was statistically significant (Table 3). The peroxide number of all samples increased during the storage, however the peroxide value of the samples stored 3 months was not statistically significant from that of the samples stored for 6 months. Kavurma Standard (TS 978) states that peroxide level of kavurma shall be less than 20 meq O_2/kg, and all of the current samples contanied peroxide levels under that limit. Sarigol reported that home or industrial type kavurma samples had the peroxide value of 5 ve 9 meq O_2/kg, respectively, and the number increased depending on the storage time. Tiryakioglu and Yucel (1995) investigated the peroxide value of kavurma marketed in Bursa and measured an average of 61.44 (meq O_2/kg) peroxide. Kavurma is not consumed right after the manufacture; therefore it should keep its quality during the storage. The fat used in kavurma production is an important factor for the deterioration of quality of the product since it is prone to rancidity formation due to the oxidation (Vural and Oztan, 1989). For this reason, the use of certain amounts of nitrite could be recommended in kavaurma production to retard oxidation of the fat present in kavurma.

FFA Value

It was determined that the addition of nitrite had a significant effect on the FFA (Free Fatty Acid) value of the samples. The addition of nitrite caused a significant increase in the FFA values samples (Table 2). The FFA value of the control sample was 0.879 (mg KOH/g fat) while that of sample 2 (containing 100 ppm nitrite) was 1.036. Additionally, storage time significantly affected the FFA value of samples with FFA in kavurma samples increasing during storage. As seen in Table 3, average initial FFA value of samples was 0.79, and it increased to 1.07 after 6 months of storage.

Conclusions

The results of this study revealed that *C .sporogenes* count decreased during cooking of kavurma but they were not completely eliminated and survived during storage. The number of *C. sporogenes* slightly decreased during storage which could be attributed to proper storage conditions. *C. sporogenes* was not fully inactivated during kavurma processing in the samples inoculated with the bacteria, and it was concluded that they might reproduce and might pose a potential health risk, if the product is stored under inappropriate conditions. Nitrite addition reduced the TBA value and peroxide number of kavurma. Since higher TBA value and peroxide number is related to the oxidation of lipids, nitrite addition limited the rancidity formation in kavurma by lessening the autoxidation. In conclusion, considering the facts that nitrite has a slight antimicrobial effect and inhibits the autoxidation of fat in product while enhancing the other quality characteristics of meat product, a certain amount of nitrite could be added to traditional kavurma processing.

ABSTRACT

This review summarises information that is relevant to concerns that have recently been expressed about stunning and slaughter. It is known that captive bolt stunning can result in brain material passing to the lungs via the jugular veins. If future studies show that BSE prions pass beyond the lungs to the edible carcass, there will be a move away from captive bolt stunning in large cattle towards electrical stunning. Greater use of electrical stunning in large cattle will increase the importance of blood splash in the beef industry. The theoretical causes of blood splash are reviewed to improve our understanding of this problem. In some situations it can be due to excessive venous pressure causing rupture of a capillary bed some distance from the source of the pressure rise, but it is not known whether this applies to electrical stunning. Gas stunning is replacing electrical stunning for poultry because it can reduce blood spots, which is a similar condition to blood splash. Several gas stunning methods are now being used, but it is not clear which of these is the most humane. Anoxic stunning leads to carcass convulsions and this causes more carcass damage. In fish, recent developments in electrical stunning are showing promise in overcoming problems with carcass damage. It is recommended that rock lobsters should be chilled or frozen before butchery, to ensure a humane death.

Keywords: electrical stunning – gas stunning – captive bolt stunning – BSE – petechial haemorrhage – meat quality – shechita - restraint

INTRODUCTION

There have been two excellent reviews recently on concussion stunning and electrical stunning (Shaw 2002; Schütt-Abraham 1999). The focus in this paper is on recent information not covered in those reviews, and on aspects of stunning and slaughter that are likely to become more important in the next five to ten years. The topics that are discussed include

- BSE and stunning
- Electrical stunning in red meat species
- Electrical stunning in poultry
- Harvesting foetuses
- Fish and crustaceans
- Electrical stunning monitors
- Blood splash and bleeding efficiency
- Religious slaughter
- Gas stunning

In recent years, a large number of abattoirs have changed from working a single shift to two (night and day) shifts. This has allowed better use of infrastructure, and closure of excess slaughter capacity. The effects on the plants that have stayed open include, the need for increased chiller capacity, more precise scheduling of the arrival of stock or greater capacity in the livestock holding area or lairage, and closer attention to rectifying line breakdowns including failure of stunning equipment. Reliability of stunning equipment has become a higher priority, and there is greater willingness to invest in reliable and if necessary sophisticated equipment, especially if there are carcass or meat quality advantages.

BSE and Stunning

There is growing concern that captive bolt guns might be encouraging the distribution of BSE prions from the brain to the edible carcass. In addition, there have been worries about abattoir staff safety when handling CNS material, and particularly from the aerosol of cerebrospinal fluid and spinal cord macerate created during carcass splitting. The history and theory behind these threats is as follows. BSE was first discovered in the UK in November 1986, and by July 1991 about 60,000 cases had been confirmed in Britain. At that time it was well recognised in the medical profession that brain emboli can pass from the brain to the lungs in humans who experience penetrating head injuries (Ogilvy *et al* 1988; Kunz *et al* 1990). For example, brain material had been identified in the pulmonary blood vessels following gunshot wounds in the head (Hatfield & Challa 1980; Miyaishi *et al* 1994), and it had even been known for a bullet to migrate with brain matter to the pulmonary artery (Nehme 1980). The explanation is that when the brain is disrupted, homogenised material can be forced under pressure into the sinuses that drain the brain. Provided the heart is still beating, the particles of brain matter are carried to the heart and then lodge in the capillary bed of the lungs. The lung capillary network has a relatively fine diameter, and so it acts as quite an efficient filter for particulate brain matter that is irrigated out of the brain wound and into the pulmonary circulation (Conhaim *et al* 1998). It would not, however, filter out soluble proteins released from the brain.

In 1991, an attempt was made to introduce a pneumatically powered captive bolt stunner into Europe (Hantover ®). This gun was manufactured in the USA, and it vented some of the spent pneumatic pressure through its bolt into the cranium. This disrupted the brain and produced a relaxed carcass through a pneumatic pithing effect. The gun was disallowed in the UK because it was prone to forcing brain material out of the brain cavity through the bolt hole in the skull and into the operator's face. This was recognised as a hazard for the operator. At about the same time, a hot chining method was developed in the UK which avoided the inhalation of CSF aerosol by abattoir staff (Gregory & Murray 1992). The spinal column was removed intact from the eviscerated carcass using knife work and a pig breastbone opening saw. However, this method was not adopted by the UK meat industry at that time.

The next development came from the USA in 1996, when Garland *et al* (1996) reported that brain emboli could be recovered from 3% of the lungs of cattle stunned with the Hantover stunner. This finding was the death knell for that gun, which is now no longer allowed in the States. Schmidt *et al* (1999a) examined the hearts of cattle stunned with three types of captive bolt gun, for the presence of blood clots. They assumed that clots within the chambers of the heart were a sign of the presence of brain material which acted as nuclei for clot formation. This assumption was never evaluated and is now not widely accepted, and so this piece of work led to some confusion. Shaw & Gregory (2000) subsequently found that modest-sized blood clots occur in the chambers of the heart in over 8% of cartridge-powered captive bolt shot cattle, and in only one of the recovered clots was there material that could be confirmed histologically as originating in the brain. Schmidt *et al* (1999b) developed an assay for detecting filamentous protein of brain origin in beef, but it was not tested sufficiently to demonstrate whether the meat from captive bolt shot cattle presented a risk. Love *et al* (2000), using an ELISA for syntaxin 1B, subsequently found that brain material passes from the head in the blood carried by the jugular vein in captive bolt shot cattle, and the same group confirmed this phenomenon for sheep (Anil *et al* 2002). Daly *et al* (2002) confirmed earlier work by Mackey & Derrick (1979) that marker bacteria that gain access to the brain from captive bolt stunning equipment can end up in muscle. Daly emphasised that if bacteria can be distributed by this route, then so could prion proteins that leak from the brain. The magnitude of the threat of brain material passing through the lungs to the edible carcass in large enough quantities to pose a health risk for consumers has not been established, and it will be difficult to provide any precise answers without having a good estimate of the infective dose required to produce clinical Creutzfeldt-Jakob disease. If the outcome is that captive bolt stunning has to be discontinued, there would be a move towards electrical stunning. Non-penetrating bolt guns cause damage to the brain in some animals, and so they may have a comparable effect to the captive bolt. In which case they would be considered an inappropriate alternative.

When a captive bolt is used, brain tissue and cerebrospinal fluid can leak from the bolt hole in the head for at least 55 min in a suspended carcass (Prendergast *et al* 2003). This leakage contributes to contamination of the surrounding area of the hide as well as the bleeding area plus equipment in the abattoir, and it is thought that it may spread to carcass surfaces especially during the physical movement associated with hide pulling and head removal.

Electrical stunning in red meat species

The potential move away from the captive bolt method towards electrical stunning, raises two questions. How should electrical stunning be applied in large cattle, and does it have any drawbacks ? When using the Jarvis Electrical Stunner that was developed in New Zealand, the recommended minimum current to achieve a satisfactory stun is not less than 1.2 amp, and the current necessary to fibrillate the heart is greater than 1.5 amp (when using nose to brisket electrodes) (Wotton *et al* 2000). One of the shortcomings of electrical stunning in cattle is that it can cause blood splash (ecchymoses or petechial haemorrhage). Anecdotal experience at one plant in New Zealand indicates that blood splash is worse in cattle that carry hormone growth promoter implants, but this has not been authenticated with a controlled study. In earlier work with electrical stunning in cattle there were problems with broken sacrums, but this has now been controlled by using a brisket instead of rump electrode when fibrillating the heart.

About ten years ago, a survey in the UK showed that about 16% of pigs that were electrically stunned manually, were subjected to a repeat application of the current (Anil and McKinstry 1993). Some animals received a second application because the first failed to produce a satisfactory stun. Other pigs received a second current to control carcass kicking and facilitate shackling and hoisting. Some pigs were given a second stun because of an inadvertent delay in sticking. McKinstry & Anil (2004) showed that the effectiveness of a second stun is comparable to that of the first stun, in terms of the duration of epileptiform activity in the EEG, and the time to return of physical brainstem reflexes. The implication is that repeat application of a stunning current is an acceptable procedure when it has to be used, but that situations giving rise to its use should be controlled as far as possible.

Analysis of EEGs using Fast Fourier Transformation has allowed a finer interpretation of EEG traces in electrically stunned animals. This has modified some of our thinking. For example, Velarde *et al* (2002)

concluded that in sheep, normal rhythmic breathing activity restarts before epileptiform activity in the EEG has subsided following electrical stunning. Previously, it had been thought that breathing at this stage was abnormal and an involuntary consequence of the physical convulsions. Nevertheless, the resumption of breathing is still regarded as a useful indicator of the imminent return of consciousness.

PSE meat continues to be a problem for pigmeat processors. Besides causing drip, PSE meat is more prone to falling apart when it is sliced thinly. PSE can be limited to zones within a ham and this can make it more difficult to identify suspect carcasses (Franck *et al* 2003). Channon *et al* (2003) confirmed that over-application of electrical stunning increases the risk of PSE meat. This can happen in two ways. Either the current is applied for too long (e.g. 19 *vs* 4 s), or the current is too high (2.0 *vs* 1.3 A). Bertram *et al* (2002) came to the logical conclusion, from using ^{31}P NMR spectroscopy, that the early utilisation of phosphocreatine is an important component determining the link between the physical contractions at the time of stunning and slaughter and post-mortem pH decline.

Electrical stunning in poultry

Blood spots continue to be a problem in the poultry processing sector. However, two developments have helped to reduce their importance; high frequency electrical stunning and gas stunning. In many countries, high frequency electrical stunning has replaced 50 or 60 Hz frequency waterbath stunners. It is well recognised, from work on laboratory animals, that high frequencies (450 Hz and higher) produce less initial spiking and a more even muscle contraction when the current is applied (Rosenblueth and Cannon 1940). During sustained application of the current, muscle tension is lower and the physical contractions are more prone to subsiding, when using high frequencies (Rosenblueth and Luco 1937; 1939). High frequency electrical stunning in poultry usually results in a shorter-lasting stun, and following the current there can be more physical activity (Hillebrand *et al* 1996; Mouchonière *et al* 1999). The greater physical activity is presumably fascicular rather than fibrillary in origin, as it involves whole body responses, but it could also be linked to a lower prevalence of cardiac arrest and hence better oxygenation of nervous as well as muscle tissues. The main commercial advantage with high frequencies is fewer blood spots and other haemorrhages in the carcass, and this could be linked to the reduced muscle tension during stunning. High frequency stunning can also lead to less blood retention in the viscera, and this has benefits in terms of yield of trimmed livers for foie gras production (Turcsán *et al* 2003).

When unrestrained poultry are electrically stunned across the head, they develop severe wing flapping, and because of this, whole-body stunning in a waterbath is preferred. However, a system recently developed at Silsoe Research Institute employs head-only stunning immediately followed by a head to vent current, and this does not provoke any wing flapping. Savenije *et al* (2002a) showed that convulsions involving wing flapping are associated with an impressive acceleration in breast muscle ATP and glycogen depletion, pH decline and lactate accumulation, and the meat has a poorer water holding capacity. Electrical stunning promotes greater depletion of muscle glycogen in Type IIB myofibres (fast twitch glycolytic) in comparison with type IIA fibres (fast twitch oxidative glycolytic) (Iwamoto *et al* 2002).

Electrical waterbath stunners still operate at a constant voltage, even though constant current stunners, that supply current separately to each bird in a waterbath, have been designed, tested and developed (Kettlewell *et al* 1995).

Layer hens are more prone to a cardiac arrest at stunning than broilers, but in practice they are often poorly stunned because of loose-fitting shackles (Schütt-Abraham 1999). When a tissue develops hypoxaemia from a cardiac arrest, the endothelium of the blood vessels becomes leaky and a serous fluid accumulates in the extravascular space. Savenije *et al* (2002b) demonstrated that the accumulation of this fluid in the brain, as measured by the drop in impedance, is very rapid, and that electrical stunning without a cardiac arrest results in a more delayed accumulation of electrolytes in the extravascular space. The significance of these effects in practical terms is not clear, but it is a novel approach to studying the effect of electrical stunning on cell and brain function.

The stunning current recommended for ostriches has been 400 mA or 500 mA when using a 50 Hz AC head only system (Wotton & Sparrey 2002). In practice, currents are often higher than this. For example, the largest ostrich processor applies 400 to 800 mA for 8 to 10 s using 105 V / 50 Hz. Regurgitation during bleeding is a problem at some ostrich processing plants.

Harvesting foetuses

Occasionally there is concern about whether foetuses are conscious when removed from pregnant animals at slaughter. In some countries invasive procedures, such as cardiac puncture for serum collection and recovery of foetal tissues for the Asian health product market, are performed on the foetus as soon as the dam is eviscerated. Under normal circumstances, the foetus is not conscious when it is in the uterus (Mellor & Gregory 2003). In lambs, a relatively high oxygen tension is required to support consciousness, and the p_aO_2 of the foetus is below this level (28 mm Hg pressure) until the lamb starts breathing air. Provided the lamb does not start breathing when it is removed from the amniotic sac, it will not become conscious.

Fish and Crustaceans

The welfare issues associated with killing farmed fish has been reviewed by van de Vis *et al* (2003), and those linked to marine harvesting by Gregory (1998). There has been controversy amongst scientists as to whether fish can feel pain. Some take the view that fish probably cannot feel pain (Rose 2002), whereas others consider that elasmobranches have diminished ability to feel pain but teleost fish probably can (Sneddon *et al* 2002), but it is not clear which types of pain they can feel (Chervova 1997; Gregory 1999). In scientific terms, it is considered that a species can feel pain if it has eight physiological, behavioural and neuroanatomical features (Gregory, 2004). Few species have been examined for all eight criteria, and none of them are fish. In the absence of this information, judgements in the short term will have to be based on individual criteria that seem to be particularly convincing.

Righting behaviour is being used as an indicator of return of consciousness following stunning, and presumably a return of ability to feel pain (Robb *et al* 2002). However, in other species, and in other contexts, this criterion is falling from favour as a good indicator of the interface between consciousness and unconsciousness. It is a cerebellar reflex which can occur in subconscious states, at least in arboreal species such as the Australian brushtail possum (Littin 2004). The difference in value attached to this criterion needs to be reconciled.

The minimum current necessary to stun eels is 600 mA (Lambooij *et al* 2002a). This recommendation was based on the induction of an epileptiform EEG in the brain, and it applies to head only stunning, which is not a feasible method in large scale eel farms (Robb *et al* 2002). Lambooij *et al* (2002b) tested the more practical alternative of passing current through a tank of eels in water, and concluded that a satisfactory amp/dm^2 was 0.64. However the eels were prone to recovering before they died, and so it was recommended that the current should be followed by a second lower but longer-lasting current plus partial deoxygenation of the water using nitrogen. This additional procedure ensured that there was no recovery. When eels were killed in this way, their meat was less prone to oxidative rancidity, and was firmer and redder in comparison with the traditional method of placing the live eels in a bin with crushed salt (Morzel & van de Vis 2003). An in-line semi-automated rotary electrical stunning unit has been developed by Silsoe Research Institute (Lines *et al* 2003).

Concussion seems to be the stunning method that has the least effect on post-mortem muscle metabolism in fish (Ruff *et al* 2002). Linked to this, rigor sets in later, and there is reduced risk of meat gaping. Electrical stunning suffers from the disadvantage that it can result in blood spots (van de Vis *et al* 2003), but in trout this defect can be controlled by using a high frequency (1000 Hz) current (Lines *et al* 2003).

Iso-eugenol (Aqui-S) continues to be used for pre-slaughter sedation of salmon in the aquaculture industry in New Zealand, in spite of concerns by Japanese consumers about flavour residues. Aqui-S and clove oil have been trialled successfully in crabs (*Pseudocarcinus gigas*) destined for human consumption.

The methods used in some Asian restaurants for killing rock lobsters have been receiving media attention. A range of methods are used, including those shown in Figure 1. They are 'drowning' in freshwater, boiling, head spiking, chest spiking, splitting, tailing, and they may or may not be preceded by chilling or freezing. Most lobsters are split longitudinally and the carapace is used in presenting the meat, and they may or may not have been chilled, given a head or chest spike, or tailed before splitting. It is recommended that the lobsters are chilled to less than 4 °C before they are killed (Lowe and Gregory 1999).

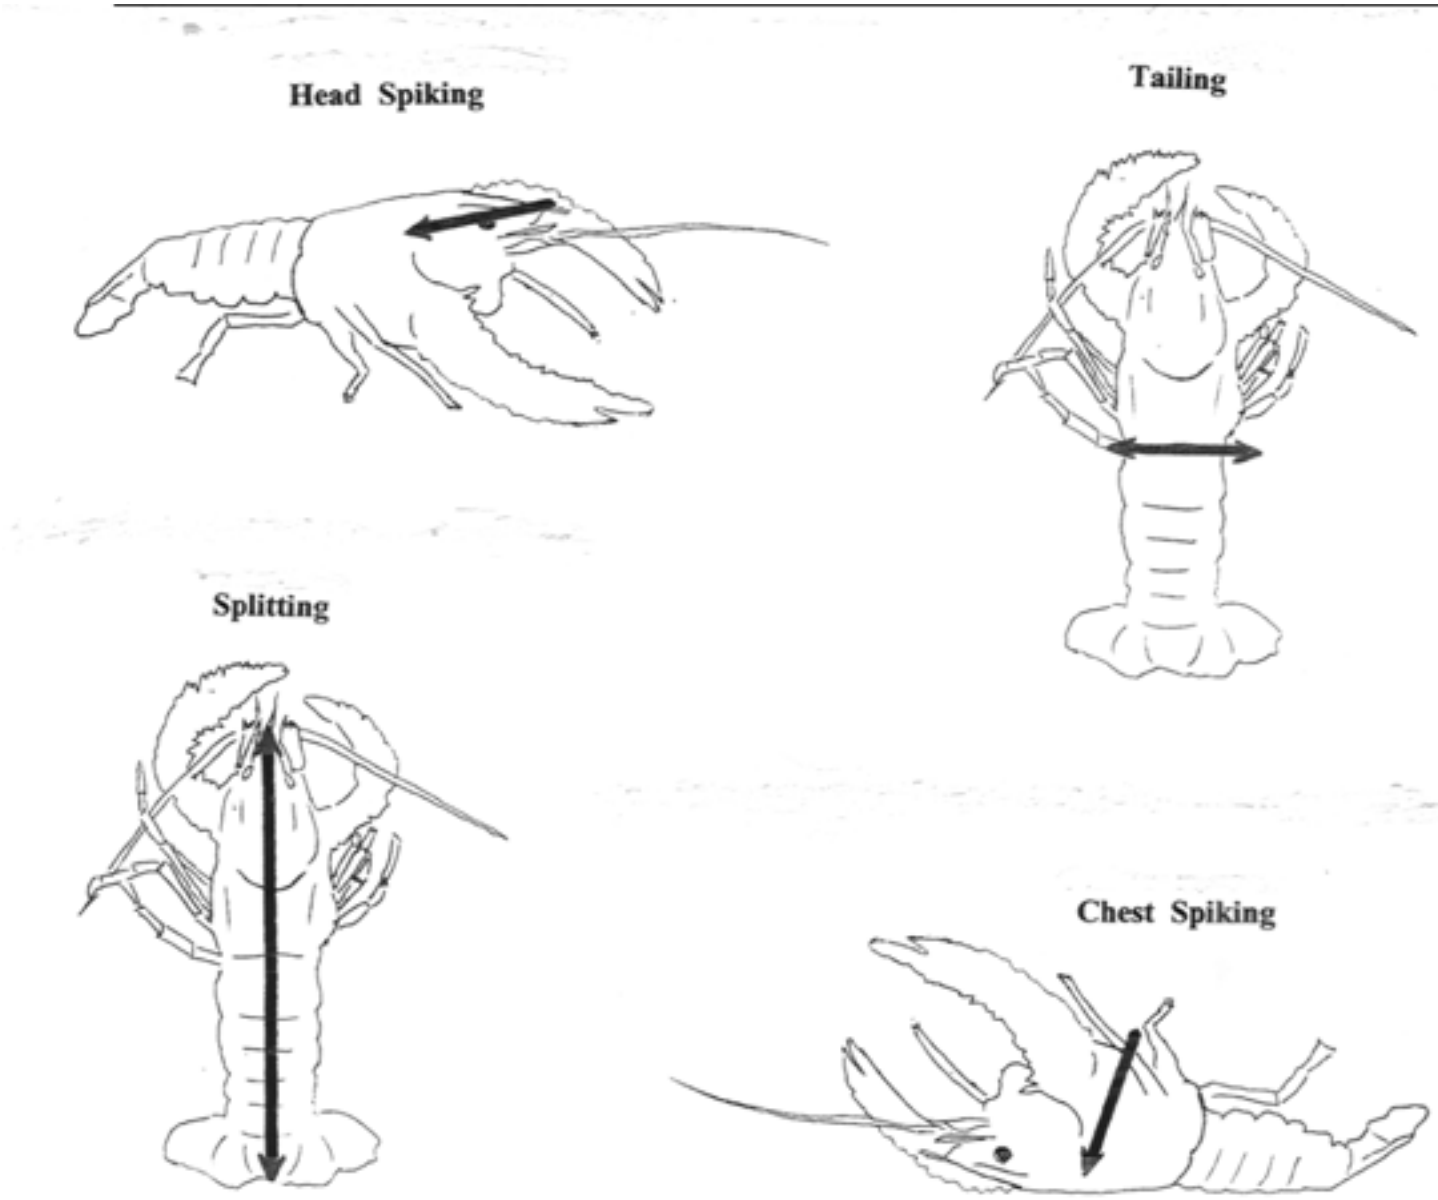

Figure 1. Approaches used in restaurants for killing rock lobsters with a knife or cleaver.

Electrical stunning monitors

Electrical stunning monitoring systems have become more sophisticated in recent years (Berry *et al* 2002; Gregory 2001). The advantage of stunning monitors compared to visual inspection of animals, or looking at the needle of an ammeter connected to the circuit, is that they can identify problems such as pre-stun shocks, interruptions in current flow at the start of stunning, and slow ramping up of the current as it is delivered. A system developed by Silsoe Research Institute for poultry waterbath stunners uses a data logger which is fitted between the shackle and an individual bird. It records rms current, peak current, voltage and duration of current flow for that bird, and the AC and DC measurements are used for determining true rms current.

Blood splash and bleeding efficiency

Four theories have been put forward to explain the cause of the blood capillary rupture that leads to blood splash, but none of these have been proven. Firstly, it could be due to counteracting muscle contractions during stunning causing localised tearing of the capillary bed (Gregory 1998). However, haemorrhages can be induced electrically in tissues such as the brain, which does not possess any skeletal muscle (Hassin 1933). If this applies more broadly, it is unlikely that localised striated muscle contraction is the only cause of vessel rupture. Secondly, Shaw *et al* (1971) suggested that one of the contributing factors may be arteriolar dilatation. This was based on the finding that, in rats, propranolol reduced and phentolamine increased the extent of blood splash. The effects of these drugs would not necessarily be limited to the arterial side of the circulation, as venous dilatation could also play a role (Vanhoutte *et al* 1981). Presumably, it is engorgement of the capillary bed which encourages rupture of vessels when placed under pressure. Thirdly, the blood vessels may be unduly fragile. Histological examination of blood splash in meat has shown that the vessels that burst are on the venous side of the capillary bed, which has less elastic walls than the arterial side, and so are weaker and more prone to damage. Blood splash is common in animals that have died from anticoagulant poisoning and these animals have raised capillary fragility (Littin 2004; Fulton & Berman 1964). It has been noted that lambs in a flock that had a high prevalence of blood splash had poor blood coagulation in terms of prothrombin time (Restall 1980/81), and it was suggested that the common link might be ingestion of excessive amounts of coumarins from pasture. The raised susceptibility to blood splash in unweaned lambs might be a low Vitamin K status because of their milk-based diet. Fourthly, during intense generalised muscle body contractions, such as those during electrical stunning, the venous and arterial systems experience severe external pressure. Squeezing of the veins results in large rises in venous pressure, which is transmitted to the capillary system at sites that can be some distance from the contractions. The venules in the capillary bed probably burst where they are weakest, or where venous pressure is particularly high. This referral of pressure, causing distant petechial haemorrhage, has been seen in other contexts when sudden intense pressures have been applied to veins (French & Callender 1962). Engorgement of the venous circulation would presumably exaggerate this effect.

It is not clear whether blood splash could be due to a direct effect of electrical current on blood vessels, but it seems unlikely. Electrical stimulation of tissues, even at low currents (e.g. 20 μA), will promote extravasation of blood cells from the capillary bed, but this is an inflammatory response and is slower than the time available under slaughtering conditions (Nanmark *et al* 1985). Leakage permitted by electroporation would only occur in the track of an applied current, but since current pathways are not properly understood it is not possible to conclude whether this mechanism is important.

It is well recognised in the broiler processing industry that high frequency currents result in fewer birds with engorged wing veins and wing haemorrhages in comparison with low frequencies (50 or 60 Hz). This has recently been confirmed for turkeys (Wilkins & Wotton 2002), and it was found that the effects of high frequency electrical stunning on breast meat pH fall and quality were minor. High frequency electrical stunning resulted in fewer carcases with broken coracoid and furculum bones, and a lower prevalence of haemorrhages in the meat at these sites. Bleeding efficiency is greater with high frequencies, and the prevalence of cardiac arrest at stunning is lower (Mouchonière *et al* 1999).

Bloody pygostyles can be an unsightly blemish in poultry. McNeal *et al* (2003) found that one way of reducing this problem was to decapitate the birds after stunning, instead of using the normal neck cutting

method. Decapitation after electrical stunning also had the advantage that the body lost physical activity sooner after cutting. Evidently, disruption of neurotransmission through the spinal cord led to earlier termination of the convulsions. Gregory *et al* (1999) found in a limited trial that when the prevalence of blood spots in breast muscle was high, it could be reduced by performing a ventral neck cut instead of the conventional dorsal cut. Head only stunning results in breast muscle haemorrhages at the humerus-coracoid joint, whereas with whole body stunning the haemorrhages tend to be in the middle of the muscle (Hillebrand *et al* 1996).

Bleeding efficiency and bleeding rate at sticking are influenced by the factors listed in Table 1. A cardiac arrest at the start of bleeding will slow the rate of blood loss, and in some situations it can result in less blood loss, but this is not an inevitable consequence of inducing a cardiac arrest during electrical stunning (Gregory 1998). Velarde *et al* (2003) showed that lambs that were hoisted and bled without being stunned, released less blood from the sticking wound than lambs that were electrically stunned (250 V, 50 Hz, 3 s), hoisted and then stuck. A likely explanation is that the muscle contractions associated with electrical stunning forced blood away from skeletal muscle towards the vessels in the thorax and abdomen. The implication is that bleeding efficiency in animals slaughtered without stunning is poorer by comparison with animals bled following electrical stunning. The role of severing the vagus nerves at sticking on subsequent bleeding efficiency and residual blood in the carcass has not been examined, but it is known that vagal severance affects the distribution of blood flow in different organs and it reduces the blood pressure and cardiac output responses during haemorrhage (Schertel *et al* 1991). This could have implications for different sticking methods.

Head to back stunning has fallen from favour since its successful introduction in the 1980s. It is not compatible with Halal market requirements and so it is no longer widely used for lambs in New Zealand or Australia. There are still some pig abattoirs using head to back stunning, and unlike the situation in lamb, it does not seem to reduce or prevent blood splash in pigs. Channon *et al* (2003) reported that the haemorrhages following head to back stunning in pigs were not always due to broken vertebrae.

Table 1. Factors affecting bleeding rate or bleeding efficiency at sticking

• Blood vessels that are severed
• Size and patency of the sticking wound
• Cardiac arrest at stunning
• Orientation of the carcass - positioned horizontally or vertically
• Vasodilatation or vasoconstriction in the capillary bed
• Tonic muscle contractions squeezing blood capillaries and vessels
• Clonic activity causing movement of blood towards the sticking wound

Religious slaughter

The welfare issues during slaughter without stunning include the stress of restraint, whether the cut is painful, and whether the animal experiences undue distress whilst it is bleeding out. Inverted restraint has been replaced by upright restraint in some countries, and it is worth considering the evidence behind this change. Over the years, six methods have been used for restraining cattle during Shechita. They are casting with a rope, hoisting by a hindleg, restraint in a straddle conveyor or restraining (V-shaped) conveyor, half inversion in a rotary pen, full inversion in a rotary pen, and restraint whilst standing upright. Koorts (1991) compared the prevalence and severity of struggling in over 1,500 cattle that were either inverted in a casting pen and subjected to Shechita, or were held in the same pen and stunned whilst in an upright position. The prevalence and severity of struggling was graded subjectively by a panel from the first attempt at loading the casting pen either up to the time the animal was stunned, or up to the time of Shechita. The system using stunning was quicker and involved less struggling (Table 2). 4% of the animals due to be killed by Shechita escaped from the casting pen, either because they were oversize or because they were frantic. 9% of the cattle subjected to stunning had to be restunned. In 15% of the cattle, more than one attempt was made at tipping them to the inverted position. A comparable study was conducted by Dunn (1990). The behaviour

of cattle in a casting pen was compared with that in an upright pen. The duration of struggling was shorter lasting in the upright pen (1 s *vs.* 11 s, $p<0.001$), the number of vocalisations was higher, and serum cortisol concentrations were greater. Van Oers (1987) found that when head restraint was applied after an animal was inverted, there was more vigorous struggling in comparison with head restraint before inversion. Studies on blood gas tensions indicate that the changes likely to occur during inversion for Shechita are not severe enough to cause serious respiratory embarrassment (Wagner *et al* 1990). Two disadvantages in using upright restraint are that the cut has to be made upwards instead of downwards, and this can be more awkward. Secondly, the Shochet is more likely to get covered with blood because of his position relative to the cut.

Table 2. Average time spent in the casting pen and prevalence of stressed behaviour before stunning or Shechita. After Koorts (1991)

Category	**Average time spent in the casting pen before stunning or Shechita s**				**Prevalence of stressed behaviour %**	
	Secular	*n*	*Shechita*	*n*	*Secular*	*Shechita*
Calm	7	1,085	33	511	69.4	31.4
Nervous	14	418	62	868	26.7	53.3
Wild	22	58	81	208	3.7	12.8
Frantic	35	2	99	41	0.1	2.5

The likely physiological events occurring when a neck is cut in the unanaesthetised state have been discussed by Gregory (2004). In summary, when the neck is cut with a knife there will be direct activation of neurones by the blade as it transects the nerves. This produces an intense but brief injury discharge in the afferent nerves. Thereafter the cut end of the nerves is depolarised and unable to respond to further stimuli. The afferent pathways that are severed serve a range of functions including pain, cold, heat, kinaesthesia, itch, and stretching or distortion of the skin. The sensations produced during the injury discharge is likely to be an amalgam of all such inputs, and the overall effect is likely to be a sense of shock, comparable to an electric shock. There is no reason to assume that one sensation (such as pain or cold) will over-ride all the other sensory input when the nerves are being cut. Subsequently, undamaged nerve endings in the neck wound could respond if stimulated or disturbed, and so the way the wound is managed before consciousness is lost, could be important in determining whether there is pain. Wound management has not been studied in any detail during Shechita.

Barnett & Cronin (in press) have performed an important study on time to loss of consciousness in 41 broilers during Shechita. The birds were taken from the shochet as soon as the cut was made, and placed on their feet on the floor. The time to loss of posture was recorded, and in this situation, this should be a good indicator of loss of balance associated with impaired consciousness. On average the time to loss of posture was 14 sec, and the range was 8 to 26 sec. The implication is that some birds could be fully conscious for up to 26 sec following the cut.

Gas stunning

In some countries, poultry waterbath electrical stunners are being replaced by gas stunning units. Gas stunning is being promoted because it results in less blood spots in the meat and fewer haemorrhages on the surface of the carcass. Five gas stunning methods are being used commercially and they differ in the gas composition. Two methods are used in the UK; 60% argon + 30% CO_2 and less than 2% O_2 using Ar in air. The anoxic method (less than 2% O_2 is falling from favour because of the severity of the carcass convulsions and the cost of Ar. In mainland Europe a mixture of 40% CO_2 + 30% O_2 + 30% N_2 is used for induction of

unconsciousness, followed by 80% CO_2 + 20% N_2 for killing. This method is being promoted by Stork PMT. In Japan and Italy, 40% or more CO_2 is applied for over a minute. In the Italian system the birds are lowered into a well containing a gradually increasing CO_2 concentration, with a final concentration of 60% or more CO_2. In the Japanese system the birds are suspended on shackles which are conveyed through the CO_2 unit. The argon-CO_2 method produces greater physical activity as the bird dies in comparison with the Stork method (Gerritzen *et al* 2000), and this is reflected in a slightly faster rate of post-mortem muscle glycolysis in breast muscle (Savenije *et al* 2002a). Whether the accelerated glycolysis is a disadvantage depends on how the carcasses are managed. If they are promptly chilled, it should not be a problem, but where this is not possible, it could result in firmer, if not tougher, breast meat.

There is some debate at the moment as to which of these gas mixtures is most humane. The primary concern is about breathlessness before loss of consciousness. It is recognised that in the human, CO_2 induces a sense of breathlessness with dypnoea. Whereas, hypoxia is not a potent stimulus of breathlessness and dypnoea (Manning and Schwartzstein 1995). During gas stunning the EEG can be divided into three phases. In phase 1 there is normal activity which lasts for 5 to 10 s. In phase 2 the amplitude of the EEG is reduced, and in some birds there is an increase in frequency. It is during this phase that consciousness starts to fail. In phase 3 the EEG is suppressed. Gasping in a standing bird during phases 1 and 2 is a concern from the animal welfare perspective as it indicates breathlessness whilst the bird is conscious. Coenen *et al* (2000) did not observe any intense gasping during phase 1 when comparing 40% CO_2 + 30% O_2 + 30% N_2 with 40% CO_2 + 15% O_2 + 45% N_2. During phase 2, there was less gasping in the higher O_2 mixture. The birds collapsed towards the end of phase 2, and there were no differences between the treatments in time to collapse. This work is not conclusive, because of the limited number of birds in each treatment (four), but as a preliminary finding it raised the possibility that there could be welfare advantages in supplementing CO_2 with O_2.

Some of the work by McIntyre *et al* (in preparation) supports the view that there could be advantages in supplementing CO_2 with O_2. They found that there was less gasping following a ten second exposure to 40% CO_2 + 30% O_2 + 30% N_2 in comparison with 40% CO_2 in air. However, there was no difference in the prevalence of gasping between 40% CO_2 + 30% O_2 + 30% N_2 and 40% CO_2 + 60% N_2. In other words, there was less gasping following 40% CO_2 in N_2 in comparison with 40 % CO_2 in air. More importantly, they found that 25% CO_2 in either air or N_2 resulted in considerable gasping in comparison with any of the 40% CO_2 mixtures. The time to collapse and loss of consciousness is longer with lower concentrations of CO_2.

The work by Raj and by Lambooij indicate that there are welfare advantages from using very low levels of oxygen, or a low (30%) CO_2 in combination with hypoxia, in comparison with 40% CO_2 + 30% O_2 + 30% N_2. Lambooij *et al* (1999) showed that before physical collapse, the birds subjected to 40% CO_2 + 30% O_2 + 30% N_2 showed 9 gasps per bird, birds subjected to 30% CO_2 + 60% Ar showed 3 gasps per bird, and those inhaling 90% Ar in air were almost gasp-free (all the treatments were significantly different from each other, $p < 0.05$). In addition the times to physical collapse were 32, 17 and 16 s respectively, and the 40% CO_2 + 30% O_2 + 30% N_2 treatment was significantly longer than the other treatments ($p< 0.05$). This strongly suggests that breathlessness is a greater problem with the 40% CO_2 + 30% O_2 + 30% N_2 method in comparison with the UK method (30% CO_2 + 60% Ar).

Raj *et al* (1998) examined the rate of induction during 40% CO_2 + 30% O_2 + 30% N_2 and 30% CO_2 + 60% Ar, in terms of the time to EEG suppression and the time to loss of somatosensory evoked potentials in the EEG. The 40% CO_2 + 30% O_2 + 30% N_2 mixture was slower acting than the 30% CO_2 + 60% Ar method. Whether this is important depends on the relative unpleasantness of the two systems. Since Coenen *et al* (2000) observed more intense gasping during the relatively long phase 2 with the 40% CO_2 + 30% O_2 + 30% N_2 mixture compared with 30% CO_2 + 60% Ar, it is thought that the CO_2-Ar method could be more humane. Here again the number of birds in each treatment was very small. Further work is needed using larger numbers of birds, before we conclude which method is more humane.

Headshaking is sometimes used when monitoring the effects of gas stunning, but it is a confusing indicator. In other situations, chickens perform headshaking when they have an irritation such as ear mites, or when consciousness is beginning to be clouded during an intravenous infusion of pentobarbitone. In the context of gas stunning, it is not clear whether headshaking is an indicator of irritation or failing consciousness. The

time to loss of posture (physical collapse) is a better indicator of failing consciousness (Mohan Raj and Gregory 1990a). It has been found to coincide with the onset of a high amplitude low frequency waveform in the EEG during anoxic stunning, and with the onset of suppression in the EEG during 31% CO_2 + 2% O_2 stunning in hens (Mohan Raj *et al* 1991; 1992). Convulsions are not usually a cause for concern from the welfare perspective as somatosensory evoked responses are lost and a high amplitude low frequency EEG waveform has set in by the time they occur (Mohan Raj *et al* 1990; Forslid 1987). The convulsions occur when somatomotor activity in the brain is no longer being controlled by activity from higher centres, and so they are a sign of neurological impairment.

Practical experience indicates that the convulsions associated with the 60% argon + 30% CO_2 cause more wing damage than the Stork system. The argon-CO_2 system is also more expensive in terms of gas cost, and it has been claimed that the engineering associated with this system introduces a longer delay in exposure to the final stunning concentration of the gas, and this could slow the onset of unconsciousness.

Practical experience has also shown that pork quality defects can be reduced by using gas stunning in place of electrical stunning. This was confirmed by Channon *et al* (2003) in a study which compared 1.3 A for 4 s with 90% CO_2 for 103 s. It was found that the prevalence of PSE meat and blood splash were lower with gas stunning. The reduction in PSE meat, however, was not reproducible between studies. Anoxic stunning using Ar has been evaluated in pigs. It produced very severe carcass convulsions, but the kicking can be reduced by adding CO_2 to the mixture (Raj, 1999). The concentration of CO_2 that suppresses convulsions can be critical (Mohan Raj and Gregory 1990b)

CONCLUSIONS

Based on the information examined when preparing this review, it is recommended that the following should be considered as future aims. The effect of captive bolt stunning on the presence of BSE prion in beef needs to be examined. If the prion is present in meat, and it is decided to use electrical stunning in place of the captive bolt, the next requirement will be to develop methods for preventing the blood splash that is caused by electrical stunning. We need to determine which of the main gas stunning systems used for poultry are acceptable from the humane standpoint. Work is in-hand in the UK, which should help meet this aim, and once that work has been published, it should be possible to reach a decision. Further development and extension is required on fish stunning methods.

EFFECTS OF HEAT ON MEAT PROTEINS– IMPLICATIONS ON STRUCTURE AND QUALITY OF MEAT PRODUCTS

E. Tornberg

Department of Food Technology, Engineering and Nutrition, Lund Institute of Technology
P.O. Box 124, S-221 00 Lund, Sweden.

Abstract

Globular and fibrous proteins are compared with regard to structural behaviour on heating, where the former expands and the latter contracts. The meat protein composition and structure is briefly described. The behaviour of the different meat proteins on heating is discussed. Most of the sarcoplasmic proteins aggregate between 40 and 60°C, but for some of them the coagulation can extend up to 90°C. For myofibrillar proteins in solution unfolding starts at 30-32°C, followed by protein-protein association at 36-40°C and subsequent gelation at 45-50°C (conc.> 0.5 % by weight). At temperatures between 53 and 63°C the collagen denaturation occurs, followed by collagen fiber shrinkage. If the collagen fibers are not stabilised by heat–resistant intermolecular bonds, it dissolves and forms gelatin on further heating. The structural changes on cooking in whole meat and comminuted meat products, and the alterations in water-holding and texture of the meat product that it leads to are then discussed.

Introduction

Cooking of meat products is essential to achieve a palatable and safe product. The meat proteins, approximately 20 % of a muscle's weight, represent the main constituents that make up the structure of the meat product. They undergo substantial structural changes on heating and therefore the quality of the meat product, which is mainly governed by the meat structure, also changes drastically after cooking. This review will try to cover the aspects of structural changes on cooking for meat proteins *per se*, in whole meat and comminuted meat products, and the quality alterations of the meat product that it leads to. Earlier reviews in this area are among others Hamm, 1977, Offer, 1984 and Asghar et al., 1985.

Proteins in general

A protein is built up from a long polymer chain of amino acids, a polypeptide chain. The variable side chains give each protein chain its distinctive character. There are three general categories of side chains: nonpolar, polar but uncharged and charged polar (Dickerson and Geis, 1969).

The build-up of the polypeptide chain of the proteins is called the *primary structure* (Figure 1). This polypeptide chain tends to form specific conformations in solutions, the so called localised *secondary structures,* i.e. α-helix, β-pleated sheet or random coil (Figure 1). *Tertiary and quaternary structures* of proteins are the denomination of the three-dimensional structure and the association of protein entities in solution, respectively (Figure 1).

The stabilisation of these structures of a given protein system is dependent mostly on non-covalent forces, such as hydrogen bonding, van der Waal's forces, electrostatic and hydrophobic interactions. The formation of *globular* proteins is a typical example of how hydrophobic interactions stabilises this type of tertiary structure. There is a driving force for the nonpolar, hydrophobic side chains of a protein to be removed from an aqueous to a nonpolar environment. The protein gains an extra 4 kcal of free energy stabilisation for every

nonpolar side chain group buried in the interior of the globular protein, mainly as an entropy effect (Kauzmann, 1959). Among the meat proteins myoglobin, giving meat its colour, is a typical example of a globular protein (Figure 2). Another structural form of proteins, which is highly prevalent among meat proteins, is the *fibrous* form of proteins. Actin, myosin and collagen in meat are typical fibrous proteins. These proteins are built up from three main structures, namely the α-helix, the antiparallel β-pleated sheet and the triple helix. Myosin is α helical, whereas collagen uses the triple helix (Figure 2). To stabilise these structures hydrogen bonding is frequent (Dickerson and Geis, 1969).

What happen to these type of protein structures on heating? At increased temperatures the hydrophobic side chains, for entropy reasons, can more favourably stay in the aqueous environment and in the case of the compact globular proteins leads to an expansion and partial unfolding. Furthermore, a free energy gain can be achieved by the association of two partially unfolded proteins, thereby shielding the hydrophobic side chains from the aqueous environment.

If the degree of association of protein entities is too large, leading to less colloidal stability of the system, the *solubility* of the proteins is lowered, and a precipitate is formed. If, however, the three-dimensional association of the proteins occurs in such a way that the attractive and the repulsive forces are so well balanced that a three-dimensional network is formed, a gel has set. This gel binds the water in the former solution, mainly by capillary forces, being solid-like in its mechanical behaviour. The gels can in turn vary from being transparent, containing a network of strands of small cross-sections to opaque gels containing much coarser aggregated structures (Hermansson, 1986). For one of the latest review on thermally-induced gelling of globular proteins see Clark, 1998.

For the fibrous proteins the large amount of hydrogen bonds and electrostatic interactions that keep the stretched molecules in register in the large building blocks, where the fibrous proteins take part, are broken on heating. This results in the molecules having a greater freedom to form any random configuration, as driven by entropy. Since the proteins are relatively stretched in the fibrous form fibrous proteins contract on cooking in contrast to globular proteins which expand.

Meat proteins, composition and structure

The muscle consists of 75 % water, 20 % protein, 3 % fat and 2 % soluble non-protein substances. Out of the latter 2 %, metals and vitamins constitute 3%, non-protein nitrogen 45 %, carbohydrates 34 % and inorganic compounds 18 %. The proteins can be divided into three groups; myofibrillar, sarcoplasmic and stromal proteins. The myofibrillar proteins constitute between 50 to 55 % of the total protein content, while the sarcoplasmic proteins account for approximately 30 to 34 %. The remaining 10 to 15 % of the proteins is the stromal fraction, frequently referred to as the connective tissue proteins.

The myofibrillar proteins are further divided into three subclasses: the myofilamentous fibrous proteins myosin and actin building up the myofibrillar structure, the regulatory proteins including the tropomyosin-troponin complex, α- and β-actinin, M-protein and C-protein and ultimately the scaffold proteins, such as titin, nebulin, desmin, vimentin and synemin, supporting the whole myofibrillar structure. Titin is a massive protein with a molecular weight of around 1 million Dalton.

The sarcoplasmic proteins are the soluble proteins of the sarcoplasm, to which belong most of the enzymes of the glycolytic pathway, creatine kinase and myoglobin. About 100 different proteins are known to be present in the sarcoplasmic fraction and they are globular proteins of relatively low molecular weight ranging from 17000 (Myoglobin) to 92500 (Phophorylase b).

The structures built up by the connective tissue proteins starts with an external covering sheet of connective tissue, the epimysium, around the whole muscle. This layer of connective tissue binds the individual bundles of muscle fibres into place and also binds groups of muscles together. The muscle fiber, which is the muscle cell, can vary in diameter from 10 to 100 μm and have a length of up to 30 cm. The cell has a membrane, called the sarcolemma, and is also surrounded by another type of connective tissue called the endomysium. The fibers are collected into fiber bundles, where the third type of connective tissue (perimysium) envelopes the fiber bundle (Ashgar and Pearson, 1980).

The connective tissue proteins collagen, reticulin and elastin are all fibrous proteins. Collagen, a glycoprotein, is the main structural component of the connective tissues (55-95 % of the dry matter content) and is composed of tropocollagen monomers about 2800Å long and 14-15Å in diameter with a molecular weight of 300,000. These tropocollagen molecules aggregate to form either extended fibers in the epimysium and perimysium or as a structural matrix in the endomysium. Collagen exists in several different genetic forms (I-V), which are present in muscle. Bailey et al., 1979 used immmunoflourescence to show that type I is present in the epimysium, types I and III are present in the perimysium and types III, IV and V collagen are present in the endomysium.

The muscle fibers constitute 75-92% of the total muscle volume and it holds long, thread-like structures, the myofibrils, wherein the sarcomere, the smallest contractile unit, is lined up.

The structural build-up of the sarcomere can be overviewed in Figure 4. The diameter of the myofibrils is about 1 µm and the length of a sarcomere is about 2.2 µm in a resting muscle.

According to Figure 3 the sarcomere is built from two ”building blocks”, that consist of a thick filament, extending over the A-band and a thin filament, extending from the Z-line towards the A-band in the H-zone. The thick filaments are composed of myosin. There are 200-400 molecules of myosin in each thick filament, with each being 1.5µm long and 130 Å in diameter(Knight and Trinick, 1987). By tryptic digestion, the myosin filament can be split into a heavy head, called heavy meromyosin (HMM), and a tail called light meromyosin (LMM). The water-insoluble LMM fraction has a molecular weight of 150,000 and is composed of either a double or triple-stranded α-helical structure. The head region consists of two globular units, each about 70 Å in diameter with 45 % α-helical content (Knight and Trinick, 1987).

The second major myofibrillar protein is actin. The fibrous actin (F-actin) is formed from longitudinal polymerization of globular actin (G-form, M_W 47,000 Da). In solution at low ionic strength actin exists in the monomeric globular form. When the ionic strength is raised, the monomers are polymerized into the fibrous structure, consisting of a double, twisted helix with a diameter of 70 Å (Figure 4, Ashgar and Pearson, 1980).

Behaviour of meat proteins in heating

Conformational changes of the proteins occurring on heating are usually called denaturation. The cooking temperature, where conformation changes occur is commonly called denaturation temperature and has been mostly investigated using differential scanning calorimetry (DSC). The unfolding of the proteins (the loss of helical structure) can also be followed by optical rotary dispersion (ORD) and circular dichroism (CD). Another away to follow the unfolding of the proteins is to measure the surface hydrophobicity of the proteins, using a flourescent probe 8-anilino-1-naphtalene sulfonate (ANS). The next step in the structural changes to occur on heating are the protein-protein interactions, resulting in the aggregation of proteins. These processes are mainly studied by turbidity measurements and loss in protein solubility. The gel forming ability and the type of gels formed by the proteins are usually studied, using some sort of mechanical and micro-structural measurements.

Sarcoplasmic proteins

According to the review by Hamm, 1977 most of the researchers have found that most sarcoplasmic proteins (i.e. those muscle proteins soluble in water or at low ionic strength) coagulate or aggregate between 40 and 60°C. Davey and Gilbert, 1974 found for the bull neck muscle that the heat coagulation of the sarcoplasmic proteins could extend up to 90°C. They were also the first to suggest that the sarcoplasmic proteins might have a role in the consistency of cooked meat in such a way that the heat-induced aggregated sarcoplasmic proteins can form a gel in between the structural meat elements and thereby link them together. In our investigations on tenderness of meat cooked to different temperatures (Tornberg et al., 1997) our measurements suggest that might well be the case. The mechanism by which this will operate will further be elaborated on later in this review.

Of special interest among the sarcoplasmic proteins is the myoglobin, as it is the carrier of the colour of meat. Myoglobin aggregates at about 65°C in meat, whereas in pure solution it denatures at a higher temperature (Draudt, 1969).

Another interesting aspect of the sarcoplasmic proteins is the tenderizing effect these enzymes can have, using low temperature long time heating (heating rate of 0.1°C/min) on beef muscles. Laakkonnen et al., 1970 have shown that collagenase could remain active in the meat at cooking temperatures < 60 °C, whereas at faster heating and reaching a higher end temperature of 70-80°C they were inactivated. They also showed that a heating time of at least six hours was needed to achieve a substantial lowering of the shear force, i.e. a tenderizing effect. Over the same time most of the water losses between 25 and 30 % (w/w) had occurred.

Myofibrillar proteins

Changes in secondary and tertiary structure

With regard to changes in secondary structure on heating of myosin Morita and Yasui, 1991 have for example measured the change in helix content (circular dichroism) and surface hydrophobicity (ANS) of LMM, i.e. the tail portion of the myosin molecule, at pH 6 and 0.6 M KCL. The helix content of LMM began to decrease at about 30°C and attained a minimum at 70°C. Simultaneously, heating to 65°C progressively increased the surface hydrophobicity, whereas at higher temperatures it decreased again. The decrease in hydrophobicity observed at the higher temperatures suggests that part of the hydrophobic residues take part in protein-protein interactions leading to a network formation of aggregates, a gel.

The advantage of the DSC method is that it can be used in complex mixtures and at high concentrations of proteins, which are the situation occurring in meat. A typical curve (Figure 4) from thermal transitions found in a muscle is composed of three major transition zones A, B and C. The first transition displays its maximum between 54 and 58°C and has been attributed to myosin (Martens and Vold, 1976, Wright et al., 1977). The second transition, which occurs between 65 and 67°C, was assigned to collagen (Martens and Vold, 1976, Stabursvik and Martens, 1980) and to sarcoplasmic proteins (Wright et al., 1977). The third transition has been assigned to actin and is found between 80 and 83°C (Wright et al., 1977). For the second transition it has also been shown that both isolated actomyosin and myosin and its sub-units undergo transitions in the same temperature range (Wright and Wilding, 1984). Recently, the thermal denaturation of titin from pork and beef has been investigated , using DSC. Denaturation was characterised by a single DSC peak at 78.4 and 75.6°C for beef and pork titin, respectively (Pospiech et al., 2002).

Ziegler and Acton, 1984 reviewed and summarised conformational changes of natural actomyosin. In the 30-35°C range, native tropomyosin is dissociated from the F-actin backbone, while at 38°C the F-actin superhelix dissociates into single chains. The myosin light chain sub units dissociate from the heavy chains at about 40°C, followed by conformational changes in the head and the hinge regions of the myosin molecules. Dissociation of the actin-myosin complex occurs at 45-50°C and light meromyosin (LMM) undergoes a helix-to-coil transformation at 50-55°C. Above 70°C major conformational changes in globular actin takes place. However, the exact temperatures for these changes is influenced by such factors as ionic strength, pH, heating rate, muscle source and type.

Changes in quaternary structure

Xiong and Brekke, 1990 have studied salt-soluble proteins (SSP, the myofibrillar proteins) from pre- and postrigor chicken on heating at 0.6 M NaCl, pH 6, using ANS, turbidity and rigidity measurements for unfolding(hydrophobicity), protein-protein association and gelation, respectively (Figure 5 a-d). Despite some differences between breast and leg muscles and between pre- and postrigor SSP samples, a general trend was seen in all samples that protein- protein association beginning at 36-40 °C was preceded by protein unfolding at 30-32°C. Gelation at 45-50°C was initiated after interactions of proteins had taken place. They further stated from these investigations that the hydrophobicity was not dependent on the type of muscle (white, breast and red, leg) nor on muscle rigor state, but rather the protein-protein association varied due to these variables, thereby forming different type of gels. According to Figure 5b the optical density of the SSP solution increased drastically above 40°C and after 45°C the increase was less. There are no differences between pre- and post-rigor meat, which could be due to the fact that actomyosin complex dissociate at 40-45°C. However, breast SSP showed a great difference from leg SSP in aggregation behaviour. But when gels are formed the penetration force is the highest for the breast post-rigor SSP (Figure 5c). Comparing the water-holding of these different gels, as visualised in Figure 5d, the best is achieved by breast, pre-rigor.

High penetration force for gels usually reflect highly aggregated junction points in the gel, as Hermansson, 1982 has shown for blood plasma gels, and good water holding gels suggest a fine-stranded gel with a higher amount of junction points per volume unit. This suggests that breast prerigor SSP form more the last type of gel, as revealed by figure 8b,d, having a lower degree of aggregation and better water-holding, whereas the leg SSP forms the former type of gel, having a high degree of aggregation and a higher penetration force.

As shown above the denaturation of myofibrillar proteins in solution usually results in gel formation, because especially myosin is unique in the sense that it form gels at very low concentration of 0.5 % by weight (Hermansson and Langton, 1988). For comparison sarcoplasmic proteins need about 3 % by weight to gel (Hamm and Grabowska, 1978). When purified myosin is heated, the firmness of the gel reaches its maximum at 45°C at pH 5.5 or at 60°C at pH 6 (Sharp and Offer, 1992). If actin is present in the solution a firmer gel is obtained (Yasui et al., 1980). Ionic strength and pH are important factors since they determine if the myosin exists in monomeric form or as filaments. At ionic strengths >0.3 and at neutral pH, the myosin molecules are dispersed as monomers, forming a coarse network with large pores. At lower ionic strength the myosin molecules are assembled in filaments, resembling the natural thick filaments in the muscle. During heating a firmer gel is formed, especially if the filaments are very long. Such a gel consists of a finer and more uniform network, with smaller pores (Sharp and Offer, 1992).

The gel formation of myosin occurs in two steps, in two separate temperature regions on heating. The first part of the reaction occurs between 30-50°C and the second step at temperatures above 50°C.The first step involves aggregation of the globular head of myosin. Sharp and Offer, 1992 have studied heating of purified myosin at different constant temperature for 30 minutes in an electron microscope. They found that after heating at 30°C in 30 minutes the appearance of the myosin molecule had not changed. After heating at 35°C, the presence of native myosin molecules with two heads was still dominating, but other types of new structure had been formed, such as two myosin molecules that had aggregated by dimerisation of their heads. After heating at 40°C there were no native myosin molecules left and the only monomers present had coalesced heads. Heating to 50°C resulted in further aggregation. At this temperature it was hard to distinguish between the individual tails. Heating at 50-60°C lead to the formation of large globular aggregates. No tails where seen after these temperatures. The second stage involved structural changes in the helix-structure of myosin leading to network formation, where hydrophobic groups interact with each other.

Connective tissue proteins

At temperatures between 53 and 63 °C the collagen denaturation occurs according to DSC measurements (Martens et al., 1982), which probably involves first the breakage of hydrogen bonds loosing up the fibrillar structure and then the contraction of the collagen molecule. If unrestrained, collagen fibers shrink to one-quarter of its resting length on heating to temperatures between 60 and 70°C. If the collagen fibres then are not stabilised by heat-resistant intermolecular bonds, it dissolves and forms gelatine on further heating. The presence of heat-stable bonds means that intermolecular linkages are retained at these temperatures and a proportion of the fibre matrix does not dissolve (Light et al., 1985). In young animals the epimysium contains primarily of thermally labile cross-links, the perimysium a mixture of thermally labile and stable cross-links and the endomysium of thermally stable cross-links (Sims and Bailey, 1981). As the animal age increases the thermally labile increasingly converts into thermally stable cross-links (Shimokomaki et al., 1972). Higher levels of heat-stable cross-links lead to the development of greater tension in the connective tissue during cooking (Sims and Bailey, 1981).

Wu et al., 1985 have followed the structural alterations, using scanning electron microscopy, of the epimysium, perimysium and endomysium from Bovine *sternomandi bularis* caused be heating to 60 and 80°C for 1 hour. The epimysium did not show large alterations after cooking, whereas the perimysium and endomysium became granular at 60°C and start to gelatinise at 80°C. There are also differences in solubilisation for the different type of collagens, where type I is more easily solubilised on heating than type III (Burson and Hunt, 1986).

Structure and qulity of meat products on cooking

Different quality aspects of meat peoducts

Important quality aspects of meat can embrace quality factors, such as fat- and water-holding, appearance, and the eating quality of meat products. The concept of the eating quality implies texture/tenderness, juiciness, flavour and aroma. In this review we will confine ourselves to quality aspects such as water-holding and texture of meat products

Besides whole meat, meat products, such as hamburgers and emulsion sausages, will be referred to in this review. The procedure of manufacturing hamburger patties normally includes mincing, blending and forming, after which the patties are either frozen or fried and then frozen. Frankfurters and similar sausages are made by chopping meat, with the addition of water and NaCl, in a bowl chopper into a fine meat homogenate, in which pork fat and is further dispersed and emulsified. Heat treatment of the stuffed sausage batter is performed in a smoke-chamber. The microstructure of the different meat products, such as a transverse cut of whole meat (A), a beef burger (B) and an emulsion sausage (C) can be compared in Figure 6. A hamburger is composed of more or less intact meat fibers and fiber bundles up to 50 - 70 % but randomly distributed compared to the well-defined anisotropic structure of the whole muscle. In the emulsion sausages, however, meat protein network formation constitutes the major part of the structure, as shown by Andersson et al. (2000).

Structural changes of meat products during cooking

Whole meat

The structural events during cooking of the different proteins in their structural environment of the meat have been investigated by among others by Cheng and Parrish, 1976; Jones et al., 1977 and Bendall and Restall, 1983. During heating, the different meat proteins denature as described above and they cause meat structural changes, such as the destruction of cell membranes (Rowe, 1989), transversal and longitudinal shrinkage of meat fibers, the aggregation and gel formation of sarcoplasmic proteins and the shrinkage and the solubilisation of the connective tissue.

Transverse shrinkage to the fibre axis occurs mainly at 40-60°C, which widens the gap already present at rigor between the fibers and their surrounding endomysium. There is, however, a controversy regarding these observations. Davey & Gilbert (1974) for example found no change in the cross-sectional area on cooking of the neck muscle, whereas Bendall & Restall (1983) found that the transverse shrinkage of both fibres and fibre bundles of M. psoas major starts at about 40°C. There is also a disagreement between the results presented in the literature with regard to the temperature, where the longitudinal shrinkage of the fibre starts. Offer, 1984 and Bendall & Restall, 1983 have observed that fibres do not shorten until 60°C, whereas Hostetler & Landman, 1968 have reported that both sarcomere and fibre shortening usually begin at temperatures of 40-50°C. At 60-70°C the connective tissue network and the muscle fibres co-operatively shrink longitudinally, the extent of shrinkage increasing with temperature. This is mainly based on the fact that the intra-muscular collagen (mainly perimysium) shrinks longitudinally at 64°C (Mohr & Bendall, 1969).

We have in one of our investigations (Tornberg et al., 1997) followed the structural changes in the different protein systems of the meat during cooking. Firstly, we separated the water phase from whole meat and studied the aggregation of the sarcoplasmic proteins, recording the change in absorbance in a spectrometer (Figure 7 a). From this figure it can be deduced that the increase in absorbance starts at about 40°C and is more or less terminated at 60°C. This is in accordance with the behaviour of the sarcoplasmic proteins on heating as discussed earlier. Secondly, the shrinkage during cooking of the separated connective tissue per se and fibre shrinkage, both transversally and longitudinally, have been followed under the light microscope during cooking. The micrographs taken continuously during heating were quantified with an image analysing system (Figure 7 b-d).

The transverse shrinkage of the fibre starts at 35-40°C and then increases almost linearly as a function of temperature. The total shrinkage at 80°C can, though, according to Figure 7 b, vary from 3 up to 14 % area. The shrinkage of the connective tissue per se starts at 60°C, where after at around 65°C it contracts more intensively. However, the amount of shrinkage varies substantially from about 7 % area up to 19 % area. The

discrepancy in results could, among other things, be due to large biological variation within a muscle and between different muscles. These observations are similar to those observed by Bendall and Restall, 1983.

Comminuted meat products

Comminution in combination with salt addition and subsequent heating, which are processes used in the making of hamburgers and emulsion sausages, drastically alter the structure of the meat system. On cooking hamburgers the higher occurrence of whole fibers and pieces of fibers causes more shrinkage as compared to emulsion sausages. In the latter product, higher amounts of myofibrillar proteins are extracted, which on heating create a dense protein network, a gel, that holds water efficiently by capillary forces.

The quality of that protein network is influenced by a number of factors interacting in a complicated way as visualised in Figure 8. The amount of myofibrillar proteins which are extracted into the water-phase during comminution and blending is generally considered to be the most important factor for the quality of the meat network. Moreover, the type of gel matrix formed is related to the disperse or aggregated state of the protein prior to gelation. The complex meat system consists of, not only dissolved proteins, but also insoluble components like meat fibers, connective tissue and fat. The amount and state of these components have a large impact on the gelation properties. The properties of the gel are also influenced by the heating process.

Water-holding of meat products on cooking

Whole meat

Considering the structural basis of water-holding in whole meat, the work of Offer *et al*. cannot be overlooked (Offer, 1984, Offer and Knight, 1988 and Offer et al., 1989). It is important to point out that the structural origin of water-holding in whole meat and highly comminuted products is different. In the former it is the shrinkage and swelling of myofibrils that is the crucial factor (Offer & Knight, 1988), whereas the ability of meat proteins to form different types of gel comes more into play in comminuted meat products (Hermansson, 1986).

Water loss from whole raw meat can be obtained by evaporation from the surface and as exudate, when a muscle is cut. This exudate, a solution of sarcoplasmic proteins, is drained from the cut surface of the meat by gravity, if the viscosity of the water is low enough and the capillary forces do not retain it. Offer *et al.* (1989) have confirmed that this drip loss arises predominantly from the longitudinal channels through the meat between the fiber bundles. The main question then arisis, in order to be able to control and understand changes in water-holding, is how water is accumulated and lost in those channels.

Most of the water in the living muscle is held within the myofibrils (≈ 80 %), in the spaces between the thick and thin filaments (Offer *et al.,* 1989). Any large changes in the distribution of water within the meat structure, by necessity, originate from changes in this spacing. Lateral shrinkage of the filament lattice is brought about by a pH-fall closer to the isoelectric point, rigor contraction and myosin denaturation (Offer and Knight, 1988). There will only be changes in the water distribution, if the myofibrils change in volume. The fact that fiber and fiber bundles shrink when their constituent myofibrils shrink, has been shown by Offer and Cousins (1992), thereby giving rise to the two extracellular compartments around fibers and fiber bundles.

Cooking induces structural changes, which decrease the water-holding capacity of the meat. The review by Offer (1984) summarises the structural changes occurring on cooking as follows: When the transverse shrinkage to the fibre axis occurs mainly at 40-60°C this widens the gap already present at rigor between the fibers and their surrounding endomysium. At 60-70°C the connective tissue network and the muscle fibres co-operatively shrink longitudinally, the extent of shrinkage increasing with temperature. This longitudinal shrinkage causes the great water loss that is obtained on cooking. It is then presumed that water is expelled by the pressure exerted by the shrinking connective tissue on the aqueous solution in the extracellular void.

A convenient way of studying water holding in meat is to investigate the multi-exponential decay of the relaxation time, T_2, of water protons in the muscle, using the ^{1}H-pulse-NMR (Nuclear Magnetic Resonance). Two dominating, discernible relaxation processes have mostly been observed, where the major fraction (≈ 80 %) of the muscle water has a T_2 (called T_{23}) between 35-50 ms, while the rest of the water relaxes in the range of 100-150 ms (called T_{22}). The percentage of water relaxing with the shortest relaxation time can be considered as mainly held by the myofibrils, since a very high fraction of the water is occupied by the myofibrils. Tornberg and Larsson (1986) have further shown, by comparing the percentage

of water having a T_2 = 100-150 ms with the percentage of area around the fiber bundles (evaluated by light microscopy), that the latter could be predicted with an 80 % probability using the pulse-NMR method.

Studies of the water distribution on cooking of meat, using ^{1}H-pulse-NMR, have been done by Fjelkner-Modig and Tornberg, 1986; Tornberg and Larsson, 1986 and Borisova and Oreshkin, 1992, Tornberg et al., 1993; Micklander et al. 2002 and Bertram et al., 2004. It was noted both by Fjelkner-Modig & Tornberg, 1986, Tornberg and Larsson, 1986 and Tornberg et al., 1993 that the T_2 for the major fraction of the water (T23) in both beef and pork was lowered on cooking from around 40 ms to around 30 ms. This suggests a more aggregated, dense protein structure in the myofibrils on heating, which is in accordance with the denaturation behaviour of the proteins as discussed earlier.. For the cooked meat samples, the percentage water of T_{22} and extracellular space around fiber bundles, as evaluated by light microscopy, was compared at the different cooking temperatures (Figure 9). The amount of water around fiber bundles increases up to 50°C, in comparison with the raw meat, which seems to be in accordance with the transverse shrinkage of fibers and fiber bundles. Above 50°C this widened gap diminishes, again up to 70°C, probably mainly due to the shrinkage of the connective tissue. The increase in extracellular space from 70 to 90°C is more difficult to comprehend but, according to the light micrographs a swelling of the perimysium seems to occur at these cooking temperatures.

Comminuted meat products

On comminution of meat and salt addition, leading to the extraction of meat proteins, which occurs when producing hamburger patties and/or emulsion sausages more of the structure consists of a protein gel network after heat treatment. This is especially the case for the highly comminuted emulsion sausages(4 % salt on meat basis), which is reflected in the water-holding of this meat product, being superior to both hamburgers (0.4 % salt) and whole meat, reflected in Figure 15. In this figure the cooking loss of the whole meat, the hamburger and the emulsion sausage of beef *M. biceps femoris* can be compared at different cooking temperatures (The heating gradient was 1.5°C/minute up to 60°C, thereafter 0.7°C/ minute was used until the final temperature was reached in the centre of the meat sample). The temperature dependence on cooking loss for the whole meat shown in this Figure, where the highest increase in water loss is achieved in the temperature region of 60 to 80 °C, is similar to other investigators (Davey and Gilbert, 1974; Bouton et al., 1976; Bendall and Restall, 1983; Honikel, 1987). It is further interesting to note that although the hamburgers have been comminuted, the cooking losses are almost as large as for the whole meat. This is probably due to the more prevalent shrinkage of whole fibers and pieces of fibers, causing larger water losses in the hamburgers as compared to emulsion sausages. Because in the latter product, the higher amounts of myofibrillar proteins extracted create a dense protein network that holds more water (in combination with 4 % added potato starch, which is usually added in Swedish emulsion sausages).

In one of our latest study on beefburgers patties was fried on a double-sided pan fryer to a mid-temperature of 72°C, having different pan temperatures (100, 150 and 175°C). Kovascne et al., 2004 found that the water losses, sometimes reaching up to 60 % of the initial water content, never went below 80 % drip loss. This means that the pressure driven water loss, due to meat protein contraction, is a substantially more important mechanism governing the water loss on frying of beefburgers, than the evaporation losses occurring at the surface crust formed at the higher frying temperatures of 150 and 175 °C.

Textural properties of meat products on cooking

Whole meat

Meat texture can be evaluated by both sensory and instrumental methods. Numerous studies have been conducted in the area of meat cookery, but especially attempts to relate sensory evaluated tenderness with mechanical and structural changes in the meat during cooking are scarce (Martens et al., 1982, Josell and Tornberg, 1994 and Tornberg et al., 1997). Textural properties of meat with emphasis on the instrumental methods have been reviewed by amongst others Purslow (1991), Lepetit and Culioli (1994) and Harris and Shorthose (1988). In this review only the cooking temperature dependence of texture properties of meat will be dealt with.

During the mastication of meat, deformation and fracture of the samples takes place. The mechanical forces acting on meat can include shear, compressive and tensile forces and they should be defined in the mechanical test in use. As meat is a composite, it is important to study in which structural elements failure takes place, and where cracks propagate, to be able to understand its mechanical properties. Tensile tests on cooked strips of both beef (Bouton & Harris, 1972; Munro, 1983; Purslow, 1985) and pork (Josell and Tornberg, 1994; Mutungi et al., 1995; Christensen et al., 2000) have been used.

For the assessment of the texture of whole meat, the empirical method of the Warner-Bratzler shear device is the most widely used (Bratzler, 1932). The most commonly used configuration is the one in which the shearing plane is perpendicular to the muscle fibres. Tensile, shear and compression forces operate in this type of test. The W-B-technique is, however, the instrumental technique that usually yields the best correlation with sensory panel scores for meat toughness.

When relating the sensory properties of the meat with the mechanical, structural traits Josell and Tornberg, 1994 and Tornberg et al., 1997 used in the former case *M. longissimus* from pork and in the latter case whole and minced meat from beef (M. *biceps femoris*). From the former investigation the sensory evaluated tenderness of pork loin increases substantially from 50 to 65°C, where after it decreases again to 80°C (Figure 11). In this study also the temperature dependence of longitudinal and transversal fracture stress and strain were recorded, using tensile measurements(Figure 12 a and b). As shown by Purslow (1985) for beef the longitudinal rupture of the fibers require higher stresses than transversal rupture, which was also the case for pork. The increase in tenderness in the temperature interval 50-65°C was observed as decrease in the transversal fracture stress and in the transversal and longitudinal fracture strain (Figure 12 a, b). The elastic modulus of the meat registered both at small and large deformations increased with cooking temperature from 50 up to 80°C (Figure 12 d).

Bouton and Harris, 1981 showed, using W-B shear peak values, that there is a decrease between 50 and 65°C, which they attributed to a weakening of the collagenous connective tissue, due to denaturation. This phenomenon could also be the reason for the fracture stress to diminish from 50 to 65°C in our investigation. However, we are more inclined to suggest another hypothesis to explain the observed phenomena. In the tensile measurements the strain at fracture tells us how much the meat yields on tearing and this yielding would increase between 50 and 65°C, if the weakening of the perimysium connective tissue would be the dominating mechanism in the tensile measurements. However, the opposite is observed, i.e. from 50 to 65°C a decrease in fracture strain from 70 to 30 % is achieved (Figure 12 b). Concomitantly, the elastic modulus of the whole meat system increases (Figure 12 c, d), which means that the meat converts from a viscoelastic to a more or less elastic material.

We suggest that the reason for the toughness observed for the raw meat up to about 50°C is based on the fact that the applied stress during mastication is reduced by viscous flow in the fluid-filled channels in between fibres and fibre bundles. This situation is, however, improved from 50 to 65°C by the formation of a gel of aggregated sarcoplasmic proteins gluing the fibres and fibre bundles together. The viscous flow becomes then lower as the elasticity of the meat increases in that temperature region. That means there is a higher probability of the applied stress being transferred within the material to the crack without any viscous dissipation of energy and there propagating it. The piece of meat is then more easily fractured in the mouth and mastication is facilitated and tenderness improved. Above 65°C elasticity acts adversely and impairs the tenderness. For a fully brittle fracture in a linearly elastic material (which we suppose cooked meat above 65°C behaves like) higher elastic modulus gives rise to larger tensile stresses to extend a crack (Jowitt, 1979), i.e. a tougher meat. We suggests that the contraction of the connective tissue, mainly occurring after 65°C as seen in Figure 10, gives rise to an increase in the elasticity of the meat by forming a much denser material in the temperature region of 65 to 80°C and thereby a tougher meat.

Comparison between whole and minced meat

These findings are further substantiated, when comparing the rheological properties of whole and minced meat (M.*biceps femoris*, beef) in relation to sensory and structural characteristics (Tornberg et al., 1997). The sensory evaluation (Figure 13) showed that, for the whole meat, the toughness decreased drastically from 55 to 60°C, thereafter increased again up to 80°C. For the minced meat, however, the hardness increased over the whole temperature range and was significantly lower than the toughness of the whole meat at cooking

temperatures below 60°C. The rheological properties of the whole meat, cut transversally to the fibre direction, and the minced meat were also recorded, using a low deformation dynamic shear test, and the results can be seen in Figure 14. The storage modulus increases steeply with the temperature from 50 to 65°C both for the whole and the minced meat, where after it levels off to values for the modulus of 80 kPa and 70 kPa for the whole and minced meat, respectively. The phase angle, which is the quotient between the loss and the storage modulus, decreases already from 35-40°C down to a low plateau round 65-70°C. These results tell us that the spacial arrangement of the fibers is of utmost importance for the textural behaviour of the meat. In the whole meat the crack that fractures the meat has to pass over the fluid filled channels at temperatures below 55 °C (for the case of biceps femoris) and therefore the fracture energy will dissipate as viscous flow and is therefore anticipated as tough. For the minced meat, however, the structure is no longer anisotropic and the more or less disintegrated muscle fiber and bundles are now randomly distributed in the batter and the crack then preferentially goes through the extracted myofibrillar mass that holds the fiber together in the batter. The fracture stress to propagate a crack in that material is much less than the stress needed to pass through a meat fibre. As the temperature increases from 45 to 65°C in the beef burger batter the extracted proteins form a gel and after 65°C the contraction of the connective tissue and the substantial loss of water contribute to a denser product. All these structural changes give rise to an increased elasticity of the minced meat (Figure 14), and also an enhanced sensorial perceived toughness (Figure 13).

If this increased toughness of the minced meat on heating was beneficial for the overall impression of it was not investigated in that study. For an emulsion sausage, however, where different textures were produced by using varying recipes, salt concentrations and pH (Andersson et al., 1997), the overall acceptability of the emulsion sausage was mostly governed by the properties of the protein network. This was best characterised by the fracture strain in the tensile test used. When comparing the stress-strain curves obtained for aggregated and non-aggregated sausages, the latter were characterised by having larger fracture strains and they were also rated the highest overall acceptability. Even the elastic modulus (G') was significantly higher for non-aggregated sausage (31.5 kPa) compared to the aggregated (24.9 kPa). Evidently, a dense, elastic meat protein gel is sensorially preferred to a more brittle, grainy protein gel in an emulsion sausage.

PHYSICOCHEMICAL PROPERTIES OF MEAT BATTERS WITH ADDED WALNUT: EFFECT OF SALT LEVELS

Ayo, M. J., Jiménez Colmenero, F. , Carballo, J. and Ruiz-Capillas, C.
Instituto del Frío (CSIC). Ciudad Universitaria. 28040-Madrid. Spain.

Background

Epidemiological studies show that frequent consumption of nuts in general, and walnuts in particular, correlates inversely with myocardial infarction or death by vascular ischaemic disease (Sabaté, 1993). This effect has been associated with the peculiar blend of nutrients and phytochemical compounds found in walnuts, which exert beneficial effects on serum lipid profiles and other risk factors that can cause or exacerbate cardiovascular diseases .

One of the various strategies that have been adopted to achieve healthier meat products is the reformulation of meat derivatives to incorporate ingredients like walnut that can confer potential heart-healthy benefits. Meat products have been formulated with added walnuts, resulting in products with acceptable physicochemical and sensory properties (Jiménez Colmenero *et al*., 2003; Carballo, *et al*., 2003; Cofrades *et al*., 2004).

Since high salt intake has been related to high blood pressure and a considerable proportion of dietary salt comes from meat and meat products, there is growing interest among consumers and processors in reducing the use of salt (minimizing sodium) in meat processing. However, reducing salt limits the extractability of proteins and alters the pattern of denaturation and thermal aggregation of the major muscle protein (Trout & Schmidt, 1986), thus influencing the characteristics of meat products. No data are available on how salt level affects meat batter physicochemical properties formulated with added walnut.

Objectives

The purpose of this study was to determine how the percentage of NaCl (1.5 and 2.5 %) influences the effect of added walnut (0 and 20 %) on physicochemical properties (texture, binding properties) of raw and cooked meat batters.

Materials and methods

Pork meat and walnut (particle size approx. 12 μm) were used to prepare four different meat batters. Two control lots (C) were prepared with 85% meat, 0.18 % sodium tripolyphosphate, water, and salt in two concentrations: 1.5 % (LS) and 2.5 % (NS). Two samples with added walnut (W) were also prepared, in which 20 % of the meat was replaced by an equal percentage of walnut. The ingredients were homogenized and ground in a chilled cutter (2 °C) (Stephan Universal Machine UM5, Stephan u. Sóhne GmbH & Co., Hameln, Germany). Mixing time was standardized to 5 min and the final temperature was below 10 °C in all cases. The batters (60 ± 0.5 g) were placed in jars (diam = 33 mm), and some were heated to an internal temperature of 70 °C. After tempering for 1 hr, weight loss (WL) was determined and expressed as % initial sample weight. Determinations were carried out in quadruplicate.

Protein, fat, moisture, ash and pH of the raw samples (non-heated) were determined as in Jiménez Colmenero *et al*., (2003). Penetration tests were carried out (6 determinations) on raw samples in their containers once they attained ambient temperature (20-22 °C). The tests were performed with a 5 mm diameter cylindrical stainless steel plunger attached to a 50 N cell connected to the crosshead of a TA-XT2 Texture Analyser (Texture Technologies Corp., Scarsdale, NY). Force-deformation curves were obtained at 0.8 mm/s crosshead speed. Gel strength (GS) (J) was estimated as the force-deformation area after penetration to 3 mm. Texture Profile Analysis (TPA) was performed as described by Bourne (1978). Six cores (diam = 30 mm, height = 20 mm) from cooked samples were axially compressed to 30 % of their original height. Force-time deformation curves were derived with a 250 N load cell applied at a crosshead speed of 0.8 mm/s.

Two-way analysis of variance by F test and least squares differences by Statgraphics 2.1 (STSC Inc., Rockville, MD) were used to compare mean values and to identify significant differences ($P<0.05$) among treatments (added walnut and salt levels).

Results and discussion

Addition of walnut increased ($P<0.05$) fat (C 2.6 %, W 14.5 %) and decreased ($P<0.05$) moisture (C 75.7 %, W 62.5) contents in meat batters. Ash proportions were lower ($P<0.05$) in LS (2.4 %) than in NS (3.6 %). The pH values of meat batters increased ($P<0.05$) with added walnut (C 5.6, W 6.0) .

Higher levels of salt translated into higher ($P<0.05$) GS values in raw meat batters (Figure 1). The difference was only significant with 1.5 % NaCl, indicating that the effect of walnut addition on GS was influenced by the salt concentration. In meat batters containing 2.5 % NaCl, weight losses were lower than 4 %, indicating good water and fat binding properties. Values were similar in LS sample containing 20 % of added walnut (Figure 2).

Some textural parameters (e.g., Hd and Cw) of heated samples varied according to the salt concentration, but not significantly (Table 1). There has been conflicting reports on the effect of salt on texture, and it has been suggested that these have to do with the diversity of factors that can influence thermal gelation processes (Jiménez-Colmenero et al., 1998). When walnut was added, gel/emulsion structures exhibited lower ($P<0.05$) values of Hd, Sp, Ch and Cw (Table 1). The changes induced by walnut were possibly due to a number factors Walnut addition caused an increase in the fat level (and a decrease in the percentage of moisture) of the meat batters. Contrary to the results of this experiment (Table 1), it has been reported that a higher protein/moisture ratio produces harder structures (Carballo et al., 1996). On the other hand, while protein contents were comparable (19.4 %), the addition of walnut entailed a decrease in the amount of meat protein in favour of globular (walnut) proteins, which generally tends to interfere with muscle protein interactions (Lee, Wu and Okama, 1992). This limited the formation of a thermal gel matrix system, resulting in softer structures (Table 1) with good water and fat binding properties (Figure 2).

Conclusions

Walnut affected the properties of meat batters. Their presence limited the gel forming ability of protein matrixes so that meat batters were softer and less cohesive, but they did maintain good water and fat binding properties. Salt levels did not influence the effect of walnut on texture (TPA parameters) and weight loss. These results suggest that addition of walnut may be a way not only of promoting the various bioactive compounds existing in walnut but also of reducing sodium content in meat products of this kind. Such characteristics are highly appreciated by the growing number of consumers currently interested in functional foods.

EFFECTS OF BLENDING CHICKEN BY-PRODUCTS WITH PALM FAT OXIDATION AND SENSORY PROPERTIES OF CHICKEN BOLOGNA DURING FROZEN STORAGE (-18°C)

Wolyna, P. and Babji, A. S.

Food Science Programme, School of Chemical Science and Food Technology,
Faculty of Science and Technology, Universiti Kebangsaan Malaysia,
43600 Bangi, Selangor, Malaysia.

Background

Traditional meat products are commonly associated with high fats and cholesterol. As cholesterol and unhealthy PUFA / SFA ratios are adversely related to coronary heart disease (Muguerza et. al 2001), it is only prudent for meat producers in the food industry to offer less cholesterol / less fats processed meats to the consumer. Some meat processing methods such as pre-emulsion, blending vacuum chopping and tumbling of poultry by-product such as mechanical deboned chicken meat (MDCM), spent hen meat and chicken trimming have been efficiently utilized as raw materials in the production of emulsion-type, value added, meat products (Seri Chempaka et. al 1996). Palm fats were successfully incorporated in some meat product formulations on a direct weight per weight substitution with animal fats (Babji et. al 2001).

Objectives

The purpose of this work was to study the utilization of chicken by-products and palm shortening on the TBA value and sensory properties of chicken bologna stored as frozen (-18°C).

Materials and methods

Chicken bologna was produced using 45% mechanical deboned chicken meat, 30% spent hen meat and 15% chicken trimming. Five chicken bologna formulations containing 10% of various fats were studied. Chicken fat was used as the control formulation (C), red palm fat (T1), 1:1 combination of chicken fat and red palm fat (T2), white palm fat (T3) and 1:1 combination of chicken fat and white palm fat (T4).

Thiobarbituric Acid (TBA) Test

The development of oxidative rancidity was measured by distillation method of Tarladgis et al. (1960).

Sensory Evaluation

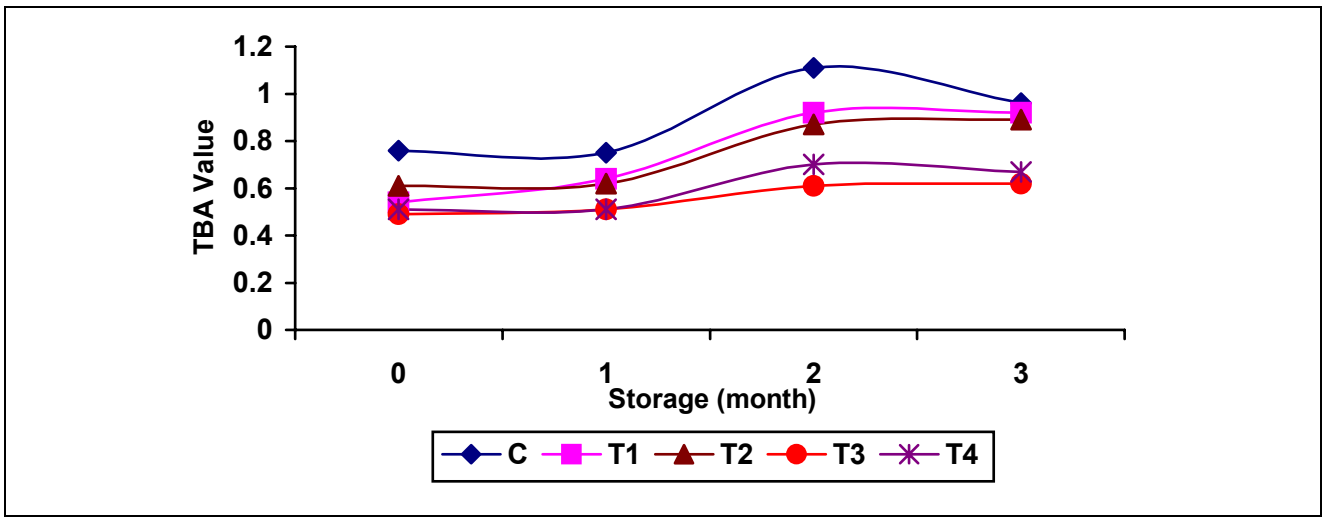
Sensory evaluation was carried out by panel consisting of students and staff of the Department of Food Science and Nutrition, Universiti Kebangsaan Malaysia; 60 panelists altogether. The sensory technique adopted was hedonic test using a seven-point scale. Attributes evaluated included colour, aroma, hardness, springiness, juiciness, oiliness, chicken flavour, off-flavour and overall acceptability. Samples were presented in sample cups coded with 3 digit random numbers and were presented to panelists using random numbers of permutation. Sensory evaluation was conducted in a Sensory Evaluation Laboratory equipped with six isolated booths (School of Chemical Science and Food Technology, Universiti Kebangsaan Malaysia).

Data were subjected to analyses of variance (ANOVA), using the SAS package software (SAS, 1985).

Results and discussion

Thiobarbituric Acid Value (TBA)

Over the entire storage period (3 months), the TBA values of chicken bologna prepared with chicken fat (CF) was higher than those with red palm fat (RPF) and palm fat (PF) (Figure 1). It was clearly shown that the incorporation of red palm fat (RPF) and palm fat (PF) had reduced the TBA values of bologna compared to chicken fat (CF). Substitution of palm fat (PF) in formulation T3 and T4 gave significant differences ($P<0.05$) for the TBA value, when compared to the control formulation (C). Whereas, no significant difference was observed in TBA value between control formulation (C), T1 and T2 ($P>0.05$). Generally, the TBA values of chicken bologna decreased after 3 months of frozen storage ($P<0.05$).



(C= 100%CF; T1=100%RPF; T2=50%CF+50%RPF; T3=100%PF; T4=50%CF+50%PF)
CF : Chicken Fat **RPF** :Red Palm Fat **PF** : Palm Fat

Figure 1: Thiobarbituric Acid Values of Chicken Bologna Stored at -18°C for 3 months.

Sensory Evaluation

Mean scores for various sensory attributes are shown in Table 1. Storage as frozen did not significantly affect ($P>0.05$) consumer acceptance for attributes such as colour, aroma, hardness, springiness, juiciness, oiliness, chicken flavour, off-flavour and overall acceptance for the chicken bologna. Consumer test showed no significant differences ($P>0.05$) between formulation for attributes such as colour, hardness, springiness and oiliness. It was observed that bologna prepared with red palm fat, namely, T1 and T2, received very low sensory score and these scores were significantly lower than control formulation (C) in the chicken flavour rating at the 3 months of storage ($P<0.05$). Bologna prepared with CF was most accepted by the consumer both in chicken flavour and off flavour attributes. However, there were no significant differences ($P>0.05$) between formulations in terms of off flavour attributes at 3 months of storage. The control formulation (100%CF) had the highest scores for the overall acceptance. The study showed that substitution of palm fat (PF) into formulation T3 and T4 in terms of overall acceptance was not significantly different from that of the control formulation (100% CF). Whereas the incorporation of red palm fat (RPF) into chicken bologna, T1 and T2 showed an overall acceptance scores that were significantly different ($P<0.05$) compared to the control formulation (C). The overall acceptance scores were highly correlated to the chicken flavour ($r = 0.89$, $P<0.05$) and springiness ($r = 0.98$, $P<0.05$).

Table 1: Means for Various Sensory Attributes of Chicken Bologna Stored at -18°C for 3 months.

Attributes	Storage Time (Month)	Treatment

$^{a-b}$Mean values within the same row bearing different superscripts differ significantly (P<0.05)
$^{x-z}$Mean values within the same column bearing different superscripts differ significantly (P<0.05)
C = (100% CF), **T1** = (100%RPF), **T2** = (50%CF + 50% RPF), **T3** = (100% PF),
T4 = (50%CF + 50% PF)

Conclusions

This study pointed out the potential of palm oil product, especially palm fat (PF), to be used as fat sources in the production of comminuted meat products. The results also indicated that incorporation of palm fat did not adverely affect the sensory rating attributes of bolognas. In the storage study, bologna containing red palm fat (RPF) and palm fat (PF) showed lower TBA values than bologna with 100% chicken fat. This study indicated that addition of red palm fat and palm oil resulted in chicken bologna with better sensory properties and lower TBA values, when combined with MDCM, spent hen meat and chicken trimming.

EFFECT OF ADDING TUMERIC AND LEMON GRASS DURING MARINATION ON THE QUALITY OF ROASTED CHICKEN

Babji, A.S., Hui Vern, N., S. E. Ch'ng, C. L. Siaw

School of Chemical sciences and Food Technology
University Kebangsaan Malaysia
43600 Bangi, Selangor, Malaysia

Background

Today's consumer is looking for easy-to-prepare, juicy and tasty products. Marination is an excellent way to turn ordinary and less value meat cuts into succulent food products. Marinating not only adds value to cheaper cuts, but also creates new products with specific taste profile: Rhizome *Cucurma longa*, tumeric have been reported to exhibit antioxidative activity (Toda et al 1985), while Uhl (2000) noted antimicrobial effect of lemon grass, *Cymbopogon citratus* used in marinations of meat and roast chicken.

Objectives

This study monitored the antioxidative and sensory properties of tumeric and lemon grass extracts in marinated roasted chicken.

Materials and methods

Freshly slaughtered broilers and hen carcasses were deboned and the breast meat was separated and kept frozen at -18ºC until used for marination. The formulations were indicated in Table 1.

Table 1. Formulation of five treatments of marinades for boiler meat and spent hen meat.

Ingredients	C1 (%)	C2 (%)	C3 (%)	C4 (%)	C5 (%)
Salt	8.00	8.00	8.00	8.00	8.00
Sodium Nitrite	0.08	0.08	0.08	0.08	0.08
Sodium Erythrobate	0.30	0.30	0.30	0.30	0.30
Sodium tripolyphosphate	1.50	1.50	1.50	1.50	1.50
Sugar	5.50	5.50	5.50	5.50	5.50
Citric acid	0.60	0.60	0.60	0.60	0.60
Curry powder	5.00	5.00	5.00	5.00	5.00
Meat tenderizer	-	3.00	3.00	3.00	3.00
Tumeric	-	-	3.00	-	1.50
Lemon grass	-	-	-	3.00	1.50
Water	79.02	76.02	73.02	73.02	73.02
Total	100.00	100.00	100.00	100.00	100.00

Marination involved soaking of chicken breast meat (200g) with skin in treated marinades at 4ºC for 0, 8 and 24 hours. After marination, the samples were kept at 4ºC for 24 hours, then roasted using a microwave oven.

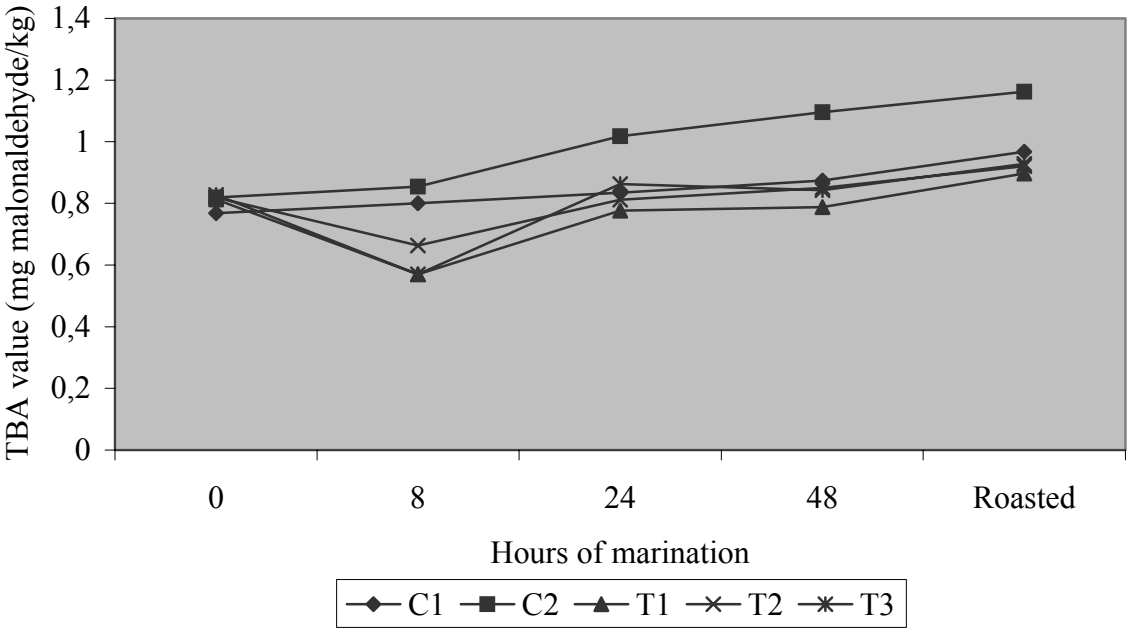
TBA value was determined using the method by Tarladgis et al (1960).

Sensory evaluation was carried out using the Hedonic Scale of 1= lowest, and 7= highest for scoring various attributes. A panel of 50 people was used to evaluate color, aroma, taste, juiciness, tenderness and overall acceptance of the samples.

Statistical analyses were done on the results using SAS, 1985 with Duncan test to differenciate among treatment at $P< 0.05$.

Results and discussion

Results of TBA test indicated a significant (P<0.05) decrease for marinated chicken treated with tumeric, lemon grass and combinaion of tumeric and lemon grass for spent hen, particularly after 8 hours of marination (Figure 1). The two control samples of spent hen and broiler meat had increased TBA values throughout the 48 hours of marination. The antioxidative effect was probably contributed by natural compounds such as cucurmin and citrolene present in tumeric and lemon grass respectively (Priyadarsini, 1997)



C1: Control (Broiler Meat)
C2: Control (Spent hen)
T1: Spent hen + tumeric
T2: Spent hen + Lemon grass
T3: Spent hen + tumeric: lemon grass (1:1)

Figure 1. Changes in TBA values (mg malonaldehyde/kg) for five formulations of marinated chicken meat at various time of marination and roasting.

Table 2 showed the sensory scores of color, odour, taste, texture, juiciness and overall acceptance of four treatment of marinated spent hen meat and two treatments of unmarinated broiler and spent hen meat respectively. Addition of tumeric and lemon grass and combination of these spices resulted in increase in the overall acceptance of roasted spent hen compared to control spent hen. However, the control broiler chicken was softer and more juicy compared to marinated spent hen meat. Marination with tumeric, lemon grass and combination of these two spices increased consumer acceptance for the softness and juiciness of spent hen meat when compared to the control spent hen meat. There were significant differences (P<0.05) for softness for lemon grass and combination of lemon grass and tumeric, when compared to the control non marinated spent hen meat. The problem of toughness with spent hen meat still remained, due to inherent accumulation of connective tissue in older bird. (Roland et al, 1981).

Table 2. Sensory evaluation using hedonic scale of 1= most dislike and 7= most acceptable of five marinated chicken breast meat.

	Formulation				
Attributes	C1	C2	T1	T2	T3
Color	4.20^{AB}	4.60^{AB}	4.72^{A}	4.24^{AB}	4.08^{B}
Odor	4.66^{A}	4.32^{A}	4.18^{A}	4.52^{A}	4.44^{A}
Taste	4.44^{A}	3.82^{B}	3.98^{AB}	4.14^{AB}	3.98^{AB}
Softness	4.62^{A}	3.00^{C}	3.36^{BC}	3.64^{B}	3.90^{B}
Juiciness	4.34^{A}	3.34^{B}	3.74^{B}	3.66^{B}	3.84^{AB}
Overall acceptance	4.52^{A}	3.62^{B}	3.94^{B}	4.12^{AB}	4.10^{AB}

Mean score n=50
$^{A-D}$: Means with different superscript for row are significantly different ($p<0.05$).
C1- Control (Broiler Meat)
C2-Control (Spent Hen)
T1-Spent Hen + tumeric
T2-Spent Hen + Lemon grass
T3-Spent Hen + combination of lemon grass and tumeric (1:1)

Conclusions

Tumeric and lemon grass added to marinades were effective in reducing oxidation in hen meat. Addition of tumeric and lemon grass and their combination in marinades also resulted in improving consumer acceptance of the roasted spent hen breast meat.

EFFECTS OF COOKING ON CAROTENE AND FREE FATTY ACID CONTENTS OF CHICKEN BURGER INCORPORATED WITH PALM FATS

Babji, A.S.[1] ., Nor Aishah, M.S.[1] ., Alina, A.R.[2] Wan Rosli, W.I.[1] & Ch'ng S.E.[1]

[1]School of Chemical Sciences and Food Technology, Faculty of Science and Technology, Universiti Kebangsaan Malaysia 43600 Bangi, Selangor, Malaysia.

[2]Food Science and Biotechnology Programme, Faculty of Science and Technology, Islamic University College of Malaysia.

Background

Oxidative rancidity is one of the limiting feature of prolonged storage of fresh meats at frozen temperatures as lipid peroxidation contributed towards the nutritional deterioration of such products. Processing techniques prior to freezing burgers involved comminuting the meat, disrupting the tissue membranes and dislodgement of iron from heme compounds, thus exposing the fats to oxygen and prooxidants such as sodium chloride and free iron. Heating/cooking release iron from heme compounds and disrupt the cellular integrity of muscle food, accelerating the process of oxidation. As chicken fat is highly unsaturated, studies of chicken fat being replaced with palm fat (PF) were done (Babji et al 2000, Babji et al 2001) to delay oxidation. Palm fats are a natural source and provider of vitamins A and E. However, the retention of carotene after cooking in processed meats with PF substitution had not been studied.

Objectives

The purpose of this study is to evaluate the changes in peroxide value (PV), free fatty acid (FA), thiobarbituric acid (TBA) and carotene content of raw and cooked chicken burgers incorporated with red palm fat, palm fat and control.

Materials and methods

Palm stearin (PS) and red palm stearin (RPS) burger were compared with control chicken fat burgers (C) at a fixed level of fats (15%). The burgers at 70 g each were cooked on an open flat pan by flipping every 3 minutes until the final internal temperature of 70^0C was reached. The duration of heat treatments were three and ten minutes. The fats from the samples were extracted at the 1, 2 and 3 months of storage at -18^0C. Chloroform/methanol lipid extraction of the samples was done, based on the method of Folch et al., (1957). Test done were on the free fatty acid content (PORIM 1995) and thiobarbituric acid values (TBA) as described by Tarladgis et al (1960). Carotene content analysis was carried out using the method of Hart and Scott (1995). Data were subjected to analysis of variance (ANOVA), using the SAS software package (SAS 1985).

Results and discussion

Free fatty acid (FA) was the highest in burgers with chicken fat (C), followed by palm stearin (PS) and red palm stearin (RPS) treated chicken burgers (Table 1). Prolonged heating resulted in increasing values of FA, peroxide (PV) and thiobarbituric acid (TBA) (Table 2). On the first month of storage (-18^0C), carotene content of RPS burgers were at 298 ppm (raw) and 86 ppm (10 min of cooking). After the third month of storage, the carotene content were significantly reduced to 180 and 38 ppm (raw and 10 min of cooking) respectively. The Red Palm Stearin (RPS) treatment had the lowest FA, PV and TBA values throughout the 3 months of shelf life study.

Means within the same column (a-c) with different small letters are significantly different (P<0.05)

Conclusions

Substitution of 15% chicken fat with palm stearin and red palm stearin improved the products' shelf life quality with decreased values of free fatty acids, peroxide and thiobarbituric acid values. The presence of carotene in RPS treatments further enhanced the oxidative stability of the products.

THE EFFECT OF SODIUM CHLORIDE, SOYBEAN PROTEIN AND STARCH ON GEL PROPERTIES AND COLOR OF BEEF SURIMI

Baohua Kong, Yujie Chi, Boxun Li, Zhong Jin
College of Food Science, Harbin 150030, Northeast Agricultural University, China

Background

The quality of meat surimi products is determined by the functional properties of muscle protein, which are water-holding capacity, gel and emulsification properties. These functional properties are based on the solubility of protein and can also determine the binding properties and physical stability of meat surimi.
Myofibril protein, which is composed of myosin and actin, is not only the major protein in muscle, but also the main component of extractable protein. Myosin is insoluble at normal ion strength (0.15 to 0.20M) in muscle of live animals, while it can dissolve at higher ion strength and proper pH. Adding sodium chloride and phosphate can increase the ion strength range from 0.3 to 0.6M. As a result, myosin dissolved can be extracted effectively. Furthermore, the increased pH is also helpful for myosin extraction. Stanley (1994) pointed out that increasing ion strength to a specific extent would improve gel properties and water-holding capacity of beef significantly. Siegal (1979) reported that phosphate and sodium chloride could improve cohesiveness of myosin thus, improve gel properties. Liu et al. (1996) studied the influence of ion strength on heat gel properties of myofibril protein of chicken myosin. The result indicated that the gel formed by protein solution with low ion strength (0.2M KCl, pH6.0) is very soft, while hardness of gel increased gradually along with the increasing ion strength. LesioÂw et al(2001) reported mechanism of rheological changes in poultry myobrillar proteins during gelation.

Non-meat proteins have been widely used in surimi-based meat products to improve gelation strength. The most commonly used were beef plasma protein (BPP), soybean protein, egg white protein, and whey protein concentration (Porter, 1993; Park, 1994). Soybean protein plays an important role in increasing fat usage factor and modifying the texture and emulsification properties of meat products. Soybean protein concentration or soybean protein isolate are usually added to meat surimi in the form of powder or emulsion. These merits make it widely used in meat industry in these days. Although the emulsification properties of soybean protein have been well documented, there is little study on its influence on beef gel properties.
Starch worked as a thickening ingredient in meat production. It is widely used in both traditional Chinese meat products and Western meat products. Natural starch contains two kinds of starch, namely straight-chain starch and branch-chain starch. Generally speaking, the more branch-chain starch added to the product, the better the thickening function is, the greater the gel strength is, and vice versa. Zhou (2003) compared the properties of sausages with added potato starch, cassava starch, wax cornstarch, and cornstarch. It suggested that the palatability, color, springiness and texture of sausages with added potato starch were the best. Adding starch in the production of meat surimi can improve water-holding capacity and modify texture of final products. This is mainly because starch can adsorb water, swell and form gel in the process of heating. According to earlier study, the gelation temperature of starch particles was higher than the denaturation temperature of meat proteins. As a result, meat proteins had been denatured and formed matrix when starch particles began to gelatinize. Starch particles captured weaker-binding water and immobilized it to improve the strength of matrix thus, enhanced the water-holding capacity. At the same time, starch particles swelled, moistened as it adsorbed water. Therefore, starch can improve elasticity and texture of final products by binding minced meat and stuffing the holes between it. Furthermore, adding starch particles can reduce fat loss and increase yield of final product by binding melted lipid in the process of heating as well (Kong, 1996).

Objectives

The objective of this research was to determine the effect of varying concentrations of the additives, such as sodium chloride, soybean protein and four starches (cornstarch, mung bean starch, potato starch and modified starch) on the quality of a beef based meat surimi product. Gel properties and color were measured as indicators of quality.

Materials and methods

The basic formula of the beef sausage was as follows, 1kg of loin from 3 years old local Mongolian cattle, 30g sodium chloride, 100g potato starch, 50g soybean protein, 10g carrageenan, 4g monosodium glutamate, 10g sugar, 3g pepper, 20g garlic, 10g ginger powder.

The sodium chloride, soybean protein and starch content of the product were modified by the following changes to the basic formula. The product was prepared with 1%, 2%, 4% and 5% (w/w) sodium chloride per kg of raw beef in stead of the basic formula content of 3%. The product was prepared with 1%, 2%, 3% and 4% (w/w) soybean protein per kg of raw beef in stead of the basic formula content of 5%. The product was prepared with 5%, 15% and 20% (w/w) of starch per kg of raw beef in stead of the basic formula content of 10%. Additionally, product was prepared with mung bean, modified starch and cornstarch replacing potato starch at all four concentrations. Sausages produced following the basic formula but without corresponding materials in the specific experiment, such as sodium chloride, soybean protein and starch, were taken as controls.

Raw beef was cut into pieces and minced after removing connective tissue. Then the minced meat was cured with sodium chloride at 4□ for 24h. The cured meat was chopped and blended with additives and filled into nature casing. Then the sausages was cooled to 4□ after cooking at 90□ for 30min. Sausages produced by this procedure were taken as samples in this research.

Samples were prepared for texture analysis by removing the product casing and into cylinders of 3cm length. Texture analysis was performed using a TA.XT2i/25 texture analyser, supplied by Stable Micro System Company, England. The sample was penetrated twice with a 50 mm diameter probe and double apex profiles were generated automatically for each sample. Distance, time and force measured by the texture analyser were used to calculate the parameters of hardness, springiness and cohesiveness of the meat surimi products.

The color of samples was measured using a WSC-S color difference instrument, supplied by Shanghai Physical Optical Instrument Factoryi, China. Samples were prepared for color measurements by removing the casing and cutting to form a 1cm long cylinder. The sample was then placed into the sample case and the brightness (L*) and redness (a*) values determined.

Data were analyzed by one way analysis of variance. When significant differences among treatments were detected, treatment means were compared using the least significant difference method. The comparison error was 0.05.

Results and discussion

The effect of sodium chloride on gel properties of beef surimi was shown in table 1. The hardness, springiness and cohesiveness increased from 1890.06, 0.649, 0.359 to 2937.10, 0.722 and 0.471 respectively along with the amount of sodium chloride increasing. It had been well documented that the solubility of myofibril protein, cohesiveness and amount of actomyosin, which was formed by the connection of myosin and actin, would increase with the amount of sodium chloride increasing from 1.7 percent to 11.2 percent. As a result, gel strength increased as well. Although in theory, the more sodium chloride added, the more salt-soluble protein extracted, it was unacceptable for consumer to add so much sodium chloride in meat product. So the amount of sodium chloride in meat products is usually no more than 3.5 percent of meat weight, or the products will be too salty for consumption.

The effect of sodium chloride on the color of beef surimi was presented in table 2. Brightness of beef surimi decreased significantly (from 46.72 to 42.70) with the amount of sodium chloride increase, while the effect of sodium chloride on redness was not significant. So increasing the amount of sodium chloride added to beef surimi would decrease brightness of final products.

The stability of gel is mainly determined by the amount of functional proteins. So it is necessary to add some functional proteins for the purpose of strengthening the gel in meat surimi products. As the optimum pH for the formation of soybean protein gel is in the range of that of meat products, it is a suitable functional protein additive in the production of meat surimi. Soybean protein can form gel before myofibril shrinkage in the

cooking process of sausage and other meat surimi products. It can also form a compact film surrounding muscle tissue. As a result, there is less water as well as water-soluble vitamin and minerals loss during cooking process.The effect of soybean protein on beef gel properties was shown in table 3. Hardness of gel increased from 1955.02 to 2890.66, while springiness reduced from 0.829 to 0.779 with the amount of soybean protein isolate increasing. There was no significant change in cohesiveness (from 0.513 to 0.467). Soybean protein was able to disperse fat, form matrix, concrete and gelate while heating, thus increasing gel strength of product after cooking. But the more soybean protein added, the more solute in final products. High content of soybean protein may compete limited water with meat proteins and thus reduce springiness of the final products.

The effect of soybean protein on the color of beef surimi products was shown in table 4. Brightness of beef sausages decreased significantly(from 40.91 to 38.72) with increasing amount of soybean protein($P < 0.05$). But the influence of soybean protein on redness was not significant.

The effect of different kinds of starch on gel strength of beef surimi is shown in table 5. The gel strength of beef surimi made with various kinds of starch increased compared with that of control. The more starch added, the greater the gel strength is. The main reason is that starch particles absorbed water and swelled, thereby increased water-holding capacity and enhanced the strength of matrix during heating. Starch can bind proteins, fat and water together and make beef surimi more viscous. The capacity of starch increasing gel strength varies from kinds to kinds (Ma L. et al., 1996). The capacity of mung bean starch and modified starch is the largest because mung bean starch has a higher content of branch-chain starch and higher water binding capacity. So it could swell to a relatively large volume (Wu et al., 1987); the swelled starch particles would bring about greater stress on beef protein. The most obvious characteristic of modified starch is that hydroxymethyl group and hydroxyethyl group endow modified starch with excellent hydrophilic and lipophilic properties, thus improve the quality of surimi-based meat products. As the branched chain starch content of cornstarch was relatively lower than others, the gel formed by it was relatively weaker (Okada, 1985).

The effect of different starches on gel springiness of beef surimi was shown in table 6. The springiness decreased gradually compared with that of control when the amount of starch added to beef surimi increased gradually. The extent to which the springiness of beef surimi decreased varies from kinds to kinds as well. The springiness of beef surimi made with mung bean starch was the best, while that of beef surimi with cornstarch was the worst.

The effect of different starches on gel cohesiveness of beef surimi is shown in table 7. Adding starch decreased the gel cohesiveness of beef surimi in comparison with that of control. The gel cohesiveness decreased with gradually increasing amount of starch added to beef surimi. The effect of different starches on cohesiveness varied from kinds to kinds. Cohesiveness of beef surimi made with modified starch is the best, while that of beef surimi with cornstarch and potato starch was relatively worse.

The effect of different starches on the brightness (L^* value) and redness (a* value) of beef surimi products was shown in table 8 and 9.Adding starch decreased the L^* value and a* value of beef surimi in comparison with that of control. With the gradually increasing amount of starch added to beef surimi, the L^* value and a* value decreased gradually. The effect of different starches on L^* value made some differences, among them, the lightness of beef surimi made with mung bean starch and potato starch was better, and that of with cornstarch and modified starch was lower. On the other hand, the effect of different starches on the a* value made some differences, but the difference was insignificant ($P > 0.05$).

Conclusions

Adding sodium chloride and soybean protein had a great influence on the gel properties and color of beef surimi products. The hardness, springiness, cohesiveness of beef surimi gel increased, while brightness decreased with the amount of sodium chloride increasing. But there is no significant influence on redness ($P > 0.05$). The gel hardness increased gradually with increasing amount of soybean protein added to beef surimi, but cohesiveness and a* value changed little, and L^* value decreased significantly($P < 0.05$). Adding various starches increased gel strength of beef surimi products; on the other hand, gel springiness and

cohesiveness decreased. The effect of different kinds of starch on gel properties of final products varied greatly. The mung bean starch was the best as meat additive, while cornstarch is the worst for that use. Adding starch decreased the *L** value of beef surimi products, and the more starch added to beef surimi, the more *L** value decreased. The effect of starch on *L** value varied from kinds to kinds. The effect of beef surimi made with mung bean starch and potato starch was better, while that of cornstarch and modified starch was worse. No matter what kind of starch added, a* value of beef surimi products decreased.

RESIDUAL LEVELS OF THREE PRESERVATIVES AND ECONOMICAL VIABILITY OF SURFACE TREATMENTS APPLIED IN PORTUGUESE SMOKED DRY SAUSAGES

Teresa J.S. Matos[a], António Barreto[a] and Fernando Bernardo[a]

[a] Faculdade de Medicina Veterinária. CIISA. UTL. R. Prof. Cid dos Santos - Polo Universitário, Alto da Ajuda, 1300-477 Lisboa, Portugal.

Background

In Portugal, as in the E.U., benzoates, sorbates and the esters of *p*-hydroxy-benzoic acid (parabens) may only be used in surface treatments of dry sausages casings. Legislated values are *Quantum satis* (without specified maximum level, these addictives should be added in agreement to the good manufacture practices, using the necessary amount to reach the proposed objectives) however, there is no reference about residual values in the final product (Decreto-Lei nº274, 2000; Decreto-Lei nº363, 1998). Residual levels vary with the method of application, time length of exposure, salt concentration, type of food, porosity of the food, shape and size of the food, and handling after exposure to the additive (Sofos, 1989). In this way, before a given application, tests should be conducted to determine appropriate solutions, exposure times, and handling of the necessary residual preservative levels in the product. In spray, dipping, or immersion uses, it is important to know the uptake, migration, diffusion, and residual levels of the preservative into the product. This will be useful in determining levels needed, time of exposure, expected inhibitory activity, and potential undesirable effects on product quality.

Objectives

In this contest, the main goals of this study were to investigate, in Portuguese smoked dry sausages, the residual amounts of potassium sorbate (PS), sodium benzoate (SB) and methyl *p*-hydroxybenzoate (MHB) applied as surface treatment and also, the viability of such treatments regarding the production costs.

Materials and methods

Samples studied for this project were "chouriços" type Alentejano (A) and Ribatejano (R) produced by a large factory in Portugal as outlined by Matos et al. (2003). In control chouriço type R samples, surface treatment applied in casings was only cleansing with water to remove the salt and then immersion in cold water until fill up. In chouriço type A control samples, first casings were dipped in a solution of 30 kg of water and 1.5 l of commercial vinegar for 10 minutes, secondly cleansing with water and finally immersion in tap water until filling. These were normal plant practices for natural casings. For both sausage types, in test samples, casings were surface treated with three different salts in seven different combinations (Table 1), after water washing. Casings were immersed for 15 minutes in these solutions until filling. The experiments were divided in four trials. Each trial was conducted in batters of 560 kg. In the first trial the surface treatments were performed with potassium sorbate (PS), sodium benzoate (SB), methyl *p*-hydroxybenzoate (MHB) and control (AC1) (Table 1) in chouriço type A. The second trial was also conducted in chouriço type A and the surface treatments with potassium sorbate and sodium benzoate (PS+SB), potassium sorbate and methyl *p*-hydroxybenzoate (PS+MHB), sodium benzoate and methyl *p*-hydroxybenzoate (SB+MHB), potassium sorbate, sodium benzoate and methyl *p*-hydroxybenzoate (PS+SB+MHB) and, control (AC2), were applied (Table 1). In the third trial were applied the treatments PS, SB, MHB and control (RC1) (Table 1) in chouriço type R and, in the fourth trial, the treatments PS+SB, PS+MHB, SB+MHB, PS+SB+MHB and control (RC2) also in Ribatejano sausage type (Table 1). From all experiments 3 samples of sausages were taken from each surface treatment and control. Sausage samples were not peeled to accomplish the chemical measurements. The determination of PS, SB and MHB residual values were performed by High Performance Liquid Chromatography (HPLC) using a NOVA PACK, part nº36975 (Waters). Solution A, with 2.5 kg KH_2PO_4 + 0.1% acetic acid solution, pH at 4.4 (reached with 20% KOH solution), was prepared for eluent composition. Eluent for HPLC was constituted by 85% solution A and 15% ethanol. Detector of UV λ at 217 nm, oven temperature was 35ºC at 1.0 ml/minute stream. Production costs concerned with the application of surface treatments in the natural casings in both types of sausages were determined according to the variable cost system and production costs were calculated as basic standard costs type (Rocha & Rúbio, 1999; Santos,

1998; Pereira & Franco, 1994). Calculations were based on real data achieved in a meat industry, under commercial conditions.

Results and discussion

Residual levels of PS, SB and MHB of sausages type Ribatejano and Alentejano are summarised in Table 2. Surface treatments production costs are presented in Tables 3 and 4 for chouriço type A and R, respectively. In Table 5 the totality of production costs for both types of sausages is shown. Values of methyl *p*-hydroxybenzoate in the accomplished analyses, were not detected (Table 2). The *p*-hydroxybenzoic esters may be linked to some extent to proteins, emulsifiers and other substrate constituents on account of their phenolic OH group (Lueck, 1980) and/or the non absorption of MHB by the casing during immersion time could be responsible for this MHB residual values absence. Residual levels of PS and of SB found in the product after immersion of sausage dry smoked natural casings for 15 min in 2.5% (w/v) solutions of these three preservatives in seven different combinations varied from 0.009 to 0.056% (w/w) in treatments with PS, SB, PS+MHB and SB+MHB and, from 0.021 to 0.030% (w/w) (addition of residual mean values obtained for both salts, PS and SB) in treatments with combination of salts PS+SB and PS+SB+MHB (Table 2).

For the same preservative, differences found between types of products may be related to the porosity of the natural casings used for each type of product (pork intestine salted for chouriço type R and beef dry casing for chouriço type A). In this way, it is very difficult to estimate expected values in the final product once the amount of addictive that will remain in the casing after dipping in salts solutions and which amount will migrate from the surface to the interior of the product are ignored.

Concerning eventually toxicological effects, Hossaini *et al.* (2000) in mouse uterotrophic assay found no oestrogenic response of methyl *p*-hydroxybenzoate and of propyl *p*-hydroxybenzoate at doses of 100 mg/kg body weight per day and for the ethyl congener even at 1000 mg/kg body weight per day. The authors concluded that parabens are not potent oestrogens *in vivo.* Binstok *et al.* (1998), in a meat system containing 200 mg of sorbates and 150 mg of nitrites, heated at 60^{o}C for 5 hours, found that a mutagenic compound, ethyl-nitrolic acid (ENA) can be formed. More research is required to determine the minimum ENA amount for genotoxic activity and for establishing its health implications. Sodium benzoate toxicity in rats F344 and mice B6C3F1 was investigated by Fujitani (1993) reporting that levels of 2.4% in male rats and 3% in male mice of SB administrated in the diet for 10 days were toxic. The cost of surface treatments applied in the casings can increase from 0.0006 € up to 0.0024 €, per kilogram of final product, in sausage type Alentejano and, from 0.0001 € up to 0.003 € in sausage type Ribatejano, depending on the salt combination used for surface treatment (Tables 3 and 4).

Conclusions

Regarding potential undesirable effects on product quality it would seem indispensable to accomplish more experiments to establish maximum legislated values for these preservatives applied as surface treatments to dry smoked sausage casings. Also, determination of the accurate amounts to be added, time of exposure, diffusion and migration must be performed in order to obtain the expected residual levels into the product. Surface treatments represent less than 0.5% of the production costs in both types of sausages. Nevertheless, treatment selection should be supported through a technical and economical decision well based once, meat industries, due to the specific technologies used and the smaller commercialization margins, must assure their competitiveness in a very demanding market.

STUDY ON SALT-INDUCED CHEMICAL CHANGES IN PORK MUSCLE BY FT-IR IMAGING

Böcker, U.[1], Ofstad, R.[1], Egelandsdal, B.[2] and Kohler, A.[1]

[1]Matforsk AS, Norwegian Food Research Institute Osloveien 1, N-1430 Ås, Norway
[2]Department of Chem., Biotechn. & Food Science, Agricultural University of Norway, P.O. 5036, N-1432 Ås, Norway

Background

Processing methods like heating, freezing or salting are commonly used in muscle food preparation and all may lead to changes in texture. Texture is a complex property considered to be affected by muscle microstructure and composition, i.e. myofibrillar proteins, intramuscular connective tissue and fat distribution.

Therefore, there is a demand for techniques that enable us to gain more detailed knowledge about microstructural changes in these proteins.

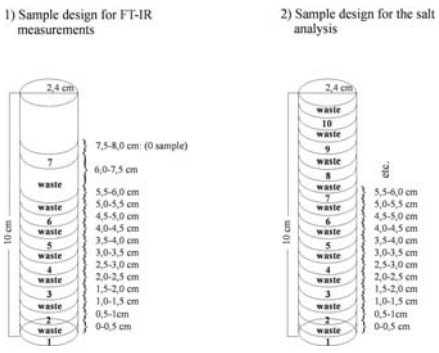
FT-IR-microspectroscopy and FT-IR imaging have been found to be a useful analytical tool so far mainly in biomedical science. Since it is a combination of spectroscopy and microscopy it allows to investigate those properties simultaneously and can provide information on chemical composition and morphology of complex tissues at the same time.
Most recently, a FT-IR imaging system was used to monitor denaturation induced by heating in beef muscle tissue (Kirschner et al. 2004).

Objective

The intention of this study was to investigate if FT-IR imaging can be used as a tool to monitor chemical changes such as denaturation processes in pork muscle tissue which occur during salting.

Materials and methods

Sample preparation



In this study samples from pork muscle (*m. semimembranosus)* with three different salt concentrations were investigated. The raw meat samples were placed in tubes (2.4 cm in diameter and 10 cm in height) that were kept in saturated brine (26% NaCl) so that the brine would diffuse into the samples resulting in salt gradient throughout the sample. After two weeks small blocks from regions of different salt concentrations were excised from the sample tube, frozen in liquid Nitrogen and stored at -80°C until use. For the FT-IR-imaging cryo-sections of 8 µm thickness (two sections each for low, medium and high salt concentration, i.e. from layer 1, layer 4 and layer 7 respectively) were prepared with a Leica cryostat CM3050 S (Leica microsystems, Nussloch, Germany) and mounted on infrared transparent CaF_2 slides.

Salt concentrations in the parallel sample (in the corresponding layers as shown above) determined by chemical Cl^--analysis were 1.6% for the low salt, 7.7% for the medium salt, and 15.4% for the high salt layer. In the following the samples will only be referred to as high, medium and low salt sample.

IR data collection and evaluation

An IR-microscope (IRscope II, BRUKER OPTICS, Germany) equipped with a 64 x 64 focal plane array detector (FPA) was used to collect 4096 spectra (a sample area of 270 µm x 270 µm which can be analysed simultaneously at a spatial resolution of 4 µm per pixel) on a pork muscle tissue sample. The analysis of the acquired IR images was done with in-house developed software in C++. The Microsoft C++ Developer

Studio was used to create Dynamic Link Libraries, that were linked to Dynamic Imager, an image analysis developer platform (Kirschner et al.2004). First, the image spectra where scatter-corrected using extended multiplicative signal correction (EMSC). EMSC is a pre-processing method that allows the separation of physical light-scattering effects (e.g. sample thickness) from chemical absorbance effects in spectra (Martens et al. 2003). Then, the raw spectra were submitted to a quality test, which among other things checks spectra for water vapour and signal to noise ratio. Spectra that did not pass the quality test were not used for further data analysis.

Results and discussion

The most prominent protein band in a FT-IR spectrum of muscle fibres is the Amide I band that appears in the frequency region of 1700-1600 cm^{-1}. It is mainly related to the carbonyl stretching vibration with minor contribution of C-N stretching and N-H bending vibrations. The Amide I vibration mainly depends on the secondary structure of the protein backbone and therefore is often used for secondary-structure analysis of proteins (Barth and Zscherp 2002).

Figure 1 displays five spectra across a randomly chosen fibre (spectrum 1 located at the periphery, with increasing numbers moving towards the centre of the fibre and 5 representing a spectrum located in the centre), which were extracted from the FT-IR image obtained from a cryo-section with high salt content. Spectra from an area around the edge of the fibre cell (Spectrum 1 and 2) exhibit a decrease in absorbance at 1654 cm^{-1} compared to those taken from inner parts of the fibre.
In order to gain a better resolution of the Amide I components derivation was applied, which is illustrated in Figure 2. The second derivatives of the five spectra shown in Figure 1 reveal the mentioned effect at 1654 cm^{-1} more clearly. The frequency region of 1648-1658 cm^{-1} is considered to correlate to α-helical protein structures (Barth and Zscherp 2002). The observed decrease at 1654 cm^{-1} might therefore indicate either an increase in denaturation with a shift from α-helix to β-sheet structure as observed by Kirschner et al. (2004) in heat-treated beef myofibre samples in the range of 45°C to 70°C, or it might be due to a salt-induced spatial diffusion of α-helix or β-sheet compounds within the fibre.

Figure 3 shows chemical images for three different salt concentrations. The chemical images were reconstructed from the spectra obtained from FDA-detection by employing the I_{1630}/I_{1654} band ratio, which gives a measure of the level of change: blue corresponds to a low while red corresponds to a high band ratio. Black domains in these images refer to spectra that did not pass the quality test, i.e. they mostly correspond to extracellular areas which can be seen when compared to photomicrographs. Figure 3c exhibits a fairly low band ratio indicated by predominantly dark blue colouration in the chemical image. Figure 3b reveals a lighter blue colour, which is caused by an increase in protein I_{1630}/I_{1654} band ratio. This effect is further increased in Figure 3a. Here, the higher degree of denaturation at the outer parts of the fibres is even more distinct than in Figure 3b. This supports the results presented in Figures 1 and 2, i.e. that the outer regions of the muscle fibre cells reveal a higher degree of either denaturation or an increase in β-sheet or decrease in α-helix structure respectively compared to the fibre centre. As seen from the photomicrograph at high salt content the fibre cell appear shrunken to high degree and thus the increase of extracellular space (Knight and Parsons 1988) is the reason for the significant increase in black pixel in the corresponding chemical image.

The possible reasons for the increase in the I_{1630}/I_{1654} band ratio at the fibre periphery may be as already mentioned a change in secondary structure for individual protein types or a possible diffusion effect that causes migration of protein structures. The latter may lead either to an increase in β-sheet-components or a decrease in α-helix which causes the higher I_{1630}/I_{1654} ratio in the outer parts of the fibre cells.

Conclusions

- The FT-IR imaging technique employing FPA-detectors might provide a useful tool for the detection of chemical changes like protein denaturation or diffusion effects. These changes can be followed in a spatially resolved manner.
- It was suggested that high salt contents may induce a higher degree of denaturation on the periphery compared to the centre of a muscle fibre cell.
- This method could possibly be used also to gain a better understanding in the mechanisms in salt diffusion in muscle tissue

LOW VOLTAGE ELECTRICAL STIMULATION, HOT BONING AND HIGH TEMPERATURE CONDITIONING OF *LONGISSIMUS LUMBORUM* MUSCLE FROM *BOS INDICUS*: DRIP AND COOKING LOSS, WATER HOLDING CAPACITY AND COLOUR

Cardoso, Susana[1]; Beraquet, Nelson J.[2], Pinto Neto, Manuel[2]

[1]Universidade Federal do Rio Grande do Sul – Porto Alegre/RS/Brazil - E-mail:sucard@orion.ufrgs.br
[2]Centro de Tecnologia de Carnes do ITAL - Campinas/SP/Brazil – E-mail:beraquet@ital.org.br

Background

The interest in the technologies to accelerate conversion of muscle into meat remains. It is well established that electrical stimulation increases the rate of post-mortem glycolysis, allowing the use of hot boning and preventing that the meat becomes though (Hwang et al., 2003). Several studies demonstrated the flexibility of boning unchilled carcasses (hot boning) improving processing efficiency, functional properties, flavour, colour, juiciness, drip, and cooking loss (Henrickson, 1975; Kastner et al., 1973; Jeremiah et al., 1997). In a previous work, Cardoso et al. (2002) studied the influence of hot boning, high temperature conditioning, low voltage electrical stimulation, and aging on the rate of glycolysis, tenderness, and shear values of *longissimus dorsi* (*lumborum*). In this work were measured the effects of the same variables on water holding capacity, drip and cooking losses, and colour of *longissimus lumborum*.

Objectives

The purpose of the study was to demonstrate that hot boned *l. lumborum* from electrically stimulated *Bos indicus* carcasses can have drip and cooking loss, water holding capacity and colour, similar to those from conventionally boned meat.

Materials and methods

Forty Nelore (*Bos indicus*) pasture-fed steers with 30-36 months of age and average slaughter weights of approximately 450 kg were slaughtered at four different occasions over a three month period. Animals were stunned and bled. The beginning of bleeding was time zero for all treatments. Low voltage electrical stimulation (LVES) with a JARVIS BV 80 stimulator [20 V (rms); 60 Hz; 0.25 amps; for 90s alternating 5s on, 1s off] was applied immediately after exsanguination. Cattle were slaughtered at the Meat Technology Center of Institute of Food Technology in Campinas. Carcasses had an average weight of 250 kg. The animals were randomly assigned to five treatments (**Figure 1**) and two replications for each slaughtering session.

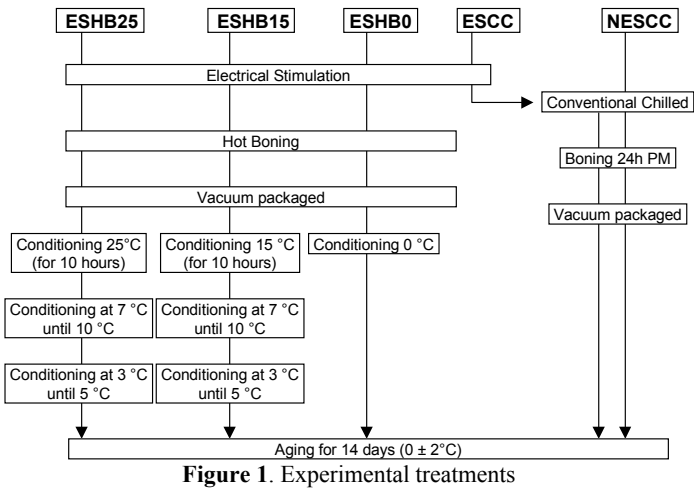

Figure 1. Experimental treatments

The *longissimus lumborum* (LL) was the muscle studied. The hot boned (HB) muscles were excised from the electrically stimulated carcasses after approximately 45 min post mortem (p.m) or conventionally chilled

(CC) and boned 24 h p.m. The LL muscle were cut in three pieces of the same size (10,16cm) and all pieces were vacuum packaged in CRYOVAC® shrinkable bags and placed into 536X235X162 mm cardboard boxes. Water holding capacity and drip loss: Muscles samples for water holding capacity (WHC) measurements, were 24 h p.m., at the 7th and 14th days p.m. For WHC determination, triplicate samples of 500 mg of muscle were placed on a filter paper (Whatmann n.2) and pressed between two plexiglass plates for 5 minutes at 500kg/cm2 on the ram of a laboratory press, following the procedure of Hoffmann et al. (1982). Results were expressed as the ratio between the areas of the liquid infiltrated (External Area=eA) and meat spot (Internal Area=iA) measured with a planimeter. The drip loss of the vacuum packaged cuts was determined by weighing the muscles before packaging and after unpacking on the 2nd, 7th and 14th days p.m. Results were expressed as percentages (%) of losses. Cooking and cooking loss: Three 2.54cm LL slices per treatment were cooked at 2nd, 7th and 14th days p.m.. The LL steaks were cooked according to AMSA (1995) guidelines, in an electrical grill SIRMAN PDL model with both plates heated, till their internal temperature reached 74°C. Temperatures were monitored using a digital thermometer NOVUS 51 with thermocouples (K type) inserted into the center of each steak. Cooking loss measurements were obtained by recording sample weights before and after cooking. Results were expressed as percentages (%) of losses. Color Analysis: Color readings were taken in the L* a* b* color space on the cross section of the LL muscle using a Minolta Spectrophotometer CM 508-d with D_{65} illuminant and 10° observer angle. Color was measured after deboning and on the 7th and 14th days p.m. with five replications. At 7 and 14 days p.m. the readings were made 30 min after unpacking and air exposure of the steaks. The mean of five replications was used as final result for reading and expressed in *L (lightness), a*(redness) and b* (yellowness) values. Statistical analysis: The results were statistically analyzed using the Statistical Analysis System program version 8.0. Analysis of variance was used to test for significance of slaughter period, treatment, ageing time and interaction treatment/ageing time effects. The mean values were compared pairwise with Duncan's Multiple Range. The significance level of 5% was used in all analysis.

Results and discussion

The drip loss, cooking loss and water holding capacity values are shown on Table 1. The drip losses of the LL were not significantly different ($p>0.05$) in relation to the treatments up to 7 days post mortem. In the 14th day of ageing the muscles of treatments ESHB15 and ESHB0 had significantly ($p<0.05$) lower values of drip losses: 1.08 and 1.22% respectively than those of the NESCC treatment (1.9%) but not significantly different ($p>0.05$) from the muscles of ESHB25 (1.35%) and ESCC (1.53%). However ageing had a significant ($p<0.05$) influence on drip losses with the higher values being reached with the higher values been reached after 7 days for all treatments except the ESHB25 one which had its highest values after 14 days of storage.

Table 1. Water holding capacity, drip and cooking losses of M. *longissimus lumborum* submitted postmortem to different treatments.

*SEM=Standard Error of Mean, n=8 replications for treatments; Same superscript letters in the same row or column among means (^{a,b,c}:rows=treatments; ^{x,y,z}:columns=ageing) indicate no significant difference by Duncan test ($p < 0.05$)

These results indicated that the drip loss is not affected greatly by the exposition of the meat immediately post-mortem to high temperatures (15-25ºC), and nor by the electrical stimulation, contrary to the results of Smith (1985), and agreeing with the results of West (1982) who found that drip loses of non-stimulated vacuum-packed *l. dorsi* stored at 0 ± 2ºC was 2.7% against 3.0 and 3.1% for low and high voltage

electrically stimulated muscles. George et al., (1980) reported drip losses for vacuum packed LL stored at 1ºC for two days p.m. of 2.2% for stimulated muscle, and 2.5% for non-stimulated muscle. These reported values were much larger than those observed in the present study. Butchers et al. (1998) reported drip losses for LL in the range of 0.65 - 1.30% when kept 1ºC for 48 h, showing statistical evidence that the electrical stimulation increased the drip losses, contrary to the results of the present work.

After 2 days of aging significant differences ($p<0.05$) in total cooking losses due to different treatments were found. The muscles from the ESCC presented significantly higher losses (29.40%) than the ones from the ESHB15 (25.03%) treatment but both treatments showed no differences in relation to the other treatments. After 7 and 14 days of storage no significant differences ($p>0.05$) among treatments were found regarding cooking losses, that ranged from 27.50 to 28.79%. These results indicate that the treatments studied have no great effect on cooking loss.

Water holding capacity (WHC) in this work is the ability of meat to retain its own water. Twenty four hours post mortem the LL of the ESHB25 and ESHB15 treatments had the lower means for WHC values (0.47) that were only significantly different ($p<0.05$) from the value determined for the meat of the NESCC treatment (0.52). After 14 days of storage at 0 ± 2ºC the lower means for WHC were of treatments ESHB15, ESCC and NESCC, respectively 0.40, 0.43, 0.44. the storage time reduced significantly ($p<0.05$) the WHC means for the treatments ESHB15, ESCC and NESCC but had no influence on the WHC values for ESHB25 (0.47) and ESHB0 (0.48) treatments.

Meat colour is the primary criterion by which consumers evaluate meat quality and acceptability. Consumers prefer bright-red fresh meat. In Table 2 is presented the means of the L*, a* and b* color parameters of LL measured after boning, at 7 and 14 days post mortem. Immediately after hot boning treatments (ESHB25, ESHB15 and ESHB0) had significantly lower L* values than those measured on ESCC and NESCC muscles. The ESCC L* values were also significantly higher than those of the NESCC muscles. After 7 days of ageing the means of L* values of ESCC muscles had significantly higher (34.77) than the values of the muscles of the other treatments with the exception of the ESHB25 (32.30). The L* values of ESCC treatment also showed the greatest variability as indicated by a standard error of mean (SE) that was more than double the values observed for the other treatments. The means L* value of muscles of ESHB0 treatment were the lowest (28.72) but was not significantly different from the others treatments. After 14 days of ageing the muscles of ESCC treatment presented the highest means L* value (34.38) and the ESHB0 the lowest value (30.85) both not significantly different ($p>0.05$) from the other treatments. Ageing time caused a significant increase in L* values for all treatments except for the ESCC muscles that showed no significant increase during the ageing period. For the LL of the ESHB25 and ESHB0 treatments there were significant increases in L* values from values observed immediately after boning and those measured after 7 days of ageing, but not significant increases from 7 to 14 days of ageing. For the ESHB15 muscles the L* values increased from boning to the 14th day of ageing. The NESCC muscles showed L* values increase from the 7th to the 14th day of ageing.

After boning	$-4.40^{b;y}$	± 0.37	$-3.92^{b;y}$	± 0.56	$-4.96^{b;y}$	± 0.47	$1.38^{a;y}$	± 0.94	$0.06^{a;y}$	± 0.38
7 days p.m.	$6.02^{a;x}$	± 0.86	$5.03^{ab;x}$	± 0.67	$3.37^{b;x}$	± 0.71	$6.93^{a;x}$	± 1.32	$5.92^{a;x}$	± 0.92
14 days p.m.	$6.61^{ab;x}$	± 0.34	$5.97^{abc;x}$	± 0.89	$3.85^{c;x}$	± 0.57	$6.94^{a;x}$	± 1.01	$4.29^{bc;x}$	± 1.01

*SEM=Standard Error of Mean, n=8 replications for treatments; Same superscript letters in the same row or column among means (^{a,b,c}:rows=treatments; ^{x,y,z}:columns=ageing) indicate no significant difference by Duncan test ($p < 0.05$)

In relation to a* values only immediately after boning significant differences were found among the treatments. The LL of ESCC treatment had a significantly higher a* value (11.99) than hot boned treatments except the ones from the ESHB0 (10.69).

In relation to the b* values, immediately after boning they were negative for the hot boning treatments, in the blue region and significantly different than the positive values situated in the yellow region observed for the ESCC and NESCC treatments. When using hot boning, the oxygen consumption rate by mitochondria is very rapid and reduced myoglobin (purple colour) is more intense (Renerre a& Bonhomme, 1991). After 7 days of ageing, the lowest value of b* was observed for muscles from the ESHB0 (3.37) treatment which was not significantly different from the ESHB15 (5.03) treatment. After 14 days of ageing the lowest mean value was still observed for the ESHB0 treatment, significantly lower than the value observed for the muscles of the ESCC treatment.

Immediately after boning, the hot boned cuts presented a darker red-bluish color. Tang & Henrickson (1980) demonstrated that electrically stimulated carcasses presented greater oximioglobina percentage, the reason for having a lighter color. Page et al., (2001) established that parameters L *, a* and the b* are inversely correlated to pH. This explains the darker color of the muscles not electrically stimulated (pH_{24}=5.91) in relation to the stimulated ones (pH_{24}=5.48) (Cardoso et al, 2002). In accordance with Page et al., (2001) a muscle with pH_{24}=5,91 would be inside the category of "dark cutting meat", as these authors established as limit for maximum normal meat pH of 5.87. The observed values of L* in this study were compatible to those measured in *longissimus dorsi* with minimum degree of maturity of the skeleton, in accordance with the classification of the USDA given by Wulf & Wise (1999) that would be of 33.70. The same applies in relation to the values of a* and b* given by the authors of 16.6 and 5.3 respectively. The values of a* in this work were in the range of 14.97-16.44 while those of b* were between 3.85-6.61.

Conclusions

1. Up to the 7th day of storage at 0 ± 2ºC the treatments studied showed no significant effect on drip losses. After 14 days of storage, non-stimulated conventionally chilled LL presented highest drip loss not significantly different ($p>0.05$) from the stimulated control.
2. The treatments did not affect cooking losses after 7 and 14 days of storage.
3. The range of WHC values observed for the different treatments at different storage times was small between 0.40-0.52 in spite of statistical differences being observed between treatments.
4. L*, a* and b* values showed that, immediately after boning, cold-boned cuts were significantly lighter and between cold boned cuts the electrically stimulated ones were lighter. Up to 7 days of storage, storage time also turned the hot boned cuts lighter.

FACTORS AFFECTING ACCEPTABILITY OF DRY-CURED HAM THROUGHOUT EXTENDED RIPENING UNDER "BODEGA" CONDITIONS

Cilla, I., Martínez, L.A., Beltrán, J.A. & Roncalés, P.

Dept. of Animal Production and Food Science. Laboratory of Food Technology. Faculty of Veterinary Science. University of Zaragoza. C/ Miguel Servet, 177, 50013. Zaragoza, Spain. E-mail: roncales@posta.unizar.es Tel.: +34-976-761582 Fax: +34-976-761612.

Background

A great number of studies have been devoted to elucidate the relationship between several chemical parameters and different sensory traits in Iberian and other types of dry-cured hams. All these studies indicate these changes contribute an improvement in the quality of the cured ham. However, when these changes are very intense a decrease of the quality is observed, since they are responsible for the appearance of defective textures (soft and pasty to the touch, and exhibits extraneous aroma and flavour). Several studies have suggested that uncontrolled proteolytic activity results in considerably impaired protein mechanical properties.
Little research has been dedicated to determine the relationship among the instrumental measurements of texture and colour, biochemical processes, sensory parameters and acceptability in quality dry-cured hams of white breeds.

Objectives

The aim of this work was to study the evolution of chemical, color, and texture parameters to investigate their influence on different sensory characteristics, and to establish which of these sensory traits show a greater effect on the overall quality of dry-cured ham from white breeds. These would be useful for ham producers, since they would allow controlling those features directly related to the acceptability of the ham.

Materials and methods

Samples were 28 dry-cured hams (9-10 kg) which were obtained from pig breeds accepted by Denomination of Origin Teruel. All hams, used in this work, had been cured for 1 year and were purchased from various retail markets. The samples were stored at 18ºC and 75% relative humidity conditions from 12 months to 26 months. The central part of the ham was used for the analysis. The *pH* of dry-cured ham samples was measured using a micro pH meter model 2001 (Crison Instruments, Barcelona, Spain). *Lipid oxidation* was measured by the 2-thiobarbituric acid (TBA) method of Pfalzgraf (1995). TBARS values were expressed as mg malonaldehyde/kg sample. *The extraction of lipids* was made by the method of Folch et al. (1957). *Acidity* was made by the determination of percentage of oleic acid which was carried out by the method recommended by International Union of Pure and Applied Chemistry. Standard Methods for the Analysis of Oils, Fats and Soaps (1964). *Non protein nitrogen* was carried out by the method recommended by Norma ISO/R 937. The supernatant were analysed for nitrogen content following the AOAC (1984) Kjeldahl method. Nitrogen content in the supernatant, referred to 100 g meat, yielded total non protein nitrogen (NPN). *TVB content* was determined by steam-distillation according to the reference method (Decision 95/149/CE). Results were expressed as mg TVB-N per 100 g dry-cured ham. *Colour instrumental measurement*: a reflectance spectrophotometer (Minolta CM-2002; Osaka, Japan) was used to measure dry-cured ham colour at the surface of *Biceps femoris* and *Semimembranosus* muscles. The parameters registered were CIE L* (lightness), a* (redness), and b*(yellowness). *Texture analysis* was made in form of texture profile analysis (TPA) (Bourne, 1978; Henry et al., 1971) with a TA-XT2 Texture Analyser (Stable Micro Systems, Godalming, UK). From TPA curves, the following texture parameters were calculated: hardness, springiness, cohesiveness, adhesiveness, chewiness and gumminess. *Sensory Analysis:* **Trained panel:** The ham samples were sliced approximately 1,5 mm thickness. Each sample was presented at room temperature for evaluation. Intensities of aroma, flavour, tastes and texture factors were based on a structured scale (1-9). **Consumers**: Thirty consumers were recruited from students, faculty and staff of Faculty of Veterinary Science. Each Panellist evaluated samples (1.5 mm thickness) at home simulating common serving conditions. The hams were evaluated at 12, 14, 16, 18, 20, 22 and 26 months of storage. The score was based

on an acceptability scale of 9 points, where 1= very disgusting and 9= very pleasant. *Statistical analysis:* the effect of maturation-ripening time was carried out by analysis of variance, using the ANOVA, and Principal component analysis PCA procedure (SPSS, 11.5).

Results and discussion

During extended ripening some changes in *acceptability* were evident (Figure 1). The *consumer panel* did not find significant differences ($p>0.05$) in hams from 12 to 26 months (total manufacturing time), despite the fact that a trend to lower values was apparent from the 18th month. Acceptance scores were above 6. The *trained taste panel* found significant differences ($p<0.05$) after 22 months. A sharp decrease was evident at this point; after which scores were below 5.

All *chemical maturation parameters* increased throughout storage time, except pH (Figure 2). The parameters which showed a major variation were the intramuscular and subcutaneous acidity, NPN and TBA. They indicated an increasing ripeness and oxidation. In the last stage (22-26 months) a larger significant change ($p<0.05$) was observed in NPN and TBA indices, whereas acidity (lipolytic index) changed more rapidly during the first months of storage. These results supported the hypothesis of a large aroma development within the first stage, whereas it became stable at the end of storage.

Figure 3 (a, b) shows the changes in the *instrumental parameters of texture*. There were evident changes in *Semimembranosus* muscle, in particular regarding hardness which reached significant higher values from the 18th month. Adhesiveness decreased, but increased significantly ($p<0.05$) at the end of storage. The same changes were observed in *Biceps femoris* muscle though they were not so remarkable.

Figure 4 shows the results of the *visual and olfactive sensory parameters.* Colour of *Biceps femoris* increased significantly ($p<0.05$). Aroma reached a maximum peak at the 18th month, then decreased probably it due to the evaporation of the volatile aromatic substances. With regard to *texture parameters* (Figure 5) crumbliness showed a significant decrease ($p<0.05$) from the 18 month of storage, whereas pastinesss and adhesiveness strongly increased ($p<0.05$) from the 18-20 months to the end of storage.

The evolution of *flavour* (Figures 6) was very similar to that of aroma; it showed no significant variation ($p>0.05$) after 20 months of storage. *Rancidity* decreased significantly ($p<0.05$) at the end of storage.

Figure 7 is a plot of the principal components analysis loadings for the first two partial least squares of components.The first component was able to predict 54.41 % of the variation of the whole study. Acceptability, crumbliness and cohesiveness reached a high negative loading on component 1, whereas chemical parameters of maturation had a positive loading on component 1. The second component explained only 18.33 % of the variation. Positive loadings had *Biceps femoris* cohesiveness and some of the colour parameters. The negative coefficients on component 2 turned out to be the pastiness, adhesiveness and the rest of the colour parameters.

Following PCA, 12-14-month-ripened hams were in the left quadrant with negative coefficients on the component 1. As storage time and ripeness increased they moved to the left quadrant with positive values in the component 2, and thereafter to the upper-right quadrant. The final trend was towards the lower-right quadrant, with positive a coefficient on the component 1 and a highly negative on the component 2. It must be emphasized that adhesiveness and pastiness were located in this same quadrant.

Conclusions

Results demonstrated that ham acceptability showed no significant differences ($p>0.05$) from 12 to 20 months (total manufacturing time), while it decreased significantly ($p<0.05$) at 22-26 months. Principal component analysis of all data brought about a comprehensive explanation of the biochemical, instrumental and sensory parameters involved in the acceptability decrease. In fact, high pastiness and adhesiveness values, as measured by both sensory and instrumental methods, appeared to be most correlated with decreasing acceptability. Those were the result of an excessive proteolysis, as revealed by biochemical maturation indices.

EFFECT OF WALNUT, MICROBIAL TRANSGLUTAMINASE AND STORAGE TIME ON THE WATER AND FAT BINDING CAPACITY OF SALT-FREE BEEF BATTERS

Cofrades, S., Serrano, A., Ayo, J., Carballo, J., Ruiz-Capillas, C. and Jiménez Colmenero, F.
Instituto del Frío (CSIC). C/ José Antonio Novais, 10. 28040 Madrid. Spain.

Background

Consumers are currently more health conscious and as a result demand healthier products. Sodium chloride intake has thus been associated with arterial hypertension and animal fat consumption with cardiovascular disease, one of the main causes of death in industrialised countries. Accordingly, current recommendations aim to reduce daily sodium and saturated fatty acid intake. One way of doing this is to reformulate meat products by reducing the salt content and incorporating fatty acids with proven health benefits.
Different studies have shown that the frequent consumption of walnuts reduces the risk of cardiovascular disease, since it lowers serum cholesterol and favourably modifies the lipoprotein profile (Sabaté, 1993). One way of promoting walnut intake would be to include it as an ingredient in frequently consumed foods, such as meat derivatives, which can thus be made to incorporate health benefits.
In meat products, salt (NaCl) extracts the myofibrillar proteins which are mainly responsible for the heat-induced development of a functional protein matrix by immobilising water (Acton *et al*., 1985). Salt reduction in most products will have an adverse effect on protein extraction, water and fat binding properties and gel strength, and will also alter palatability attributes (Girard *et al*., 1990). In an attempt to reduce the salt level, microbial transglutaminase (MTG) has been increasingly used as a cold meat binder in the absence of salt by combining it with suitable food protein (Kuraishi *et al*., 1997) and crosslinking meat proteins. However, there are hardly any studies on how the storage time in chilling (real commercial conditions) affects the characteristics of raw meat products prepared with MTG as a cold-set binder.

Objectives

The aim of this work, using response surface methodology, was to test how the addition of increasing amounts of walnut (W), microbial transglutaminase/sodium caseinate (MTG/C) and the storage time (ST) (up to 11 days) at 3 °C affect the water and fat binding properties of beef batters formulated in the absence of salt and phosphates.

Materials and methods

Post-rigor beef *semimenbranosus* (top round) was purchased from a local market, ground through a 6 mm plate and divided into 20 (400 g) batches, vacuum packed and stored at -20° C until use. Additives used for preparing meat batters included walnut, supplied by La Morella Nuts, S.A. (Tarragona, Spain), (particle size of 12μ) and microbial transglutaminase/caseinate (ACTIVA EB, Ajinomoto Europe Sales GmbH, Germany) in a formulation containing sodium caseinate 60%, maltodextrin 39.5% and transglutaminase 0.5%. Transglutaminase activity was approximately 34-65 units/g. In all the formulations the meat protein content was adjusted to a constant level (18%) with water, although the total protein content was dependent on the proportion of added walnut.

Beef meat, MTG/C (dissolved in added cold water) and walnut were homogenized in a cutter (Stephan Universal Machine UM5, Stephan U. Stephan U. Söhne GmH & Co., Hameln, Germany) under chilled vacuum conditions. Preparation of the meat batters took 3 min., during which time the final chopping temperature did not exceed 12 °C. Immediately after the homogenate preparation, the batters were stuffed into plastic tubes (diam 3.4 cm) and hermetically sealed. The homogenate samples were then stored in a cold room at 3 °C at various storage times (ST) shown in Table 1.
After the storage time required in a cold room, the meat batters in the plastic tubes were heated (30 min. 70 ° C) in a waterbath. After heating, the containers were opened and left to stand upside down (for 40 min.) to release the exudate. Total loss (TL) was expressed as a % of initial sample weight. Water loss (WL) was

determined as a % weight loss after heating the total loss (TL) for 16 h on a stove at 100 °C. Fat loss (FL) was calculated as the difference between TL and WL. Determinations were carried out in quintuplicate.
Response surface methodology (RSM) was used to study the simultaneous effect of the three experimental variables. Experimental design and statistical analysis were performed using Statgraphics plus 2.1 (STSC Inc., Rockville, MD). Five levels of each variable were chosen following the principles of the central composite design principle (Khuri and Cornell, 1996). The levels of the variables are shown in Table 1.

Results and discussion

Water and fat binding properties
Analysis of variance indicated that among the regression models for the water and fat binding properties of the salt-free beef batters with varying levels of walnut and MTG/C at different storage times, only the model for total loss (TL) was significant (Table 2), while the models for water loss (WL) and fat loss (FL) were not significant. Furthermore, the absence of any interaction effects on total loss indicates that the effect exerted by each variable was not affected by the others. The effect of the variables studied is shown in Fig. 1.
The level of the added walnut has a negative linear effect, the greater the amount of walnut in the meat batters the lower the total loss (TL) values (Fig. 1A, C). This behaviour could be due to the lower water content present in the samples with greater walnut content, since the incorporation of the walnut is at the expense of water, with the concentration of the meat protein remaining constant. Therefore, for the same concentration of meat protein, the samples with greater water content will lose more than the samples with a lower water content and a greater amount of walnut, since the water content of the walnut is very low.
The incorporation of increasing amounts of MTG/C does not seem to affect the amount of TL during heating (Fig. 1A, B). The apparently high results of total loss in this experiment in salt-free beef batters without walnut are agreed with the low ionic strength in the formulation, which reduced myofibrillar protein extraction and therefore increased cooking losses. These results are the same as those obtained by other authors in restructured meat prepared with MTG and without salt (Kerry, 1999). Although some authors suggest that non-meat proteins like caseinate with MTG are necessary to ensure proper binding properties, in the conditions assayed in this study, meat batters were obtained with poor water and fat binding properties. There are apparently contradictory results about the effect of MTG on water and fat binding properties and these differences could be due to the level and different type of MTG added and the conditions in which they are used (time and reaction temperature; presence of other ingredients such a salt, phosphates, and non-meat proteins, species of origin, etc.) (Pietrasik and Li-Chan, 2002). The storage time in chilling did not have any significant effect ($P > 0.05$) on total loss.

Conclusions

The results obtained in this study suggest that the gel/emulsion systems induced during the heating process prepared with MTG/C in the absence of salt and phosphates form structures with poor binding properties. The detrimental effects caused by the absence of salt in beef batters were not overcome by the addition of MTG/C used in this study. However, the presence of walnut in salt-free beef batters made with MTG/C reduces cooking losses, thereby improving water and fat binding properties.

Background

Sous vide processing is the application of a cooking-pasteurization thermal process to food packaged in a hermetically sealed vacuum pouch or tray (Church & Parsons, 1993). Advantages associated with *sous vide* processing include: a superior flavour profile compared to conventionally prepared food, increased tenderness and moisture, improved colour retention and reduced nutritional loss. Furthermore, processing and storage in evacuated pouch increase product shelf life by inhibiting microbiological and chemical spoilage (Vaudagna *et al*., 2002). The *sous vide* cooked beef muscle is an interesting alternative to diversify the marketing of meat, however, this type of products present technological difficulties such as the retention -inside the packaging- of the juice lost during processing (Church & Parsons, 2000). This problem is relevant, particularly regarding commercial profit and preservation of the sensorial and nutritional characteristics of the product. In order to increase water holding capacity (WHC) of meats and consequently reduce cooking weight loss, it has been suggested the use of mild thermal treatments (Vaudagna *et al.*, 2002), the addition of salts, such as sodium chloride (SC) and/or alkaline phosphates (Sofos, 1989), and more recently, the use of natural functional ingredients, i.e. whey protein isolate (WPI) and concentrate (WPC), soy protein isolate, polysaccharide gums, starches, blood plasma, etc. (Chen & Trout, 1991). The higher viscosity of the brines containing those natural ingredients resulted in a non homogenous brine distribution with detrimental consequences for WHC, cooking weight loss and sensory quality. This is particularly relevant in high quality products processed with low injection rates (10 % - 20%) where concentrated brines are used. Consequently, to improve brine distribution, the injection and tumbling procedures become critical. Mechanical treatment of meat tissue by tumbling (massaging) is well recognized and accepted techniques in the meat industry (Xargayo & Lagares, 1992). However, little information is available regarding the effect of extended tumbling procedures on binding and sensory quality of cooked beef pieces (Pietrasik & Shand, 2004), particularly when natural functional ingredients are added to them. The combination of pre- and post- injection tumbling procedures may provide a useful means to improve brine distribution, water binding properties and sensory quality.

Objectives

To evaluate the combined effect of two tumbling procedures (pre- and post- injection step) on technological parameters, physical properties and sensory quality of WPC + SC added beef muscles cooked using the *sous vide* system.

Materials and methods

A 3 x 3 factorial design with three replicates was applied in this experiment. The major variables investigated were tumbling treatments prior to injection step (pre-injection tumbling, PreIT) and after injection step (post-injection tumbling, PostIT), see Table 1. For the experimental design, fifty four *Semitendinosus* muscles were dissected from British breed steer carcasses 48 h post slaughter, trimmed free of fat, vacuum packaged (Cryovac BB4L, Sealed Air Co., Buenos Aires, Argentina), stored for 72 h at 1.5 ± 0.5°C and then processed. The trimmed raw muscles had an average weight of 1579.8 ± 166.1 g, and an average pH of 5.62 ± 0.08. Then, two procedures were carried out, by one hand, the muscles selected for PreIT were weighed, vacuum packaged in proper bags (Cryovac CN510, Sealed Air Co., Buenos Aires,

Argentina) and continually tumbled (2.5 rpm) for 1.5 or 3 h at 1.5 ± 0.5 °C in a Lance Industries tumbler (model LT-15, Allenton, USA) using a drum load of 45 kg (half of working capacity). On the other hand, the muscles non tumbled (NPreIT) were weighed, vacuum packaged in the bags previously described and stored at 1.5 ± 0.5 °C until further injection. Then, the PreIT and NPreIT muscles were weighed and injected using a hand operated brine pump (Dick Lokespritze Esslingen A.NX., Germany). Brine was formulated to give a concentration of 3.5 %WPC (Lacprodan 80, Arla Food Ingredients S.A., Buenos Aires, Argentina) and 0.7% SC (Dos Anclas, Buenos Aires, Argentina) in the injected product, and it was added at a rate of 20% (w/w). After injection, two procedures were applied, by one hand, non tumbled muscles (NPostIT) were vacuum packaged in proper bags (Cryovac CN510, Sealed Air Co., Buenos Aires-Argentina) and then refrigerated overnight at 1.5 ± 0.5°C until *sous vide* cooking was performed. On the other hand, the muscles selected for PostIT were vacuum packaged in the Cryovac CN510 bags, continually tumbled (5 rpm) for 2 or 10 h at 1.5 ±0.5°C in the equipment previously described and stored overnight at 1.5 ± 0.5 °C until *sous vide* cooking was carried out. Then, all muscles were weighed, vacuum packaged into cook-in bags (Cryovac CN510, Sealed Air Co., Buenos Aires, Argentina) and cooked in a water cascading retort (Microflow Barriquand, Roanne, France) in batches of twenty four muscles (the device was operated in static basket mode). Time-temperature evolutions in the slowest heating point (SHP) of three muscles and in the retort chamber were measured using a T type thermocouple and recorded with a digital multimeter Hydra 2625A date logger (John Fluke Mfg. Co., Inc., Everett, USA). In the present study, a processing temperature and time combination of 70°C – 2 min were applied at the muscle SHP. This treatment has been suggested in order to achieve a 6D reduction of *Listeria monocytogenes* (FAIR CT96-1020, 1999). Immediately after the heat treatment, samples were immersed in an ice-water bath until the temperature at SHP reached 10 °C and then were stored at 1.5±0.5 °C for 18 h until further testing.

The technological parameters measured on each muscle were PreIT weight loss percentage (P_1), PostIT weight loss percentage (P_2), cooking-pasteurisation weight loss percentage (P_3) and total weight loss percentage (P_T). Each weigh loss percentage was determined using the relationship $P_i = 100 \times (m_i - m_f)/m_{trm}$, where, for P_1: m_i is the mass of the trimmed raw muscle (non injected) and m_f is the mass of the muscle after PreIT treatment. For P_2, m_i is the mass of the injected muscle and m_f is the mass of the muscle after PostIT treatment, while for P_3, m_i is the mass of muscle after PostIT treatment and m_f is the mass of the muscle after thermal process. Finally, for P_T, m_i is the mass of the trimmed raw muscle (non injected) and m_f is the mass of the muscle after thermal process. All percentages were based on the weight of the trimmed raw muscle (non injected), m_{trm}. The pH values of raw and cooked muscles were measured in duplicate on an homogenate (5 g of sample: 25 ml of distilled water buffered at pH 7) with a pH-meter (Thermo Orion 710A+, Beverly MA, USA) equipped with a combination pH electrode (Thermo Orion Model 8102BN ROSS Electrode). Warner Bratzler shear (WBS) was determined on ten cylinders (3 cm height; 1.27 cm in diameter) obtained from 2.0 cm slice located in the muscle medial portion. For this purpose, Warner–Bratzler meat shear device (Chatllon, New York, USA) with a triangular shear was used. Also, visual appearance of 1.5 cm slice also separated from the muscle medial portion was judged by ten trained panellists using a Veri-Vide CAC120 box (illuminant D_{65}). A seven-point scale was used for cooked beef colour, and a five-point scale for colour uniformity, following the specification of AMSA (1991). The level of defects in the slices was evaluated by a five-point scale of 1=*None*, 5= *Extreme*. The amount of defects (percentage by slice area) was also evaluated using a seven-point scales of 1= *No defect* (0%), 7= *Total* (100%). For statistical analysis, data were analysed as a 3 x 3 factorial design with PreIT and PostIT treatments as main effects (A and B, respectively). All data were analysed by SPSS (Statistical Package for the Social Sciences) 12.0 for Windows (SPSS Inc., Chicago, IL, USA). The Tukey's multiple range test at P=0.05 was used to determine differences between means. Principal component analysis (PCA) was also performed with SPSS software.

Results and discussion

Neither PreIT nor PostIT treatments had significant effect ($P > 0.05$) on the pH of cooked muscles (injected or non injected). However, a significant pH increase was observed ($P<0.05$) for the injected + cooked muscles (pH = 6.11 ± 0.09) in comparison to, raw muscles (pH = 5.61 ± 0.08) and non injected + cooked (pH= 5.87 ± 0.07) ones. An overview of Figure 1 and Table 2, showed that the highest weight losses correspond to cooking-pasteurisation step (P_3). In addition, PostIT weight losses (P_2-Table 2) were higher than the PreIT ones (P_1-figure 1), probably as consequence of the more severe PostIT procedure. In Fig. 1 it is also observed that increasing PreIT times up to 3 h had non significant effect on P_1 parameter ($P > 0.05$),

which values were in the range of 1.0-1.4%. In the present study, PreIT treatments were applied in order to provide more suitable physical conditions for the injection procedure. These treatments were suggested considering both, the high viscosity of the brines used and the higher resistance of beef to brine addition compared to pork and poultry (Pietrasik & Shand, 2004). According to Table 2, P_2, P_3 and P_T parameters were not significantly affected by PreIT times ($P > 0.05$) but they were markedly increased ($P < 0.05$) by PostIT times (Table 2). Then, PostIT time up to 2 h had not effect on them, but the extending of PostIT time to 10 h increased significantly these variables (Table 2). None of the evaluated weight losses was affected by interactive effects between PreIT and PostIT treatments (P=0.1341, P=0.3068 and P=0.4642, for P_2, P_3 and P_T respectively). As it was expected, PostIT weight loss (P_2) corresponding to a tumbling time of 10 h was higher than those one from muscles, either tumbled by 2 h or non tumbled (NPostIT). This result could be due to a larger tissue disruption induced by the extended tumbling time. Also, muscles treated by PostIT of 10 h presented a cooking-pasteurisation weigh loss (P_3) higher than those muscles processed for 2 h or NPostIT. This effect is different from the one observed in muscles added of conventional functional ingredients, in which the extended tumbling has been described as a factor that improves the water binding characteristics and reduces purge and cooking losses. Generally, extended tumbling is required to incorporate brine into the muscle cells and to provide more suitable conditions for protein solubilization and extraction (Xargayo & Lagares, 1992; Pietrasik & Shand, 2004). The described discrepancy can be attributed to differences in formulation (WPC and SC ingredients), in injection levels, in meat composition and structure, and in cooking procedure (heating rate, temperature and time).Even though the injected muscles processed by PreIT and PostIT treatments have P_T in the range of 5 – 10 % (Table 2), these are significantly lower ($P < 0.05$) than those of non injected muscles similarly processed (25-30%, data not shown). It proved that WPC and SC addition successfully reduced weight losses between 2-3 times. As can also be seen in Table 2, neither PreIT nor PostIT treatments had significant effect ($P > 0.05$) on the instrumental tenderness (WBS) of injected + cooked muscles. However, it was detected a trend to increase tenderness in muscles treated by PostIT for 10 h. A correlation between WBS values and a hedonic scale, let us classified injected + cooked muscles as "very tender".

In Figure 2, P_2, P_3 and P_T weight losses, sensory ("cooked beef colour", "colour uniformity", "level of defects") and instrumental (WBS) parameters, and NPostIT and PostIT treatments have been plotted as it was obtained by PCA. The first and second axes (PC1 and PC2) describe 62.3 and 19.8 % of overall variation, respectively. The horizontal axis (PC1) discriminates treatments by the three weight losses (left side) and sensory and instrumental parameters (right side). Even though muscles processed by the PostIT time of 10 h had higher weight losses than those of the muscles submitted to other treatments (NPostIT and PostIT of 2 h), they showed a more uniform *pinkish-gray* colour (3= s*mall amount of variation*) and improved tenderness (lower WBS values). Since the descriptor "level of defects" presented similar loadings for both components (0.65 and 0.66 for PC1 and PC2, respectively), then this sensory parameter would also be related to PC2 axis. Thus, Fig. 2 shows that muscles without PostIT (NPostIT) or processed by a PostIT time of 2 h exhibited a higher "level of defects" than those treated by a PostIT time of 10 h (this descriptor was evaluated as s*mall* and involved 20 to 40% of slices area). Taking into account present results, the PostIT time of 10 h seemed to be the most appropriate treatment to improve quality characteristics.

Conclusions

Contrary to our expectations, tumbling procedure applied prior to the injection one did not affect either technological parameters (tumbling and cooking weight losses) or sensory quality (tenderness and visual appearance) of cooked beef muscles. As well, a post injection tumbling time of 2 h had not influence on these parameters. However, extending post injection tumbling times to 10 h, improved brine distribution and sensory quality (cooked beef colour, colour uniformity, level and amount of defects and tenderness). The drawback was that tumbling and cooking weight losses were increased by this treatment.

OPTIMISING THE MEASURING OF MEAT FLAVOURS BY MEANS OF AN ELECTRONIC NOSE VIA SENSOR SELECTION

Irina Dederer

Federal Research Centre for Nutrition and Food, Location Kulmbach , Germany

Background

A reproducible method for detecting flavours is an important precondition for the successful employment of the electronic nose when evaluating the quality of foodstuffs. The results of the executed measuring of meat flavours showed a number of factors which are to be optimised to obtain reliable results when using gas sensor arrays (Rosenbauer *et al*. 1998). The precise knowledge of the sensor selectivity, i.e. what the signals of individual sensors contribute to the differentiation, apart from the factors examined by us, like the reference air temperature and humidity, the mass flow of the carrier gas, the sample volume, the surface, the incubation period and temperature of the sample is essential for the distinctiveness of a sensor system (Dederer and Troeger 2000).

Objectives

Subsequently, the possibility to improve the efficiency of the sensor system VOCmeter (Messrs. Motech in Reutlingen) was demonstrated by selecting the appropriate sensors and by optimising the evaluation of the sensor signals by means of a practical example (comparison of beef samples with different pH values during ageing).

Materials and methods

The employed system works on the principle of mixed sensors: It contains 4 metal oxide (MOX) and 8 quartz microbalance sensors (QMB).
The sample material was beef meat (*M. longissimus dorsi*) with a pH value of 5.5 and 5.9. The samples were stored in multilayer plastic bags at +2 °C for a total of 5 weeks. In each storage week, the samples were measured in a dynamic measuring modus under the following experimental conditions: Sample volume 10 g; thermostatisation of the samples by 35 °C for 30 minutes; carrier gas – purified air with 55 % humidity (related to 30°C); flow rate of the reference air 25 ml/sec; equilibration time of the sensors 120 sec; measuring period 5 min. Parallel to their measuring by means of the electronic nose, the meat samples were evaluated sensorial according to the criteria of flavour and tenderness on the basis of a 6-point scale.

Results and discussion

To establish the sensor rate relevant for differentiating the ageing condition of the beef samples, the sensor signals of the 4 MOX sensors and the 8 QMB sensors were evaluated separately. Particularly those sensors mainly reacting on polar substances and on common hydrocarbons, showed a significant increase in the signal intensity during the meat ageing.

The Figure 1 and 2 show the mean value of the maximum of the sensor reactions for beef samples with different pH-value and storage period. In case of MOX sensors, slight differences were established in the signal intensity between all samples stored for one week and an increasing signal intensity of all sensors after the second storage week. The highest signals were established for the samples with the pH-value 5.9. In this connection, sensor MT-J20 particularly reacting on polar substances and sensor MT-J0 which reacts on common hydrocarbons showed a significant increase of the signal intensity during meat ageing. The sensor indicated by the manufacture selectively for methane and permanent gases, reacted the least on the flavour differences. Only two of the eight QMB sensors reacted on the ageing-related differences of the meat flavour.

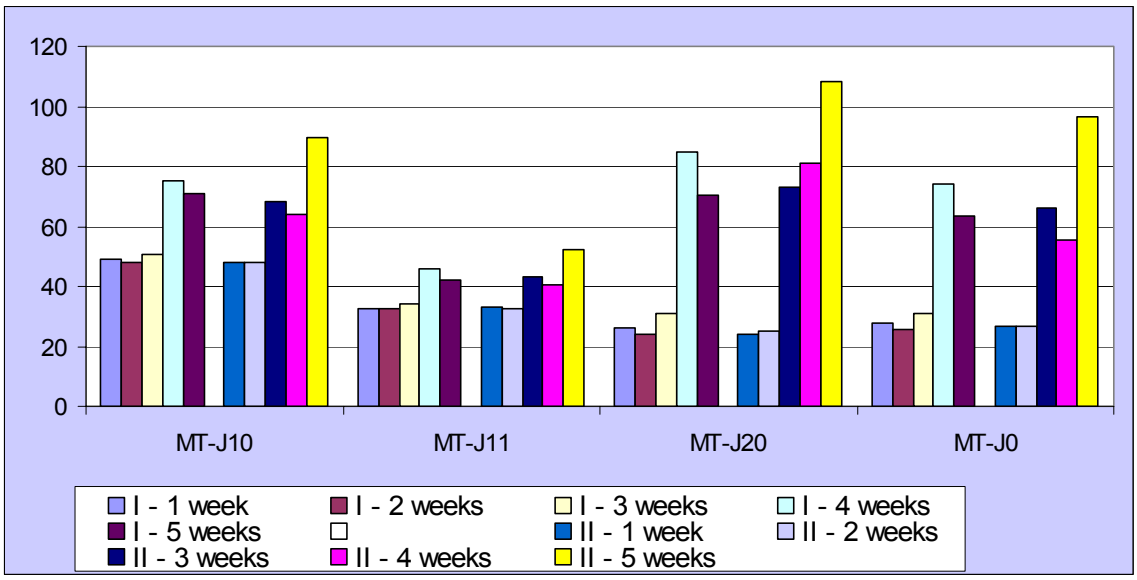

Fig. 1. Mean value of the signal maxima of MOX sensors of the beef samples with the pH-value of 5.5 (I) and of 5.9 (II) during ageing.

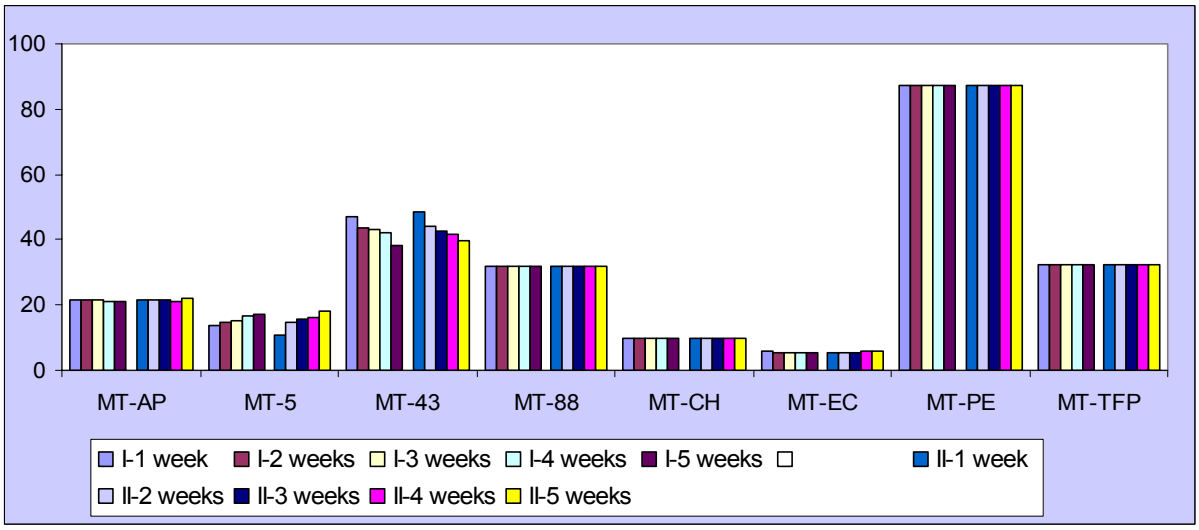

Fig. 2. Mean value of the signal maxima of QMB sensors of the beef samples with the pH-value of 5.5 (I) and of 5.9 (II) during ageing.

A smaller decrease in the signal intensity of storage of 1 to 5 weeks was determined for the sensor MT-43 specified for medium polar hydrocarbons and an increase in the signal intensity was determined for the sensor MT-5 reacting on nonpolar hydrocarbons. On the basis of the signal intensity, those sensors reacting on the differences in the meat flavour were selected and taken up for further evaluation.

In Figure 3 you can see the principal component analysis of the beef samples with different initial pH-values for the ageing process. The evaluation only contains the sensor signals reacting on differences in the meat flavour. Here it proved to show that the meat samples with a different storage period and a different pH-value can be separated by means of their sensor signals.
The differently evaluated samples in the multidimensional space are separated in a way that the differences of the sensorial testing can be found in the distances. You can see smaller distances between the clusters of the samples whose flavour has become a similar evaluation. The “good” and “bad” samples with respect to tenderness and flavour are placed in one area of the illustration. Larger differences of the gas composition

were caused by the ageing of the beef samples with the pH-value of 5.9 compared to the samples with the pH-value of 5.5.

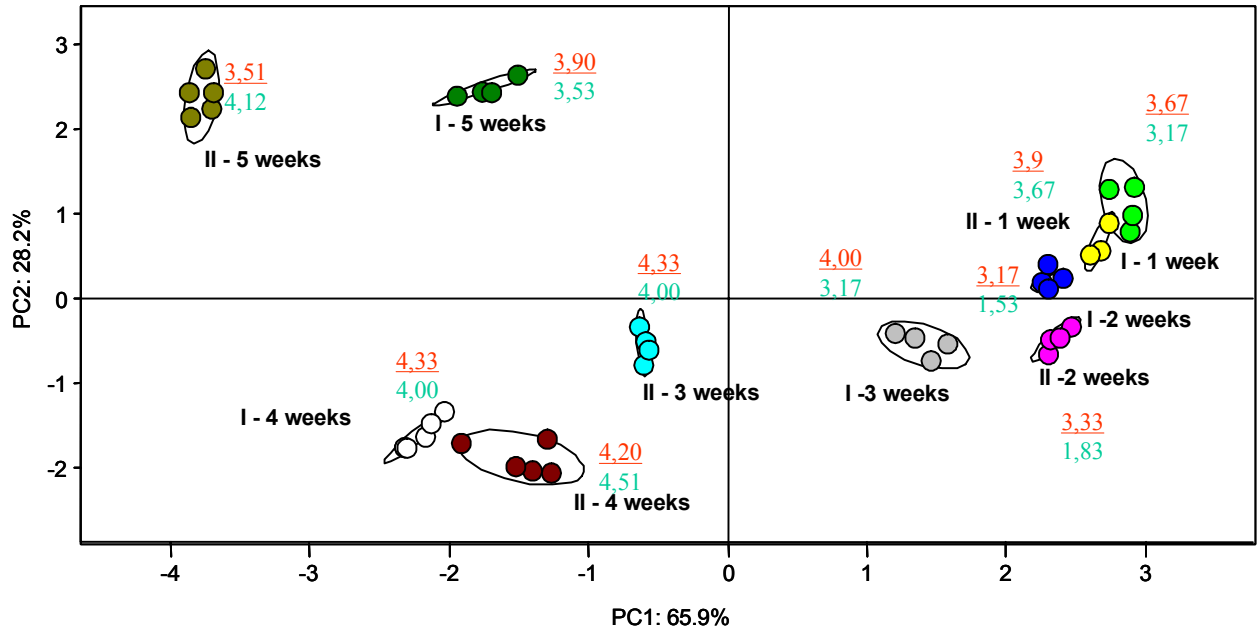

Fig. 3. Principal component analysis of the beef samples with a different pH-value during ageing (I –pH 5.5; II – pH 5.9). 3.67/3.17 – sensorial established values: Flavour/tenderness on the basis of a 6-point scheme.

The principal components analysis showed that the meat samples with a different storage period and a different pH value can be separated by means of their Headspace gas composition.

Conclusions

Due to this information, it would be possible to replace sensors with low distinctiveness by sensors of another selectivity being more relevant for the problem of separation (meat ageing), thus increasing the distinctiveness of the Cassensor-Arrays.

The available results show that the chosen sensor arrangement of 4 MOX sensors and 2 QMB sensors has been able to recognize the ageing condition of beef samples with a different pH-value corresponding to the sensorial evaluation.

Background

Traditional products of processed meat products have a positive impact on the sustainability of regional economy. Their consumption, mainly in those using raw materials from Alentejano pig breed, present some variability due to changes occurred on processing practices. Among these, meat and fat mincing size and the level of salt (NaCl) addition could fulfil a great influence on sensory and textural properties of the final product.

Objectives

The purpose of this work is to evaluate the rheological and sensorial properties occurred in "Painho de Portalegre" using low levels of salt in the formulation (0,5% and 1% NaCl) and two different minced meat called small portions and large portions.

Material and methods

"Painho de Portalegre" is a regional and traditional portuguese smoked sausage (cylindrical shape; length 30cm; diameter 25 to 40 mm) made from meat and fat obtained from Alentejano pig, a Portuguese breed.
The small portions refers to parallelepiped portions 1,7 X 1,7cm and large portions to 5,5 X 2,5cm. Two different concentrations of salt, 0,5% and 1% NaCl, were used in the formulation. Three samples of final product were used for each one of the 4 modalities (small portions with 0,5% NaCl, in the formulation; small portions with 1% NaCl, in the formulation; large portions with 0,5% NaCl; large portions with 1% NaCl).
The sensorial evaluation was a descriptive and quantitative analysis, considering a scale from 1 to 100, and the number of panellists was 12. The attributes considered were Colour Intensity, Aroma Intensity, Taste Intensity, Tenderness, Fibrouseness, Juiciness, Undesired Taste, Salt and General Appreciation.
A Texture Profile Analyze (TPA) with a compress platen and a cutting test with a blade knife was performed using a Stable Micro System TA-Hdi.in order to define the texture and compare it with the sensorial evaluation. The samples for the first test were cylindrical with 3,5cm of diameter and 3,5cm of height and were compressed twice to 10% of the initial height. For the cutting test the samples were slices with 4 mm of height and the cut was until reach 87,5% of the sample and the maximum force was measured.
Results were analysed trough an ANOVA-MANOVA considering 2 factors (salt concentration and minced) and their interactions, using the STATISTICA software. A Tukey test for comparation of means was done too.

Results and Discussion

None significant differences were found in the sensorial evaluation results (Table 1). However can be noticed that samples obtained from "Small Portions" exhibit higher values of aroma intensity and fibrouseness lower than those of "Large Portions" (Table 2).
Samples obtained with 1% NaCl exhibit higher values of tenderness (confirmed by rheological results), juiciness and taste intensity. This high classification of the two last attributes is possibly due to the salt effect on the salivation and increasing the flavour of food. Samples with 0,5% NaCl showed higher intensity of colour than those with 1% NaCl
Panellists only distinguish salt intensity for the samples produced with "Small Portions" (56 points for sausages with 0,5% NaCl and 64 points for those with 1% NaCl).
The general appreciation revealed a clear preference by the sausages produced with "Small Portions" and 0,5% NaCl.
Coutron-Gambotti *et al*. (1999) studied the effect of low concentration of salt under lipid composition and the sensorial attributes in dry ham and they observed decreasing of auto oxidation processes and a better aroma and flavour.
The analysis of the rhelogical results revealed that cohesiveness showed significant differences ($p<0,01$) for factor Minced (average value 0,74 for "Small Portions" and 0,68 for "Large Portions"). On the other hand all the other parameters didn't exhibit significant differences. Results of springiness, chewiness and cohesiveness were superior for

"Small Portions" than those of "Large Portions" due to a better binding of the meat and fat portions because after prepared they had higher contact area among them, so the extraction of soluble protein is higher too. This is corroborated by high values of cutting test found in the sausages obtained with "Small Portions" and this parameter was significant for the factor Minced ($p<0,05$).

Conclusions

A general approach of the results of Sensorial Evaluation conclude that sausages obtained through "Small Portions" exhibit a better classification than those obtained from "Large Portions". Panellists also noticed a high concentration of salt in the products from "Small Portions" and more intensity of aroma. Although none of the sensorial parameters showed significant results from Anova.
Products with 1% of NaCl (in the formulation) were classified with higher values of tenderness, juiciness and taste but lower colour intensity when compared with those with 0,5% of salt (in the formulation).
It is possible to produce sausages of high level of quality using the usual technology but with lower concentration of salt.

LIPID OXIDATION DURING REFRIGERATED STORAGE OF LIVER PÂTÉS FROM EXTENSIVELY REARED IBERIAN PIGS AND INTENSIVELY REARED WHITE PIGS

Mario Estévez, Sonia Ventanas, Rosario Ramírez, Ramón Cava
Tecnología de los Alimentos. Facultad de Veterinaria. Universidad de Extremadura. 10071 Cáceres. Spain.

Background

Iberian pigs have been traditionally reared extensively in evergreen-oak forests named 'dehesas' in which animals are fed on natural resources (grass and acorns). On the other hand, pigs from industrial genotypes are selected for high growth rates and traditionally reared intensively, under controlled conditions and fed with concentrated diets, in order to maximize benefits in the shortest period of time (Sundrum, 2001).
Oxidation of lipids is the major factor reducing quality and acceptability of meat and fat products (Morrissey et al., 1998). Lipid oxidation is a complex process whereby polyunsaturated fatty acids (PUFA) are degraded via formation of free radicals, causing flavour, texture, colour and nutritional deterioration of foodstuffs (Morrissey et al., 1998).
Liver pâté is a traditional product with excellent nutritional and sensory properties (Echarte et al., 2004). Ingredients (mainly liver, fat and meat) are finely minced and cooked during pâté manufacture that could favour the development of lipid oxidation. Thus, liver pâtés exhibit high amounts of fat and iron, and therefore, oxidative deterioration of liver pâtés during refrigeration is expected. The differences between pâtés from Iberian and white pigs in terms of their fatty acid composition and antioxidative status (Estévez et al., 2004) are expected to influence on their oxidative deterioration during refrigerated storage.

Objectives

The aim of the present work was to study the lipid oxidative changes of liver pâtés from Iberian and white pigs during refrigerated storage as assessed by PUFA degradation and generation of thiobarbituric acid reactive substances (TBA-RS) and hexanal.

Material and methods

Animals: Iberian pigs were free-range reared and fed on natural resources (grass and acorns) following the traditional livestock farming for Iberian pigs. The animals were slaughtered at ~150 kg live weight and at the age of 12 months. White pigs (Large White x Landrace) were intensively reared under controlled conditions in a typical industrial livestock farm. The animals were fed on a concentrate feed and slaughtered at 85 kg live weight and at the age of 7 months.
Samples, manufacture of pâté and refrigerated storage: After slaughter, back fat, muscle *Quadriceps femoris*, and liver were removed from the carcasses, vacuum packaged and stored at -80ºC until the day of the manufacture of the pâté. For this, ingredients were as follows per 100g of elaborated product: 28g liver, 40g adipose tissue, 5g muscle, 23g distilled water, 2g sodium caseinate, 2g sodium chloride. Sodium di- and tri-phosphates (0.3%) sodium ascorbate (0.05%) and sodium nitrite (0.03%) (ANVISA, Madrid, Spain) were also added. The protocol followed for the manufacture of liver pâtés was described elsewhere (Estévez et al., 2004). Liver pâtés were packed in glass containers prior to thermal treatment (80ºC/30min.). Liver pâtés were stored in the darkness at 4ºC during 90 days since the day of the manufacture (day 0). Liver pâtés were analysed at days 0, 30, 60 and 90 for PUFA content, TBA-RS and hexanal. After being accomplished each of the refrigeration stages, liver pâtés were stored at -80ºC until analytical experiments.
Chemical Analysis: Moisture, total protein, total fat, and ash were determined using official methods (AOAC, 2000). Fatty acid methyl esters (FAME) were prepared following the method of López-Bote et al. (1997). FAME were analysed using a Hewlett Packard, gas chromatograph, equipped with a flame ionisation detector (FID) as described Estévez et al. (2004). Identification of FAME was based on retention times of reference compounds (Sigma). Proportions of saturated, monounsaturated and polyunsaturated fatty acids (SFA, MUFA and PUFA, respectively) were calculated as percentages of total fatty acids analysed. The quantification of PUFA (sum of C18:2, C18:3 and C20:4) was carried out by using C13 as internal standard. Results are expressed as g PUFA $100g^{-1}$ pâté. TBARS were determined using the method of Rosmini et al.,

(1996). Hexanal was determined in the headspace of liver pâtés using the solid-phase microextraction (SPME) sampling coupled to gas chromatography and mass spectrometry (GC-MS) (Estévez et al., 2003).
Data Analysis: Results of the experiments were used as variables and analysed by using a Student's t-test for independent variables (SPSS, 1997) in order to compare pâtés from Iberian and white pigs. The effect of refrigerated storage on liver pâtés was assessed by using an Analysis of Variance (ANOVA) from SPSS software. Statistical significance was considered as follows: $p>0.05$ (ns), $p<0.05$ (*), $p<0.01$ (**), $p<0.001$ (***).

Results and Discussion

Liver pâtés from Iberian and white pigs showed no differences for moisture, fat, protein or ash contents (Table 1). However, compared to pâtés from white pigs, pâtés from Iberian pigs presented a larger proportion of MUFA and smaller of SFA and PUFA. Liver pâtés reflected the fatty acid composition of the raw material (fat, liver and meat) used for their manufacture (Estévez et al., 2004). Muscles, back-fat and liver tissues from Iberian pigs present large amounts of oleic acid and MUFA as a result of the intake of acorns during the last stage of their fattening period that has been linked to several quality traits (López-Bote et al., 1997).
The amount of PUFA gradually decreased in both types of pâté during refrigerated storage as a likely consequence of the development of oxidative reactions. The decrease rate of PUFA content as measured by the slopes of the calculated trend lines (Figure 1) revealed that the loss of PUFA was more intense in pâtés from white pigs than in the Iberian counterparts. After 90 days of refrigerated storage, pâtés from white pigs lose 2.3 g PUFA/100g pâté as an average while those from Iberian pigs lose a significantly ($p<0.05$) smaller amount (1.5 g PUFA/100g pâté). The oxidative degradation of PUFA led to a gradually increase in the amount of TBA-RS and hexanal between day 0 and day 90 for liver pâtés from Iberian and white pigs (Figure 2). Pâtés from white pigs presented significantly ($p<0.05$) higher TBA-RS numbers and hexanal contents than pâtés from Iberian pigs at day 0 and day 90. These results are consistent with those obtained from the PUFA degradation and agree with those obtained in previous works devoted to the study of the oxidation stability of raw and cooked meats from Iberian and white pigs (Estévez et al., 2003; Estévez et al., 2004) and could be partly explained by the equilibrium between prooxidant and antioxidant factors in the pâtés. Pâtés from white pigs presented a higher proportion of PUFA and lower of MUFA than pâtés from Iberian pigs that makes the former more prone to oxidation than the latter. Moreover, in a previous work (Estévez et al., 2004) we reported a significantly higher amount of vitamin E in the raw material used for the manufacture of pâtés (fat, liver and muscles) from Iberian pigs when compared to those from white pigs. The relationship between the nutritional background (pasture- and mixed diet finishing) and the fatty acid profile and oxidation stability of liver, pork and on them based products is profusely documented (Cava et al., 2000; Nilzén et al., 2001). The intake of pasture by animals increases in their tissues the level of vitamin E, enhancing their oxidation stability (Cava et al., 2000; Nilzén et al., 2001).

Background

Liver pâté is an emulsion-like product that exhibits high contents of fat and iron that would make of it a product with high oxidative instability (Russell et al., 2003; Estévez et al., 2004). The pâté matrix is relatively poor in natural antioxidants, which justifies the addition of exogenous antioxidants (Madhavi et al., 1996) in order to inhibit the development of the aforementioned oxidative reactions. Synthetic phenolic antioxidants, such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT) and propyl, octyl and dodecyl gallates (PG, OG, DG), are easily available and largely used in different food products (Pinho et al., 2000). Using such synthetic compounds has been linked to health risks generally referred to carcinogenic potential (Clayson et al., 1986). Consequently, many scientific efforts have been led to select different natural antioxidant extracts and prove their antioxidant activities as alternatives to synthetic antioxidants. Sage (*Salvia officinalis*) and rosemary (*Rosmarinus officianalis*) are popular *Labiatae* herbs with a verified potent antioxidant activity in meat and fat products (McCarthy et al., 2001; Yu et al., 2002). On the other hand, the compositional characteristics of the raw material influence on the quality characteristics and oxidative stability of the manufacture product (Estévez et al., 2004). Liver pâtés from extensively reared Iberian pigs demonstrated to have a higher oxidative stability than pâtés from intensively reared white pigs as a result of the fatty acid composition and the presence of higher amounts of endogenous antioxidants such as vitamin E (Estévez et al., 2004).

Objectives

The aim of the present work were to investigate the effect of the addition of natural antioxidants (extracts of sage and rosemary) on the oxidative stability of refrigerated stored pâtés from extensively reared Iberian pigs and intensively reared white pigs.

Material and methods

Animals: Iberian pigs were free-range reared and fed on natural resources (grass and acorns) following the traditional livestock farming for Iberian pigs. White pigs (Large White x Landrace) were intensively reared under controlled conditions in a typical industrial livestock farm a fed on a concentrate feed.
Samples, manufacture of pâté and refrigeration: After slaughter, back fat, muscle *quadriceps femoris*, and liver were removed from the carcasses, vacuum packaged and stored at -80ºC until the day of the manufacture of the pâté. For this, ingredients were as follows per 100g of elaborated product: 28g liver, 40g adipose tissue, 5g muscle, 23g distilled water, 2g sodium caseinate, 2g sodium chloride. Sodium di- and tri-phosphates (0.3%) sodium ascorbate (0.05%) and sodium nitrite (0.03%) (ANVISA, Madrid, Spain) were also added. Depending on the origin of the raw material (from 'Iberian' or 'white' pigs) and the addition of different antioxidants ('rosemary' and 'sage' extracts, 0.1%) different types of pâtés were elaborated. A 'control' batch without added extract was also considered. The protocol followed for the manuacture of liver pâtés was described elsewhere (Estévez et al., 2004). Liver pâtés were packed in glass containers prior to thermal treatment (80ºC/30min.). After manufacture, liver pâtés were stored in the darkness at 4ºC during 90 days in order to allow the development of oxidative reactions. Liver pâtés were analysed at days 0 and 90 for the amount of reactive substances to the tiobarbituric acid (TBA-RS), increase of carbonyls from protein oxidation and hexanal.
ChemicalAnalysis: TBA-RS were determined using the method developed by Rosmini et al., (1996) for liver pâtés. Protein oxidation as measured by the total carbonyl content was assessed following the method described by Oliver et al., (1987). Hexanal was determined in the headspace (HS) of liver pâtés using the solid-phase microextraction (SPME) sampling coupled to gas chromatography and mass spectrometry (GC-MS) (Estévez et al., 2003).

Data Analysis: Results from the experiments were used as variables and analysed by using a Student's t-test for dependent variables (SPSS, 1997) in order evaluate significant changes between days 0 and 90. The effect of the addition of the antioxidants was assessed by using an one-way Analysis of Variance (ANOVA) from SPSS software. When statistical differences were detected, data were analysed using Tukey's tests. Statistical significance was set at $p<0.05$.

Results and Discussion

The development of oxidative reactions during refrigerated storage led to a gradual increase in the amount of residual components in liver pâtés such as those generated from lipids and proteins. TBA-RS significantly increased ($p<0.05$) in all groups during refrigerated storage (Figures 1A, 2A). Similarly, the amount of carbonyls from protein oxidation had significantly increased ($p<0.05$) after 90 days of refrigerated storage in control and treated pâtés (Figures 1B, 2B). Due to significant correlations found between some particular lipid-derived volatiles and other lipid oxidation products such as TBA-RS (Shahidi & Pegg, 1994), hexanal has been considered as a fairly good indicator of lipid oxidation. During refrigerated storage, the hexanal significantly ($p<0.05$) increased in the pâtés HS (Figures 3A, 3B), agreeing with the results obtained from the oxidation of lipids and proteins. In general, the addition of sage and rosemary essential oils had a significant effect on the oxidative stability of liver pâtés but this effect was different depending on whether they were added on 'Iberian' or 'white' pâtés. In agreement with previous research on several meats and meat products (McArthy et al., 2001; Yu et al., 2002), the addition of sage and rosemary essential oils had an antioxidant effect on pâtés from Iberian pigs as long as smaller amounts TBA-RS, carbonyls from protein oxidation and hexanal were detected in treated pâtés when compared to the 'control' counterparts. In contrast, the addition of sage and rosemary in pâtés from white pigs had an opposite behaviour, significantly increasing ($p<0.05$) the generation of lipid and protein oxidation products, while no effect was detected for the generation of hexanal. Results from the present work suggest that the activity of sage and rosemary essential oils is dependent on the compositional characteristics of the food matrix. Food systems, and specifically liver pâtés, are very complex in the number and the type of chemicals in the mixture, and a combination of these compounds may behave differently from the individual components. In this sense, Wong et al. (1995) and Fang & Wada (1993) reported possible interactions between phenolic compounds from sage and rosemary essential oils and vitamin E, resulting in different activities depending on the individual amounts of these substances in the food system. Significant differences ($p<0.05$) were found between Iberian and white pigs regarding vitamin E content in muscles (6.18 vs 1.94 mg/kg muscle), livers (7.93 vs 3.49 mg/kg liver) and adipose tissues (19.67 vs 1.21 mg/kg adipose tissue) used for the manufacture of liver pâtés (Estévez et al., 2004) as a likely consequence of the intake of pasture during fattening. The presence of a certain amount of an endogenous antioxidant (vitamin E) in the raw material and manufacture product might influence on the activity of exogenous active extracts, leading to antioxidant or pro-oxidant effects.

ANALYSIS OF UNIQUE FLAVOR OF CHINESE TRADITIONAL XUANWEI HAM

QIAO Fadong[1], MA Changwei[1], WU Xiufang[2]
[1]College of Food Science & Nutritional Engineering, China Agricultural University, Beijing 100083, China
[2]Department of Foreign Language Henan Vocational Technique Teacher College, Xinxiang 453003, China

Background

The cured ham was initially intended to solve the problem of storing fresh meat. But now with the wide use of the refrigeration, the major attention has been shifted to its unique flavor. A typical flavor can provide a pleasant appreciation and wide acceptance for customers. For example, Iberian Ham has become one of the most famous meat products of high quality in Europe. Xuanwei Ham is a famous special product in Yunnan Province of China. At present, studies on the characteristics of Xuanwei Ham are not enough.

Objectives

This research was conducted to analyze the impact of the climate character in Xuanwei area, raw materials and traditional techniques on the quality of traditional Xuanwei ham.

Materials and Methods

Ham Process: Wujin Pigs were slaughtered when they grew to 8~12 month old, 90~100kg. Hams were made in traditional procedures. Green hams were held for 12~24h at 5~10℃ after slaughter. The hams were thoroughly rubbed with local salt and placed in piles with alternate beds of hams and salted for 30 days at 5~10 ℃ and 65%~85% relative humidity. The salt was added on the proportion of 7% of green legs and was rubbed two or three times at a 7 day interval. The salting started from late October and ended early February in the following year. After washing to remove the excess salt and dirt on the surface of the ham, they were hung with straw strings and dried in the sunlight for 3~4 days. The hams were hung on the strings to ripen for 8~12 months in a ventilated chamber (temperature ranging from 10~20℃ and relative humidity 60%~80%).

Sampling. The *Biceps femoris* were taken from 10 hams of 12-month maturation and the physicochemical and the volatile compounds were analyzed and identified immediately.

Chemical Analyses. Sodium chloride was determined by potentiometric titration with $AgNo_3$ in an autotitrator, and results are given as a percentage of NaCl (w/w). *Water content* was determined after drying of a 3.00 g homogenized sample at 105℃ for 18 h and subsequent cooling in a desiccator. Results are given as a percentage of water (w/w). *Water activity* (a_w) was determined at 25℃ by the graphic interpolation method using saturated salt solutions as standards. *Free amino acids*: Samples of 1 g of ham was homogenized with 25 ml of sulphosalicylic acid (8%) in a 50ml centrifugal tube and the tube was set in ice. The homogenate was centrifuged in a refrigerated centrifuge at 8000 rpm for 13 min. The supernatant was filtered through Whatman No. 54 filter paper. Some amino acids were identified and quantified were measured by L-8500 Amino Acid Analytical Apparatus. *Volatile compounds analysis*: The volatile compounds were extracted by employing a simultaneous distillation-extraction method (SDE), and were separated and identified by Agilent 6890 Series gas chromatographer (GC) and Agilent 5973 Network Mass Selective Detector (MS).

Result and Discussion

1. Physicochemical analysis of traditional Xuanwei ham

The production yield of traditional Xuanwei ham maintained about 69.30%~73.60% (Table 1). The proportion of muscle to fat varied according to the composition of raw hams. The raw hams usually come from pigs with more fat and thus, the finished ham is rich in fat.

The traditional Xuanwei ham is rich in salt, which has an influence on consumers' appreciation and acceptance. Compared with other dry cured ham products, there were almost no differences concerning water content and a_w in the *M. biceps femoris* and subcutaneous fat (Table 2).

The free amino acids in Xuanwei ham are rich (Table 3). The most abundant is Glutamic acid，followed by Alanine and Leucine. The total free amino acids are 9040.45mg·100g^{-1} *M. biceps femoris* dry matter, similar to the results obtained from Iberian ham[1, 2]. Iberian ham was processed with long ripening and drying periods (18~24 months) and Xuanwei ham only had shorter production periods (8 ~ 12 months). This illustrated that Xuanwei ham has characteristics of quicker ripening process, higher activity of proteolytic enzyme, more free amino acids formed than those of Iberian Ham. These characteristics may well be related to the climate character, under which Xuanwei hams were dried and ripened.

2. Separation, identification and content evaluation of volatile compounds in Xuanwei ham

Separating and identifying results of the volatile compounds in the *Biceps femoris* of traditional Xuanwei ham were given in table 4.

Results showed that 75 volatile components were tentatively identified in the volatile fraction, including 15 hydrocarbons, 9 alcohols, 22 aldehydes, 6 ketones, 3 acids, 7 esters and 13 others. In the recent years, studies on volatile aroma compounds about Iberian ham, Serrano ham, Parma ham and Jinhua ham have been carried out by some experts[3, 4, 5, 6]. Some of the volatile compounds separated and identified from traditional Xuanwei ham had some similarities to those results reported of those dry cured ham products, but there were some differences. For example, in our samples, less species of ketones, esters and low molecular weight compounds were identified, but more branched compounds were obtained. Short chain hydrocarbon compounds less than C_{12} were not found. Such differences were correlated with experimental methods, sampling time and materials. Therefore, as regards the typical flavor properties and the exact quantity of the volatile compounds, it is hard to identify them and needs more careful future study.

3. The traditional Xuanwei ham is the work of nature and the special terrain

Xuanwei City is located in the north-east of Yunnan Province in China, east longitude 103º35′ 30″ ～ 104º 40′ 50″, north latitude 25º53′ 30″ ～ 26º44′ 50″. It is located in the transitional draping belt of Yuannan Plateau and Guizhou Plateau, its elevation is 2,868 to 920 meters. The winter begins from November 6th and ends on March 5th of the next year, and the spring begins from March 6th and the autumn ends on November 15th. There is no summer. The main weather reports of Xuanwei town are seen in the table 5. The unique weather creates an appropriate natural climate environment of curing, drying and ripening Xuanwei ham. The hams cured in winter were dried and ripened in spring and autumn. Therefore, Xuanwei City is a natural workshop of dry-cured hams. The natural climate character is the key factor of forming high quality.

4. The special pig specie and feeding way are the quality guarantee of the traditional Xuanwei ham

Wujin pig is a typical local specie. It has higher ability of digesting crude feedstuff. It not only adapts to the climate of high and cold mountain area, but also the warm and hot river valley area. Its body fat is high, it grows slowly, and the quality of muscle is good. In the early growth stage, the greens, straw chaff and rice bran were primary feedstuff. When the weight reaches to 40～50kg, proportion of corn flour and potato were increased in primary feed. The common green stuff are the straw chaff of horsebean, pease, buckwheat and sweet potato, the wild feedstuff are sweet potato vine, potato, carrot, pumpkin, chayote, cress, and so on. According to the feeding way of the local farmers, at the beginning, the piglet is 6.5kg, after feeding for 323 days, its weight can reach to 83.5kg. The daily average weight increase is 239g. It needs about 2.34kg foodstuff and 24.25kg green stuff to increase 1kg.

Wujin pigs' intramuscular fat content is abundant(14.37±3.82%), the flesh is tender, and cooking yield is high (71.64±5.32%). The water content in buttocks muscle is 67.3%. It is an ideal material for producing the high qualtity Xuanwei ham. The aroma of ham made of Wujin pig is good than that of others. The reasons require further investigation.

Conclusion

The ratio of finished product of traditional Xuanwei ham is 69.30%～73.60%, and that the water content, salt content, a_w of *M. Biceps femoris* were 47.30%~50.50%, 9.10%～11.20%, 0.83～0.85 respectively, it has a good storage stability. The ripening ham muscle was rich in free amino acid, the free amino acid content of *M. Biceps femoris* dry matter amounted to 9040.45mg/100g, similar to that of Iberian ham. Because of the different ripening time of two finished products, the ripening process of Xuanwei ham is quicker than that of Iberia. 75 volatile compounds are tentatively identified from the extracts in the *Biceps femoris* muscle. There are 15 hydrocarbons, 9 alcohols, 22 aldehydes, 6 ketones, 3 acids, 7 esters and 13 others. The technology of Xuanwei ham showed that the unique trait of Xuanwei ham resulted from the typical climate character in Xuanwei area, the Wujin pig, and the refined traditional processing technology.

Background

Meat tenderness is one of the most important attributes for consumers and depends on a great number of intrinsic biological factors, as breed, age, sex, feeding, and kind of muscle, besides the ante- and postmortem conditions (Thompson, 2002). Meat ageing is an alternative to achieve more tenderness and improve the sensory and nutritional quality. Nonetheless, in Mexico and many countries in the world ageing or maturation process is not a common practice, due to higher storage cost and energy required. The tenderness obtained during meat ageing is attributed to the action of two endogenous enzymatic systems, calpains and cathepsins (Jaarseveld et al., 1997). Cathepsins are liberated in lysosomes due to the lipoprotein membrane breakdown caused by the low pH values achieved in the post-mortem muscle. Calpains are located in cells cytoplasm, and they can be activated by the calcium stored in the sarcoplasmic reticule. Many researches have been done to improve the tenderness of meat samples (Morgan et al., 1991; Wheeler et al., 1992; Steen et al., 1997; Pérez-Chabela et al. 1998; Aktas and Kaya, 2001; Berge et al., 2001), but results are limited to certain kind of muscles. On the other hand, marination could be employed to extend the shelf life of meat and increase the value of hard cuts with low commercial value, besides the activation of endogenous proteolytic enzymes, calpains. The most employed marinating method is immersion, with the concomitant impact of the time required (24-48 h) at low temperatures. Tumbling or massaging systems could be employed to reduce marination time since the massaging promotes a faster migration of solution into meat tissues.

Objectives

The objective of this work was to study the effect of calcium chloride marination of *brachiocephalicus* bovine muscle, a relatively tough muscle, in a tumbling system at different rpm, in order to reduce immersion time during meat marination.

Materials and methods

Bovine *brachiocephalicus* muscle (48 h post mortem) was obtained from a local abattoir. Meat was cleaned from visible connective tissue and fat, and cut perpendicularly to muscle fibers and randomly distributed in the different treatments, displayed in Table 1. In order to reduce marination times reported (Koohmaraie et al., 1990; Wheeler et al., 1997; Pérez-Chabela et al., 1998), four different tumbling levels were employed (i.e., 1000, 2000, 3000 or 4000 tumbling/min, obtained in 2, 4, 6 or 8 h, respectively), together with an immersion sample (48 h at 4-6°C), in a 150 mM $CaCl_2$ solution. An untreated sample was used as a control. Vacuum massaging was made employing a SVM-30C machine tumbling (Edel Ingenieros, Monterrey, Mexico), at –25 Hg in. Samples were vacuum packed and analysed 24 h after their respective treatments. Meat texture was determined in a TA-HDi texture analyser (Texture Technologies, Scarsdale, New York/ Stable Micro System, Surrey, England) equipped with a 50 kg load cell and a Warner-Bratzler device. Meat samples were compressed at 2 mm/s constant speed rate and the maximum force detected was reported as Warner-Bratzler shear force. Calcium chloride was determined colorimetrically with the AOAC Official Method No. 983.19 (AOAC, 1999). A total of three replications were processed and analysed. Results obtained were statistically analysed with ANOVA in the SAS Statistical Software v. 8.0 (SAS Institute, Cary, North Carolina). Significant differences between means was determined with Duncan mean test.

Results and discussion

Samples for T1 showed higher calcium chloride concentrations ($P<0.01$) than others (Table 2), probably due to the longer contact with $CaCl_2$ solution (48 h). Final calcium concentration was significantly different ($P<0.01$) between the treatments. Calcium chloride concentration was higher for immersion samples (0.91 mg Ca^{+2}/100 g), as compared to control (0.11 mg Ca^{+2}/100 g) or massaging samples (~0.70 mg Ca^{+2}/100 g in average). Control sample (T0) had the lowest calcium concentration. In the tumbling samples, no significant differences ($P>0.05$) were detected. It means that the calcium chloride absorption is independent of the number of tumbling per minutes, and marination time could be reduced until to 2 h instead the 48 h required in the immersion process. There was a significant difference in the meat tenderness, reported as WB shear forces values, by the treatment employed (Table 2). Calcium chloride had effect on meat tenderness (Morgan et al., 1991; Steen et al., 1997; Wheeler et al., 1997; Pérez-Chabela et al. 1998), activating proteolytic enzymes, calpains, which induce myofibrillar structure breakdown, since control sample was tougher than the marinated samples. In same way, no significant differences were detected ($P>0.05$) among marinated samples, despite the process employed.

Conclusions

Meat tenderness induced by calcium marination can be achieved with short massaging times (2-4 hours), where the calcium concentration achieved by tumbling was enough to promote calpains activation, modifying myofibrillar structure and improving meat tenderness in this relatively tough and low value muscle.

DISTRIBUTION OF RELATIVE HUMIDITY IN DEPENDENCE OF THE INLET AIRFLOW DIRECTION IN DRY SAUSAGE RIPENING CHAMBERS

Michael Hermle[1], Thomas Jesinger[2], Peter Gschwind[2], Volker Kottke[2] and Albert Fischer[1]

1 Institute of Food Technology, Department of Meat Technology, University of Hohenheim, D-70599 Stuttgart, Germany

2 Institute of Food Technology, Department of Food Process Engineering, University of Hohenheim, D-70599 Stuttgart, Germany

Background

Due to quality and safety issues the ripening phase is the most critical stage in the production process of dry sausage. In contrast to the traditional ways of manufacturing, dry sausages nowadays are ripened and dried in modern multifunctional chambers under defined conditions (temperature, relative humidity, airflow velocity etc.) and a defined period of time, which depends on the product [1]. However, one of the main issues in the design and operation of modern ripening chambers is to achieve a homogeneous drying flow over the chamber length and height and knowledge about it's influence on the ripening process from an engineering point of view. The influence of different airflow directions on the local velocities at the sausages surface already has been discussed [2]. However, the mass transfer also depends on the water vapor partial pressure difference between the sausage surface and the surrounding air and is limited by the effective diffusion from the core to the surface [3]. The difference between the surface activity of water and the relative humidity (RH) of the surrounding air is the driving force of the drying process. To avoid drying errors this difference should not exceed 5 % during the whole process [4, 5, 6].

Objectives

In this project a method for quality maintenance in dry sausage production through the analysis of airflow and water transport in ripening chambers is investigated. Therefore, a method of measuring the relative humidity (RH) during the regular production in ripening chambers was developed. This study discusses the effect of different airflow directions on the distribution of the RH in a newly developed type of ripening chamber. Furthermore, the effect of natural convection on RH was investigated by cyclically interrupting the inlet air flow.

Materials and methods

Ripening chambers

The investigations were conducted in two different types (type 1 and type 2) of ripening chambers. Both chambers contained 60 trolleys (three in a row) loaded with 12 tons of the same sausage in total.

Conventional ripening chambers (type 1) work on a basic principle: Inlet air flow enters the chamber via two separate nozzles batteries, located at both sides of the ceiling. A rotary valve periodically varies the amount and ratio of air exiting the two feeding ducts. The inlet air flows descend vertically along the side walls and are diverted at the chamber bottom into a horizontal flow. Both jets merge over the bottom. The merging point is shifted periodically over chamber width by the variation of the ratio of the air inlet flows between both sides. In the following upward zone, the air stream flows through the sausages towards an exhaust channel located on the ceiling midsection.

In this flow type, dry air gets transported to the lower chamber areas with high velocity. Passing the sausages, the flow decelerates and due to water transfer from the sausages the saturation level of the humidity rises simultaneously. This results in an inhomogeneous drying over the height of the trolleys.

For this reason, a new type of ripening chamber (type 2) was developed (Ness & Co. GmbH, Remshalden, Germany), which uses two additional inlet nozzles batteries installed horizontally (Fig. 1). The airflow here is also distributed periodically between the two feeding ducts by a valve. The jets merge in the headspace and pass the sausages from the top to the bottom of the rack. Afterwards the air stream flows along the floor towards an exhaust duct located at the bottom of the left side of the chamber. Through a periodic change between these two flow types (vertical and horizontal), drying errors can be avoided.

Measurement of relative humidity RH

The RH and the temperature were measured with capacitive RH sensors (Model FH A646, Ahlborn, Holzkirchen, Germany). Eight sensors were fixed on a square steel bar at intervals of 20 cm (Fig. 2). This bar was attached in the middle of a trolley. The data were recorded by a data acquisition unit (Almemo 8990-8, Ahlborn, Holzkirchen, Germany). The trolley with the sensors was placed in different positions inside the chamber, in the case shown here, in the middle of the first row.

Results and discussion

Figure 4 shows a typical trend for RH values over the height of a trolley in chambers with vertical inlet flow. Sensor 1 was below the sausages, sensors 2-7 were arranged over the height, sensor 8 was in the head space. There has been a stratification from the bottom, with prevailing dry air from the climatisation, to the top, where the air has accumulated water from the sausages surface. The cyclical variations in the diagrams are due to the rotary valve in the feeding duct. Corresponding to the valves' position the RH values differ from 6 up to 12 %. This large difference causes an inhomogeneous drying within the trolley (Fig. 3). The sausages on the top of the trolley showed a bright reddish color, which indicates a low drying rate, in the lower positions the sausages were glaring red, caused by a high drying loss.

For the investigation of the relative humidity without forced convection, the fan has been stopped for 15 minutes. In this period the RH values increased asymptotically. RH should not be increased too much, otherwise a micro-climate will develop, where moulds and yeasts can grow on the sausage surfaces. The RH difference between the lower and the upper sensors has been reduced, because the values of the lower positions increased stronger (Fig. 5). After restarting the fan the RH values rearranged themselves quickly. Stopping the fan or reducing the fan speed cyclically can therefore be used in the later ripening phase to achieve a more homogeneous drying of the sausages and to save electrical energy. Figure 6 shows the influence of changing the inlet airflow direction from horizontal to vertical inlet airflow on the distribution of the relative humidity. After changing the inlet airflow direction at a run time of 25 min, the RH values of the lower positions increased while the values of the sensors on the top decreased. The result was a "cross-over" of the charted humidity values. So the change from horizontal to vertical inlet airflow direction had a positive influence of reducing the RH values differences over the trolley height. For this reason the periodic change from horizontal to vertical inlet airflow is an adequate means to achieve a homogeneous drying rate over the height in the whole chamber.

Conclusions

The inlet air flow direction in ripening chambers influences the drying rate, not only by convection but also by the distribution of relative humidity. In chambers with vertical inlet flow (type 1), the RH is stratified with the effect of an inhomogeneous drying over the trolley height. Cyclically interrupting the inlet air flow can be used to achieve a slightly better drying result. In newly developed ripening chambers (type 2) the problem of an inhomogeneous drying by RH layers has demonstrable been improved by a periodical change of the flow direction.

EFFECTS OF COOKING TEMPERATURE AND TIME ON GEL FORMATION ABILITY AND COLOR OF SURIMI-LIKE PORK

Young-Hwa Hwang, Geun-Ho Kang, Nak-Ju Sung, Gu-Boo Park and Seon-Tea Joo[1]

Division of Applied Life Science, Gyeongsang National University, Jinju, Kyeongnam 660-701, Korea
[1]Regional Animal Industry Research Center, Jinju National University, Kyeongnam 660-758, Korea

Background and objective

Recently there has been considerable interest in manufacturing surimi-like materials (SLM) from the muscle of animal species. The characteristics of SLM from poultry meat, beef, pork, and sheep meat and also from meat by-products, such as beef or pig hearts have been studied (Kang et al., 2003; Lesiów and Xiong, 2003; Park et al., 1996). When the red meat is used to produce SLM, the high fat content of red meat, the more heme pigment and the high concentration of collagen cause several problems. Moreover, gel-forming properties are the most important attribute because surimi is formed and then cooked to make products. Several studies have been made to assess the effect of different temperatures on the gelation properties of SLM. Park et al. (1996) insisted that heating rate, endpoint temperature, protein level and source are important factors in developing gel texture of SLM. However, there is a little information on the gel forming characteristics of surimi-like pork. Understanding the gel forming mechanism of SLM by heating could increase the value of unpopular cuts or by-products of pork, increasing profitability. The objective of this study was to evaluate the effect of various cooking temperatures and times on gel properties of SLM made from pork.

Materials and methods

The *semimembranosus* pork muscle was obtained by hot boning, commercial vinyl pack-packed and stored during 3 days at cold room (2□4℃). After aging, removal of caps, vessels and external fat tissue, the lean muscle was diced into approximately 2 ㎝ cubes, and ground through a 4.7 ㎝ diameter orifice with a Kitchen Aid mince, then frozen at -60℃ until processed. The diced muscle was thawed at 4℃ for 24 hr. The lean muscle was chopped in a silent cutter with five volumes of iced water and the resulting slurry was filtered through a metal sieve of 1 mm mesh to remove connective tissue and filtered through in a metal sieve of 500 one more time. After filtered slurry was centrifuged for 15 min at 2,220 g at 4℃ and the supernatant discarded. The residue was re-washed with five volumes of water. A final wash was done in 2.5 volumes (v/w based on original weight of mince) of cold water. The washing procedure was repeated a third time. The resulting residue was centrifuged for 10 min 2,220 g at 4℃ and the supernatant discarded. For washed pork muscle, wet samples were stand upside down centrifuge bottle (500 ml) at cold temperature room for 10 min then removed free water of excess. Finally, SLM were re-mixed with 3% NaCl w/w, 0.5% tripolyphosphate w/w and 4% sorbitol w/w in a silent cutter for 4 min. The mixed SLM was stored in deep freezer at -60℃ and functional property by various cooking temperature were evaluated after 1 week. Stored SLM were kept overnight at 4℃ then stuff into a 62 mm diameter PVDC (polyvinylidene chloride) casing. SLM was heated for 20 min in a water bath at a constant of 65, 70, 75, 80 and 85℃, and heated at 75℃ for 15, 20, 25 and 30 min. Color (CIE L* and Hue) of cooked SLM was measured using a Minolta Chromameter CR-301 (Minolta Co., Japan) and Gel strength was measured with Sun Rheo Meter (COMPAC-100, Japan).

Results and discussion

The values of lightness, yellowness, chroma and hue were significantly ($p<0.05$) increased, whereas redness was significantly ($p<0.05$) decreased of cooked surimi-like pork by increasing of cooking temperature. pH and moisture % were significantly ($p<0.05$) increased as increasing of cooking temperature over 75℃. Also, hardness, springiness and gel strength were increased linearly as increasing of cooking temperature. Gel properties were evaluated by cooking times at cooking temperature 75℃. There was no significant difference in moisture % of cooked surimi-like pork among cooking time treatments. However, water-soluble protein solubility was decreased as increasing of cooking times. The values of lightness, hue and chroma were significantly increased with increasing cooking times, but lightness value was not changed over cooking of

25 min. Hardness and gel strength values of cooked SLM at cooking time of 15 min were significantly higher compared to cooking times over 20 min. However, panel evaluated the surimi cooked for 15 min as having a poor gel formation ability because it was too sticky.

Sarcoplasmic protein fraction pattern in SDS-PAGE showed that various enzymes were decreased as increasing of cooking times. The A band (phosphorylase) was remained at cooking of 15 min, but it was disappeared over 20 min cooking. The B (about 60 kDa) and D band (about 32 kDa) were remained until 30 min cooking, and they were dim at 35 min. Intensity of C band (about 46 kDa) was decreased at 20 min, and then it was disappeared. These results suggested that enzymes remained in sarcoplasmic could attribute to dark color and undesirable gel formation ability of cooked surimi-like pork. Especially it was assumed that approximately 46 kDa protein might be related to gel formation ability and color of cooked surimi-like pork.

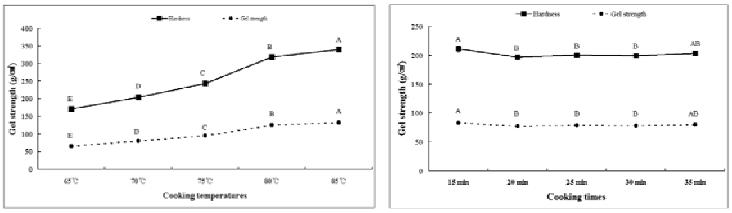

Fig. 1. Effect of cooking temperature and time on gel strength of cooked surimi-like pork.
Mean±S.E. $^{A-E}$Different letters are within a column indicate significant differences between mean values ($p<0.05$).

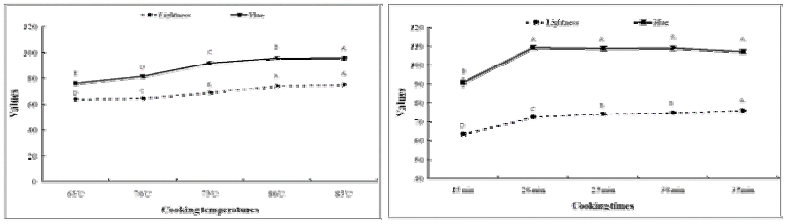

Fig. 2. Effect of cooking temperature and time on color values of cooked surimi-like pork.
Mean±S.E. $^{A-E}$Different letters are within a column indicates significant differences between mean values ($p<0.05$).

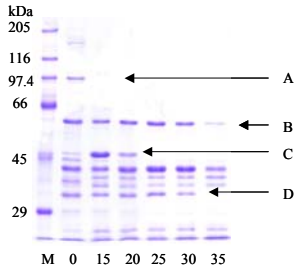

Fig. 3. Changes in protein fraction patterns of surimi-like pork by cooking times at at 75℃.

Conclusions

Gel strength and color of cooked SLM were improved as increasing of cooking temperature. Cooking time of 15 min at 75℃ was not enough for a desirable gel formation and color of SLM. Sarcoplasmic proteins that were not disappeared by cooking might be a reason for undesirable gel formation ability and color of cooked surimi-like pork.

EFFECTS OF HIGH-PRESSURE TREATMENT ON INTRAMUSCULAR COLLAGEN MOLECULE

Ichinoseki, S.[1], Nishiumi, T.[2], Sakata, R.[3] and Suzuki, A.[2]

[1] Graduate School of Science and Technology, Niigata University, Niigata 950-2181, Japan

Background

High-pressure treatment is an attractive application for foods, because that make possible non-heat food processing. High-pressure treatment is also one of the new technologies for tenderizing meat or accelerating meat conditioning (SUZUKI *et al*., 1998). Meat tenderness was determined by both actomyosin toughness attributed to myofibrillar proteins and background toughness attributed to connective tissue proteins mainly composed of collagen. It has been well known that high-pressure treatment causes the structural changes in a number of myofibrillar proteins. However, little is known about the effects of pressurization on connective tissue. We reported that intramuscular connective tissue was tenderized by high-pressure treatment and thermal stability of intramuscular collagen was decreased with pressure applied (ICHINOSEKI *et al.*, 2003). We also observed the structural weakening of perimysium and of perimysial-endomysial junction by high-pressure treatment.

Objectives

The purpose of this study was to confirm whether intramuscular collagen molecule could be degraded by high-pressure treatment. In this study, SDS-PAGE and differential scanning calorimetry of pepsin-soluble collagen and determination of collagen-derived peptide were investigated.

Materials and methods

Lean meat was removed from the shoulder of 76-86 months old Holstein cows 1 day after slaughter and stored at –20˚C. As required, it was tempered overnight in a cold room at 4˚C.

1. Isolation of intramuscular connective tissue

Intramuscular connective tissue was isolated by the method of FUJII & MUROTA (1982). After minced, muscle sample was homogenized in 10 mM Tris-maleate buffer, pH 7.2 containing 0.1 M KCl. Fibrous material in suspension was collected by passing the homogenate through a sieve with 1.0-mm pore. The residue was extracted with Hasselbach-Schneider solution and then 0.6 M KI-0.06 M $Na_2S_2O_3$. The insoluble residue containing collagen fibril was washed with distilled water. A part of the isolated connective tissue was lyophilized, and remainder was used for the following analysis.

2. Preparation of pepsin-soluble collagen

The isolated connective tissue was suspended in 0.5 M acetic acid containing 1 mg/ml pepsin and stirred overnight. The supernatant was collected by centrifugation at 100,000 *g* and precipitated by 2 M NaCl. After centrifugation, the pellet was resuspended in 50 mM acetic acid, extensively dialyzed against 5 mM acetic acid and then lyophilized.

3. Pressurization

Intramuscular connective tissue or pepsin-soluble collagen was packed in a polyethylene bag, sealed with cold distilled water and pressurized at 100-500 MPa for 5 min at about 8˚C using an isostatic press apparatus (Nikkiso KK, Tokyo).

4. SDS-PAGE of collagen

SDS-PAGE of collagen was carried out according to the method by HAYASHI & NAGAI (1979). Pepsin-soluble collagen was dissolved to a final concentration of 2 mg/ml in sample buffer (0.01 M Tris-HCl, 3.6 M Urea, 1% SDS, 1% β-mercaptoethanol, 0.01% BPB, pH 6.8). After heating at 100℃ for 3 min, the sample was subjected to SDS-PAGE analysis. Gels were stained with Coomassie brilliant blue R-250.

5. Differential scanning calorimetry (DSC)

Lyophilized pepsin-soluble collagen with or without high-pressure treatment was swollen in distilled water and then was put into the DSC stainless container. DSC was carried out using Setaram micro DSC VII at a heating rate of 0.5˚C/min and temperature range from 0 to 100˚C.

6. Determination of collagen-derived peptides

After pressurized, intramuscular connective tissue was suspended in twice volume of distilled water, and then centrifuged at 10,000 *g*. The supernatant was used for determining hydroxyproline content of collagen-derived peptides obtained by addition of trichloroacetic acid solution (final conc. 5%) (Fig.1). Hydroxyproline concentration was measured according to BERGMAN & LOXLEY (1963).

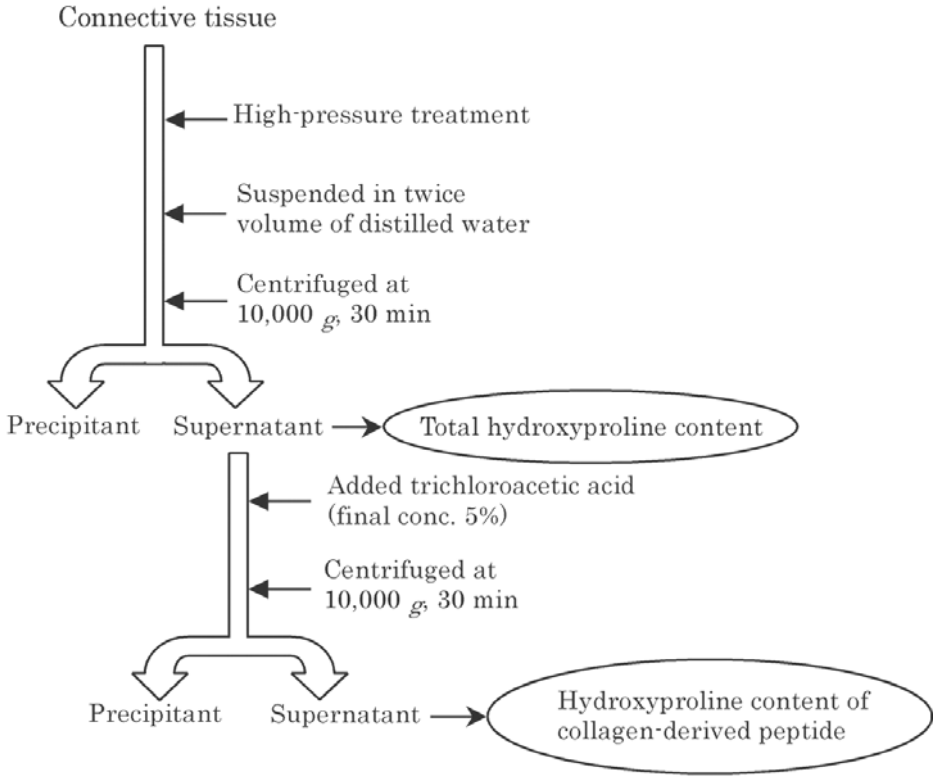

Fig.1 Scheme of determination of collagen-derived peptide.

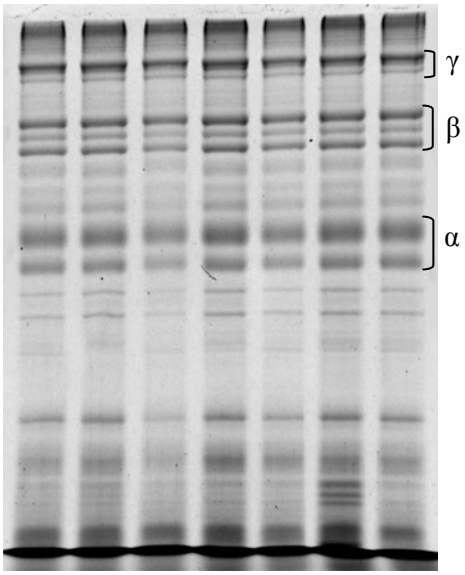
Results and discussion

SDS-PAGE profile of pressurized pepsin-soluble collagen was shown in Fig.2. It observed that α, β and γ chains of collagen had no significant changes with pressure applied, which suggests that high-pressure treatment could not degrade collagen molecule.



(0.1) (100) (150) (200) (300) (400) (500)

Fig.2. SDS-PAGE profile of pepsin-soluble collagen.
(0.1) untreated, (100) pressurized at 100 MPa, (150) pressurized at 150 MPa, (200) pressurized at 200 MPa, (300) pressurized at 300 MPa, (400) pressurized at 400 MPa, (500) pressurized at 500 MPa.

Denaturation temperature of pepsin-soluble collagen was shown in Table.1. Pressure-induced significant changes in the denaturation temperature suggesting the denaturation of collagen molecule were not observed.

Table.1. Effect of pressurization on denaturation temperature of pepsin-soluble collagen.

Pressure applied (MPa)	0.1	100	300	500
Denaturation temperature (˚C)	42.9	42.7	42.0	42.3

Total hydroxyproline content in the supernatant (See Fig.1) increased with an increasing pressure applied, while hydroxyproline content of peptide fraction did not change. The proportion of collagen-derived peptide in exudation decreased from about 50% at 0.1 MPa (untreated) to about 20% at 400 MPa. These results suggest that high-pressure treatment could not degrade collagen molecular structure but could dissociate collagen super molecular structure, e.g. collagen fibers or fibrils, to collagen molecule.

Conclusions

From these results, it is suggested that the pressurization may cause some changes in the intramuscular collagen. The changes may not be involved in the degradation of collagen molecules but dissociation of collagen fibers or fibrils.

Background

In the last few years there has been a strong increase in the request and development of light products, that is, those of low-fat contents. In conventional cooked sausages, animal fats are an essential ingredient easily representing a 20-25% of the global composition. Reduction of the fat level has negative repercussions on the sensory quality of the final product, affecting mainly its texture.
The adequate combination of several compounds such as proteins, starches and hydrocolloids allow achieving a low-fat product with similar characteristics of texture the conventional product has. (Glicksman, 1991). There are a broad group of compounds with high functionality, but it is very important its adequate combination since sausage emulsion is a complex matrix where synergetic actions or complementation of properties of ingredients bring about (Dziezak, 1991; Keeton, 1994, Ordoñez et al., 2001).
In low fat product design, extrapolation of texture properties of final product from texture measurement of emulsion characteristics would be very useful. There are two instrumental methods to study semi-solid foods as emulsions, dough, jellies, etc. Both of them give a measurement of the compression force when product is extruded. Their differences are based on method of extrusion: Direct and back extrusion.

Objectives

The aim of this work was to find an easy instrumental measurement of sausage emulsion characteristics that can predict texture properties of final product, especially to be used in low fat sausages design.

Materials and methods

Emulsion texture analysis: Three different meat emulsions were used to establish analysis conditions. These emulsions differ with respect to protein and fat contents. Emulsion A was made with 13% protein and 13,3% fat, emulsion B 10% protein and 18% fat, emulsion C 8% protein and 13% fat. The rest of ingredients (water, additives, starch, etc) were added in the same amount to the three formulations.
The three experimental emulsions were evaluated by direct extrusion (probe A/BE) and back extrusion (probe HDP/FE5) with a texturometer Stable Micro Systems TA.XT2 (Haslemere, England). Maximum force along extrusion were taken and considered related to viscosity of emulsions. According to SMS Application Studies (1995), the maximum peak force (obtained from the F/t curve) is correlated with the viscosity of the product. Differences between both tests are based on how the product is extruded. Using the A/BE probe, the product is extruded up and around the edge of the disc plunger. However, with HDP/FE5 the product is extruded through a standard size outlet in the base of a sample container. Each data correspond to three measurements on 100 g emulsion at 20ºC in standardised containers. Compression percentages of 10, 15 and 20% and speeds of 0.8, 1 and 1.2 mms^{-1} were tested with both probes to determine the analysis conditions. Final conditions were 20% of compression and cross-head speed of 1 mms^{-1}. (Severiano Pérez, 2002).

Sausage texture analysis: Texture Profile Analysis (TPA) were performed with a probe of 50 mm of diameter using a Texturometer Stable Micro Systems TA.XT2 (Haslemere, England). Analysis conditions were level of compression of 55% with respect to initial height of sample and 1 mms^{-1} cross-head speed. Sausages, vacuum packed, were heated in water at 75ºC for 15 minutes. Samples were obtained by cutting off the ends of sausage, then the remaining sausage were divided into pieces of 10 mm length. Samples were held at 70ºC during instrumental evaluation. An average curve of consecutive measurements on ten portions of each sample were obtained. Texture parameters hardness, chewiness, adhesiveness, springiness and cohesiveness were deduced from the resulting force-time curve (Breene, 1975).

Sensory evaluation of texture was performed by a trained panel, constituted by twelve members. The selection and training of panel was done according to Severiano Pérez (2002). Texture attributes elasticity, hardness, chewiness, cohesiveness, adhesiveness, juiciness and fat perception were evaluated using a nine point scale. Samples were prepared identically than for instrumental analysis.

Experimental sausages: Five sausages were prepared with different fat contents and hydrocolloids added: carrageenan and xanthan gum and Genugel®, type CHP-200 (HERCULES, Copenhaguen, Denmark), a commercial mix of carrageenan and xanthan gum. Table 1 shows the content of these ingredients added with a view to modified emulsion properties and texture of light sausages. In all formulations, sausages were made with pork meat and fat and included 2% salt, 2% soya protein, 1.3% starch, polyphosphates, nitrite, ascorbic acid, flavourings and colouring.

Sausages were manufactured following a conventional process; sausage batter stuffed in 22 mm cellulose casings (Viscofan, Pamplona. Spain) was cooked until 72ºC internal temperature. Sausages were vacuum packed and kept under refrigeration until analysis in the same week they were manufactured. Two batches were made.

Results and discussion

First at all, it was verified there was no significant difference between batches for any parameter analysed. No differences were detected neither in both types of extrusion tests nor in sausage texture parameters.

The effect of reduction of fat content was remarkable on viscoelastic properties; emulsion A presented the highest force value compared with low fat emulsions (B, C, D and E). Therefore, decrease of percentage of fat lead to lower values of extrusion force, and this parameter could be considered an index of emulsion viscosity (Figure 1). The influence of fat level on emulsion viscosity could be determined both by direct extrusion and back extrusion. On the other hand, results of back extrusion show lower force of emulsion B (0.6% commercial mix Genugel®), than the other low fat emulsions. Emulsions C, D and E have very similar viscoelastic properties. Bigger differences were expected in emulsion characteristics according to previous studies (Severiano Pérez, 2002). However, there is enough variability to be able to study the possible correlation between textural properties of emulsion and texture of sausage.

Figure 2 shows mean values of instrumental texture parameters of the two batches. No significant differences between sausages were found in springiness, cohesiveness and adhesiveness. It was expected bigger differences between sausages, especially those made without hydrocolloids. Concerning to springiness and cohesiveness, these results do not agree with Mittal and Barbut (1993), who found higher springiness and cohesiveness in low-fat products (12-14% fat) than in conventional sausages (26% fat). Sausage A (conventional content of fat) is considerably harder and presents a higher chewiness than low fat sausages, being sausage B and E sausages with medium hardness and chewiness and sausages C and D are situated in the lowest extreme with respect to both parameters. There is disagreement in previous references about texture of low fat sausages and the effect of functional ingredients, with no modification of texture (Mittal et al., 1993, Bloukas and Paneras, 1996) or decrease or increase of hardness (Hand et al., 1989, Decker et al., 1986, Ordoñez et al., 2001).

Results of sensory evaluation of texture are similar to those found in instrumental measurement as it was expected. Parameters with significant variability between sausages were only hardness, chewiness and cohesiveness. Sensory texture profile follows the same pattern described in instrumental texture, corresponding the highest and lowest values of hardness and chewiness to sausages A and B, respectively, as described above. Sensory evaluation showed significant differences in cohesiveness, but the only two sausages clearly different are A and E. No differences between sausages were detected in elasticity, adhesiveness and juiciness.

Concerning to correlation between force resulting of extrusion tests on meat emulsion and sausage texture, irrespectively of method used (direct or back extrusion) significant correlations were found only with hardness and chewiness and cohesiveness sensory evaluated (Table 2).

Conclusions

Measurement of characteristics of emulsion by extrusion tests give an easy and quick estimation of texture of sausages after processing with respect to hardness and chewiness, two of the main constituents of texture. This measurement as an index of sausage texture is also useful in low fat products and results of both direct and back extrusion tests are comparable. However, further research on emulsions and sausages with bigger differences in other texture parameters as elasticity, adhesiveness and juiceness is necessary to determine the accuracy of extrusion force to predict a wide texture profile of sausages.

GEL PROPERTY OF SURIMI-LIKE MATERIAL FROM PRE- OR POST-RIGOR PORCINE MUSCLE

Geun-Ho Kang, Han-Sul Yang, Sun-Jin Hur[1], Seon-Tea Joo and Gu-Boo Park[1]

Division of Applied Life Science, Gyeongsang National University, Jinju, Kyeongnam 660-701, Korea
[1]Regional Animal Industry Research Center, Jinju National University, Kyeongnam 660-758, Korea

Background and objective

Surimi-like material from muscle of other animal species has been hypothesized to have similar properties to surimi from fish (Park et al., 1996). However, there is a little information on the preparation of surimi-like material from beef or pork. Pre-rigor beef is generally recognized to have superior functionally when used in the manufacture of processed meat products (Hamm, 1981). Salting of pre-rigor beef is known to promote maintenance of high binding quality (water and fat stabilization, texture development) during short-term refrigerated storage, presumably by solubilization the protein prior to a tight association of actin and myosin. Park et al. (1987) reported use of cryoprotectants to stabilize functional properties of pre-rigor salted beef during frozen storage. Also Park et al. (1993) reported cryostabilization of functional properties of pre-rigor and post-rigor beef by dextrose polymer and phosphates. The objective of this study was to evaluate the effect of rigor conditions of porcine muscle on gel properties of surimi-like material (SLM).

Materials and methods

Pigs were slaughtered at a Meat Plant of Gyeongasng National University, Jinju, Korea. The *semimembranosus* muscle was obtained by hot boning. After removal external fat tissue, the lean muscle was divided into three portions. For pre-rigor sample, one of the three portions was diced into approximately 2 ㎝ cubes, and ground through a 4.7 ㎝ diameter orifice with a Kitchen Aid mince, and SLM was manufactured. The others samples are commercial vinyl pack packaged and stored at cold room (2 ˚C 4 ˚C) until processed at *post mortem* 24 or 72 hrs. The *post mortem* 24 hr (rigor-mortis) and 72 hr (post-rigor) samples were also used for SLM manufacture, and the SLM manufacture procedure was modified to method of Park et al. (1996).

SLM yield % and color (CIE L*, Chroma and Hue) of SLM gel were measured using a Minolta Chromameter CR-301 (Minolta Co., Japan). Moisture content of uncooked and cooked SLM, and water-holding capacity (WHC) and water–binding capacity (WBC) were measured. Gel strength of cooked SLM was measured with Sun Rheo Meter (COMPAC-100, Japan) and SDS-PAGE was applied to investigate changes in sarcoplasmic and myofibrillar proteins of SLM.

Results and discussion

All SLM from muscles at pre-riogor, rigor-mortis and post-rigor was a light, opaque material with a dough like consistency. When additives (salt, TPP and sorbitol) were mixed with surimi-like pork, the material became comparatively clear and sticky. Specially, SLMs of pre-rigor and rigor-mortis muscles were lighter than that of post-rigor muscle after cooking. When pre-rigor muscle was used, more color was removed with the first washing step, resulting in lighter water washed material. After cooking of SLM, there were significant differences in Chroma and Hue values among treatments (Table 1). This color effect had been reported previously by Lan et al. (1993) and Park et al. (1996). However, yield % of pre-rigor muscle was sigificantly decreased compared to rigor-mortis and post-rigor muscles. Results suggested that sarcoplasmic proteins including pigments such as myoglobin and residual hemoglobin in pre-rigor muscle could be removed easily by water washing, resulted in having decreased yield of SLM. This was confirmed in sarcoplasmic proteins fraction of SDS-PAGE. Intensities of some sarcoplasmic enzymes such as phosphoylase were dim in rigor-mortis and post-rigor muscles (Fig. 2.). The sarcolasmic enzymes were still remained with myofibrillar proteins fraction in SLM.

Although WHC of SLM from post-rigor muscle was significantly lower (Table 2), gel strength and hardness of cooked SLM were significantly ($p<0.05$) stronger and harder in post-rigor muscle than those of other muscles (Fig. 2). Gel forming ability could be influenced by differences in WHC, WBC, protein concentration, ultimate pH and heating condition of SLM (Park et al., 1996). The lower moisture % in SLM

from post-rigor muscle might be related to gel strength and hardness. The lower moisture % in SLM implied that more concentration of proteins would be in SLM. Therefore, the harder gel of post-rigor muscle might be due to a higher concentration of protein in SLM without regard to the lower WHC. These results indicated that strong gel could be obtained with post-rigor porcine muscle because of higher concentration of protein in SLM. The post-rigor muscle, however, could produce dark color that would be avoid for surimi products. It was assumed that the dark color of SLM from post-rigor muscle might be due to a high concentration of sarcoplasmic proteins, oxidation of lipid and protein and the small space of gel matrix resulted in stronger absorption nature than reflection nature of light.

Table 1. Yield % and color of cooked SLM from different rigor conditions of porcine muscle

Muscle conditions	SLM yield %	CIE L*	Chroma	Hue
Pre-rigor	82.33 ± 7.42^{B}	78.51 ± 0.22^{B}	3.16 ± 0.07^{C}	159.61 ± 1.73^{A}

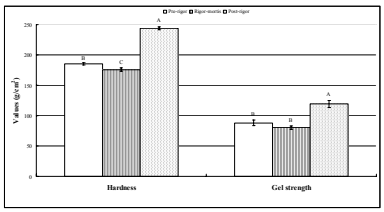

Fig. 2. Gel strength and hardness of cooked SLM from rigor conditions of pork. $^{A-C}$Different letters are within a column indicates significant differences between mean values ($p<0.05$).

Conclusions

A bright and white surimi could be obtained with pre-rigor porcine muscle, whereas a strong and hard surimi could be obtained with post-rigor muscle. However, post-rigor muscle can produce a dark color surimi and pre-rigor muscle can decrease yield % of surimi.

METHOD AND DEGREE OF MECHANICAL TENDERISATION OF BEEF MUSCLES FOR USE IN RE-FORMED JOINTS MADE WITH A COLD-SET BINDER

A.M. Lennon, S.S. Moon, T.A. Kenny and P. Ward
Teagasc, National Food Centre, Ashtown, Dublin 15, Ireland

Background

The purpose of producing reformed beef products is to effectively market less valuable carcass components. These contain high levels of connective tissue and therefore require tenderisation for such products (Rolan et al, 1988). Tenderness is the single most important factor affecting consumers' perception of taste in beef (Morgan et al, 1991). Beef round and chuck are traditionally marketed in the form of low priced steaks or roasts. The present study is part of a project designed to increase the value of some muscles from these cuts through tenderising and re-forming treatments. Glitsch (2000) found that for European consumers, tenderness and flavour were the most important factors in eating quality of beef. Numerous reports have indicated that mechanical tenderisation reduces shear force values (Jeremiah et al, 1999). It has also been established that beef steaks and pork chops are more juicy and tender when injected with a phosphate and salt-containing solution (Robbins et al, 2003). Tumbling or massaging treatment is also used in the industry to increase tenderness. In this study several tenderising methods were assessed in conjunction with preparation of re-formed beef joints using Activa ™ (Ajinomoto Ltd.). The active ingredient in Activa is transglutaminase cross-bonding enzyme which catalyses the polymerisation and cross-linking of proteins (Kolle and Savell, 2003).

Objective

The objective was to compare the effects of three different methods of tenderisation on the processing characteristics and tenderness of two muscles selected from the beef chuck and two from the round.

Materials and methods

Beef muscles used were from the chuck (*M. pectoralis profundus* and *M. supraspinatus*) and round (*M. semimembranosus* and *M. vastus lateralis*) of R4L grade steers 4 days post-slaughter. *Semimembranosus* muscles were seamed out of the topside round and *Vastus lateralis* muscles were seamed out of the knuckle. The heavy central piece of connective tissue was removed from the *Supraspinatus* and the *Pectoralis profundus* was used whole. Muscles were trimmed of all visible external fat and connective tissue. Sufficient quantity of each muscle was pooled together to make twenty 19 x 13 x 7.5 cm joints (approx. 2kg weight) for steak cutting, a quarter being assigned to one of four treatments- 1) non-tenderised, 2) blade tenderised, 3) needle tenderised and 4) injected + vacuum-pulsed, giving five replicates of each treatment. For roasting joint production, which was an additional product made in the case of the injected + vacuum-pulsed treatment, five more such joints were made for each muscle group and these were compared with five commercial silverside round roasts. Blade tenderised (BT) muscles were passed once through a commercial roller-blade tenderiser. With this tenderiser, meat is passed between two rollers of 305mm length, with 78 blades per roller (blade width 1mm, 3.9mm interval between blades). Each blade contains 20 teeth of 9mm width with a 10mm interval space. Blades from opposing rollers overlap by 10mm. Needle tenderised (NT) muscles were passed once through a commercial Tender Star Model TSE tenderiser with solid stainless steel chisel-shape needles (needle diameter 1mm, at chisel end 2mm). The needle bank area of 250mm x 80mm contained 574 needles. Injected and vacuum pulsed muscles (VP) were injected with brine using a Dorit PSM-21 Inject-O-Mat brine injector at 16% to give a concentration of 0.5% salt and 0.3% sodium tripolyphosphate (STPP) in the meat, chopped to give pieces of ~200g weight and vacuum-pulsed for 14 hours in a Rühle vacuum tumbler/ mixer (Model MKR 150-600, Rühle GmbH) using a "Tender beef " programme which alternated between 90% and 10% vacuum (100 and 900 hPa). BT and NT muscles were also cut into ~200g pieces following treatment. Activa ™TG-RM at a level of 1% (% of raw meat weight) was whisked with 4% water until homogenous, and the suspension was then mixed with meat chunks, ensuring each piece was fully coated. Meat pieces were then layered in a polythene-lined rectangular-shaped mould (1.5-2.0kg per mould), vacuum packed and held at 2ºC overnight to allow completion of the protein

cross-linking reaction. Controls (CO) were treated in the same way but omitting the tenderisation step. The formed meat was removed from moulds and liners, and cut into steaks of 2.54cm width. Steaks were vacuum packaged and held at 2ºC pending analysis, with the exception of steaks for taste testing which were frozen at –20ºC for a minimum of one week. In the case of the injected and vacuum-pulsed treatment, joints for roasting were made in the same way but not cut up into steaks. They were then vacuum packaged in Cryovac cooking bags and following overnight holding cooked in a Jugema steam/ air cooker to an internal temperature of 70ºC using a cabinet temperature of 82ºC and a relative humidity of 99%. Five commercial round roasts made from the silverside, averaging 1kg in weight were cooked for comparison. Steaks were tested for cooking weight-loss, Warner-Bratzler shear force (WBS), colour (L*a*b*) and eating quality. Total viable bacteria counts (TVCs) at 30ºC were determined for steaks from one forequarter muscle (*Pectoralis*) and one hindquarter muscle (*Semimembranosus*) on day 0 and day 7. Cook loss was measured on the day steaks were cut and WBS on the following day. Cook loss was measured by weighing both prior to and after cooking to a core temperature of 70ºC. Shear values of 7 cores of 13mm diameter sheared perpendicular to meat fibre direction were measured. Colour was measured using a HunterLab spectrophotometer (Ultrascan XE) on the cut surface of PVC film-covered steaks after 1 hour blooming in air at 2ºC on the same day that steaks were cut. Measurements were taken on 10 locations per steak and averaged. Steaks for taste panels were thawed using cold running water. Taste testing was carried out on steaks grilled to a core temperature of 70ºC by a panel of eight people experienced in tasting beef. The panellists graded the samples for tenderness, chewiness, residual connective tissue, juiciness, overall flavour and overall acceptability on a scale of 1 (worst) to 6 (best).
Roast joints were tested for cook loss, texture (Kramer Shear Force), sliceability and eating quality. Cook loss was measured by weighing beef joints before and after cooking. Kramer Shear Force (KSF) was measured by placing approximately 30g of 1mm-thick roast beef slices in the bottom of a 10-blade Kramer Shear cell attached to an Instron model 4464 texture meter. Because of unavoidable weight variability between samples, measurements are expressed as Newtons force per g of meat sample. Sliceability was determined as the percentage of broken slices upon cutting 10 x 1mm-thick slices from a roast joint. Panels assessed taste and appearance of slices of the roast beef for colour acceptability, tenderness, juiciness, overall flavour, binding/ cohesion, overall acceptability and saltiness, on a scale of 1 (worst) to 6 (best). In the case of saltiness 1 represented not salty, 6 being extremely salty.
Analysis of variance of the results was carried out using the Genstat 5 Release 3.2 (Rothamsted Experimental Station). For total viable counts the analysis used was a split plot design.

Results and discussion

WBS results and taste panel ratings showed that type of tenderisation treatment significantly affected resulting steak tenderness (Table 1). For all except one muscle, CO samples, as expected, had higher WBS values than all other treatments, the exception being *Semimembranosus*, for which CO and BT samples were not different. Sensory panel tenderness ratings showed CO samples were significantly less tender than all treatment samples for 3 of the 4 muscles. Also in the case of 3 of the 4 muscles, BT had higher WBS than VP, and for both forequarter muscles, WBS values were higher for BT than NT. *Pectoralis* CO samples had higher WBS values than BT, NT and VP ($p<0.001$). This was also reflected in taste panel results where CO samples were rated less tender than BT and NT samples ($p<0.05$) and less tender than VP samples ($p<0.001$). CO samples were also rated more chewy than BT ($p<0.05$), NT ($p<0.01$) and VP ($p<0.001$) samples. Panellists also rated CO samples as having higher residual connective tissue content than BT ($p<0.05$), NT and VP samples ($p<0.01$). Overall acceptability ratings showed CO samples to be less preferable to NT and VP samples ($p<0.01$). BT samples had higher WBS values than VP samples ($p<0.001$), and were also rated less tender ($p<0.05$), more chewy ($p<0.01$) and less juicy ($p<0.001$) in sensory panels. *Supraspinatus* CO samples also had higher WBS values than all other treatments ($p<0.001$). This was reflected in sensory panel tenderness ratings for BT ($p<0.05$), NT and VP samples ($p<0.001$); chewiness ratings for NT and VP samples ($p<0.001$); residual connective tissue ratings for NT and VP samples ($p<0.01$) and overall acceptability ratings for NT and VP samples ($p<0.001$). BT *Supraspinatus* muscles had higher WBS values than NT and VP samples ($p<0.05$) and this was also reflected in tenderness, chewiness, residual connective tissue content and overall acceptability ratings for both muscles and in juiciness ratings for VP samples only. *Semimembranosus* CO samples had higher WBS values than NT ($p<0.01$) and VP ($p<0.001$) samples, but did not differ from BT samples. This corresponds to sensory panel ratings for tenderness, chewiness and overall acceptability, although panellists did differentiate between CO and BT samples, rating BT samples

better for tenderness, chewiness and overall acceptability. BT *Semimembranosus* samples had higher WBS values than VP samples ($p<0.01$) but this was not reflected in sensory results. *Vastus lateralis* CO samples had higher WBS values than BT, VP ($p<0.01$) and NT samples ($p<0.001$) but again, this was not reflected in sensory panel ratings. Overall, for all 4 muscles, VP samples were rated significantly more juicy than all others. They were also more tender in the case of all forequarter CO and BT samples, but panellists did not differentiate between these treatments in hindquarter muscles. WBS values also showed VP samples to be more tender than CO and BT samples for three of the four muscles. These results show that the superiority of the VP treatment over other tenderisation treatments used is evident in the forequarter muscles only, these having higher shear values than the hindquarter muscles in non-tenderised samples. These results correspond with a number of previous findings which indicated that brine-injection improves eating quality of beef e.g. Vote et al, 2000. Cook loss from steaks was not affected by treatments. Colour readings showed that for both forequarter muscles, NT samples were significantly lighter in colour, i.e. had higher L values than VP samples. There was, however, no difference in the lightness value between these two treatments in hindquarter muscles. *Supraspinatus* NT samples also had higher L values than BT ($p<0.01$) and CO samples ($p<0.05$). *Semimembranosus* CO samples also, had a lower a value than the corresponding NT samples (i.e. CO samples were less red than NT samples). Both hindquarter CO and BT samples had higher values than VP samples. Even though there were some differences in b values, no patterns emerged. From these results, overall, tenderisation treatments were not shown to have a negative impact on re-formed steak colour when compared to non-tenderised samples. Results of TVCs showed that for *Pectoralis* on day 0, the VP samples had a higher count than CO, BT and NT samples (VP=$5.1x10^5$ versus CO=$2.5x10^4$, BT=$7x10^4$, NT=$1.8x10^4$). On day 7, VP samples still had a higher count than all other treatments (VP=$1.7x10^6$ versus CO=$1.9X10^5$, BT=$4.9x10^4$, NT=$4.1x10^5$). Also, BT samples had higher counts than NT samples ($p<0.05$). *Semimembranosus* day 0 samples showed no differences between treatments, but on day 7 VP had higher counts than CO ($p<0.001$) and BT and NT samples ($p<0.01$). These results indicate that the injection and vacuum pulsing process allows for greater microbial contamination than the other tenderisation treatments used.

The comparison of roast beef slices from commercial silverside roast joints with those from the reformed joints showed (Table 2) that 3 out of 4 of the latter were as tender or more tender than the retail beef. Sliceability was better for reformed joints from all four muscles than for the commercial roasts. *Pectoralis*, *Semimembranosus* and *Vastus lateralis* reformed joints gave 100% sliceability and *Supraspinatus* gave 80%, while commercial silverside roast gave 67% sliceability. There was no significant difference in cook loss between commercial roasts and any of the reformed roasts.

Conclusions

All three tenderisation treatments used in this trial significantly reduced WBSF values, and in most cases these reductions were reflected in sensory panel ratings. Needle tenderisation and injection + vacuum-pulsing treatments gave about equal levels of tenderisation, while blade tenderisation had a lesser effect on tenderness. Injected + vacuum-pulsed samples retained more juiciness than those from other treatments for all four muscles. Tenderisation treatments were shown not to impair colour of re-formed steaks. Total viable bacteria counts indicated that injection + vacuum-pulsing results in higher counts than other treatments. Texture analysis of roast beef joints indicated that the commercial silverside roasts used for comparison, along with the *Pectoralis* roasts were both less tender than those from the other three muscles. The study indicates that needle tenderisation and injection + vacuum pulsing treatments are more effective than blade tenderisation for tenderisation of beef for use in reformed joints. Account needs to be taken of the possible higher bacterial numbers arising from the injection + vacuum-pulsing treatment.

Background

The structural origins of variations in meat tenderness, arising from various treatments or animal characteristics, are far from clarified. Results from macroscopic mechanical methods can lead to conflicting conclusions. Micro-mechanical tests performed on isolated structures (Lewis and Purslow 1989) allow clear understanding of the contribution of theses structures to the overall meat tenderness. Theses techniques have been used to elucidate the mechanical changes in connective tissue and muscle fibres associated with contraction state, ageing or cooking conditions (Christensen, Purslow and Larsen 2000). Only few data are available on the variations in the mechanical properties of these structures associated with different animal characteristics.

Objectives

The purpose of this study was to quantify heat induced changes, in mechanical properties of isolated perimysium sheets from beef muscles from two breeds.

Materials and methods

Muscles : *Semimembranosus* muscles were taken from cows (6 -7 years old) Holstein (12) and Salers (12). The muscles were removed from each carcass at 24h *post-mortem*. They were divided into 2 parts which were vacuum packed and stored at 4°C for 14 days and then frozen. One part was for measurements on raw meat and the other for measurements after 90 min cooking at 70°C.

Measurements :
All the samples were thawed in water at 10°C.
Measurements on raw meat:
The resistance of muscle fibres was measured in compression according to the method of Lepetit and Buffiere (1995) using an Instron 4501 testing machine. Sheets of perimysium (approximately 10 mm long x 4 mm wide) were dissected and tested with a micro-tensile device described below, for the determination of breaking stress, breaking strain, Young's modulus, breaking energy and total energy. The width of the samples were determined using a microscope and the thickness determined with a Mitutuyo micrometer under a force of 0.2N applied on the whole surface of the sheets. During the tensile test the samples were immersed in meat drip.
Measurements on cooked meat :
The cooking was done in water bath on 10x10x4 cm samples, the length in the direction of muscle fibres being 10 cm. Cooking losses were determined. The breaking stress of cooked samples was measured in compression with an Instron 4501 (Lepetit, Grajales, and Favier 2000). Sheets of perimysium (approximately 10 x 4 mm) were dissected from cooked meat and tested with the micro-tensile device. Width and thickness were measured as above. During the tensile test the samples were immersed in the liquid lost during cooking.
Micro-tensile test :
Tensile test was carried out on a micro-tensile device developed in this laboratory (figure 1). The procedure for handling samples is similar to that described by Lewis and Purslow (1989). After dissection, strips of perimysium were glued on aluminium foil frames with cyanoacrylate glue. The samples on the aluminium frames were then fixed on the micro-tensile device so that the direction of tensile testing was in the direction of collagen fibres.
The extension rate was 130 µm/s. The software applied a slack toe correction to the force – displacement curves to remove the part of the displacement where collagen fibres are just unfolded. The actual lengths of

the samples were determined from the rapid increase in force which happened when the perimysium structure entered into tension. The Young's modulus was calculated as the slope in the straight region of the stress – strain curves.

Statistical analysis :
For all mechanical variables means were obtained from 10 measurements. Data were analysed using the general linear model procedure of SAS Software (SAS/Stat Cary, NC: SAS Institute Inc., 2000).

Results and discussion

Meat from both breeds was not fully aged after 14 days of storage at 4°C as the resistance of muscle fibres were higher than the limit of 4 N/cm2 (Lepetit and Buffiere 1995) as seen in Table 1. Maximum compression stress of raw meat did not show any differences between breeds, but drip was significantly higher in meat from Salers than in Holstein. The breaking stress of cooked meat from Salers was significantly higher than from Holstein and cooking losses were similar between breeds (Table 2). The mechanical properties of perimysium sheets in the raw and cooked states are given in Table 3. The breaking stresses of perimysium sheets did not differ between breeds when compared raw or cooked, but there was a 36% reduction of the mean stress by cooking for 90 min at 70°C. The breaking strain was similar for both breeds in raw samples. For cooked samples breaking strain was slightly higher in Holstein than in Salers. Breaking strain increased, on average by 31% by cooking. Young's modulus decreased by 52% from raw to cooked. Breaking energy showed no significant variation neither between breeds nor from raw to cooked, whereas the total energy for the disruption of perimysium sheets showed a 25% reduction by cooking. The values of drip found for both meats (Table 1) include the drip occurring during 14 days of ageing and also the exudation due to thawing which explain why these values are quite high, but they are in agreement with values given by Offer and Knight (1988). The cooking loss agrees with values observed previously for the same muscle cooked in same conditions (Lepetit, Grajales and Favier 2000).

The breaking strain of perimysium sheets increased with cooking as collagen is progressively denatured and becomes rubber-like (McClain, Kuntz and Pearson 1969). Our values of breaking strain are much lower than those found by Lewis, Purslow and Rice (1991) for two reasons. First, in the present study, a slack toe correction was applied to the force-displacement curves to remove the displacement which corresponds to the unfolding of the collagen fibers. Secondly, the perimysium sheets in the present study, are cut parallel to one of the main directions of the collagen ply whilst samples in the study of Lewis, Purslow and Rice (1991) were cut perpendicularly to the direction of muscle fibers. Under those conditions, there is not only an unfolding of collagen fibers but also a reorientation of collagen fibers in the direction of the strain during the tensile test. In our samples no reorientation of collagen fibers occurred because they already are in the direction of strain and therefore a lower breaking strain is expected.

Values of the breaking stress from the present study are about four times higher than those reported by Christensen, Purslow and Larsen (2000) but here also precise comparisons are difficult due to the different type of samples. The present study concerned perimysium sheets from cull cows (6 – 7 years old) whereas the previous study concerned perimysium from young (2-2 ½) heifers and the resistance of connective tissue changes significantly with the age of animal as shown by adhesion measurements (Bouton and Harris 1972). Also differences in breaking stresses between the two studies may come from differences in sample shape and collagen fibre direction which both affect the number of collagen fibres contributing to the stress. Comparisons of Young's moduli lead to similar conclusions as for the breaking stress as they are highly correlated ($r=0.93$, $n=24$, $P<0.01$ for raw samples ; $r=0.87$, $n=24$, $P<0.01$ for cooked samples). Breaking energy, which represents the work done up to the maximum stress, was not affected by cooking. This results from opposing variations of breaking strain and breaking stress with cooking. There is a decrease in breaking stress and an increase in breaking strain due to cooking which lead to an almost constant breaking energy from raw to cooked. The total energy needed to separate perimysium sheets was significantly reduced by cooking. The energy which is developed after breakage is due to shear between collagen fibres. It represents about 60% of the total energy in raw samples and about 45% in cooked samples. It is this energy of shear which is decreased by cooking. In a fibrous composite material the energy of shear is supported by the matrix, which, in the case of perimysium, is composed of proteoglycans.

The maximum stress of compression of raw meat reflects mainly variations in connective tissue and therefore was not expected to vary between breeds as the data on perimysium sheets did vary between breeds. The small differences between breeds in maximum stress of cooked meat could not be linked to the minor variations between breeds in mechanical properties of cooked perimysium sheets.

Conclusions

Tensile tests on perimysium sheets isolated from *semimembranosus* muscles of cows from two breeds show significant changes with cooking (90 min at 70°C) in breaking stress, breaking strain, Young's modulus and total energy. On raw perimysium sheets no differences between breeds was observed which is in agreement with compression data on raw meat. The small differences between breeds in maximum compression stress of cooked meat cannot be linked to the minor variations in mechanical properties observed on cooked perimysium sheets.

DEVELOPMENT OF TECHNOLOGY FOR PRODUCTION OF MEAT-PLANT EXTRUDATES

Lisitsyn A.B.,Krylova V.B.,Oleinikov V.V.
GNU V.M. Gorbatov All-Russian Meat Research Institute, 109316, Moscow,Russia

Background

Extrusion technology is one of the advanced methods for obtaining high quality foods. The range of products manufactured using this technology includes more than 400 items: dry breakfasts, products for nutrition of children, cracker-type bread, potato chips, corn and wheat flakes, etc. /1/.
The advantages of extrusion technology consist in flexibility of its technological systems, continuity of the process, possibilities of simultaneous homogenization of raw materials and their thermal treatment which allow to solve many important problems in foods production, i.e. : preservation of biological and food value, inhibition of development of pathogenic microflora, formation of prescribed structural and mechanical properties and organoleptical characteristics.
These advantages indicate good prospects of use of extrusion technology in meat industry for development of meat-plant extrudates. It should be noted that the problems associated with peculiarities of formation of structure in the process of thermoplastic extrusion have been little studied.

Objectives

The purpose of this work was to investigate the influence of technological parameters of extrusion process (temperature, frequency of screws rotation) on structural and mechanical properties and quality characteristics of meat-plant extrudates.

Materials and methods

As objects of investigations were chosen products of animal origin: beef of 2nd grade, dry animal broth, light food grade albumin; of vegetable origin: corn starch and wheat flour. Second grade beef was comminuted (d = 2-3 mm) and mixed with other components in different ratio: 1) 2^{nd} grade beef, dry animal broth, corn starch; 2) 2^{nd} grade beef, wheat meal, corn starch; 3) 2^{nd} grade beef, light food grade albumin, corn starch. The mixtures were maintained during 12 hours at 4^0C for moisture level stabilization. Extrusion treatment was carried out on an experimental laboratory double screw extruder with the selected profile of configuration of screw elements of shafts for treatment of meat containing mixtures with the capacity of 40 kg/hr.
During investigations standard methods of determination of microstructure, mass fraction of moisture, fat, protein, carbohydrates were used. Digestibility of meat-plant extrudates was determined by the method (2). Structural-mechanical properties of extrudates were determined on the INSTRON - 1140 apparatus. Bulk mass p (kg/m^3) was determined by weighing in the capacity 1000cm^3. Coefficient of explosion $K_в$ was found as the ratio between bulk weights of mixture and final product.

Results and discussion

Quality of final products obtained as a result of extrusion treatment of selected recipe mixtures depends on quality of raw materials and parameters of the process: temperature of treatment of mixture and rotation frequency of screws.
Analysis of influence of extrusion treatment temperature shows that with temperatures <150 ^{0}C the extrusion process doesn't reach completion (Fig.1): biopolymeric mixtures don't melt to the end. At the exit from the extruder matrix there is no explosion of starch grains; the product is low-porous with low coefficient of explosion. Increase in the temperature from 150 to 180^{0}C results in $K_в$ increase; denaturation of native proteins and gelatinization of starches occur. In this case crystalline areas of biopolymers melt and the amorphous ones change from disordered high elastic state to a viscous-flow one, and as a result of sharp pressure drop - "decompression shock" - the extrudates have good porous structure /3/.
Temperature increase to higher than 180^{o}C leads to a decrease of the coefficient of explosion. This can be explained by more intensive Maillard reaction, the extrudates are strengthened, their porosity is reduced, and

hence, the coefficient of explosion is reduced, the extrudates acquire pronounced dark color and bitter off-flavor.

The investigations of the influence of rotation frequency of screws on extrudates quality have shown (Fig.2) that with low values of rotation frequency (12.7 s^{-1}) the shear stress of extrudates is not large. This occurs because the mixture is for a long time in the chamber of the extruder and undergoes strong destructive changes.

Proteins are destroyed to amino acids, polysaccharides to dextrins which interact forming different complexes. However, as a result of long effect of temperature, "block-dextrin" complexes are destroyed which results in low value of shear stress.

When the rotation frequency of screws increases to 13.7 –14.7 s^{-1} destruction of complexes "protein-dextrin" takes place not so intensively, but rather strongly. As a result the product is stronger, and the shear stress increases.

If the extrusion process is carried out with frequency rotation of screws 15.7 s^{-1}, the obtained extrudates are porous, easily crumble, don't have burned flavor.

With frequency rotation higher than 16.7 - 18.7 s^{-1}, the extrusion mixture is subjected to the effects of large shear characteristics with the result of destruction of mixture components, and hence shear stress increases.

The obtained extrudates (Table 1) are the products with high level of protein (8.9 – 15.9%) and low level of fat (0.35 – 0.58%).

The investigations on digestibility of these products have shown high degree of availability of proteins for proteases, which indirectly proves a deep destruction of proteins of meat-plant extrudates as a result of thermoplastic extrusion.

Investigations of microstructure of the comminuted extruded product (Figs. 3,4) (x 12) made it possible to establish that the main mass of particles in extrudates has plate-like corrugated structure and flowing internal structure. Methylene dye has clearly determined linear arrangement of protein component in the volume of the investigated particles. However, during the investigation mutually perpendicular orientation of protein and carbohydrate components was revealed. Muscle fibers that occur in the product consist of destroyed bundles of myofibrils with lost sarcolemma; there was a cross striation in some of their parts.

Conclusions

Thus, the experiments have shown that the technology of thermoplastic extrusion is suitable for manufacture of new kinds of meat products. To obtain extrudates of required quality meat-plant mixtures should be treated at technological regimes, as follows: matrix temperature – 180^0C, rotation frequency of screws – 15.7 s^{-1}.

INFLUENCE OF ANATOMICAL ORIGIN OF RAW MEAT ON THE SENSORY AND CHEMICAL CHARACTERISTIC OF DRIED BEEF "CECINA DE LEON"

Molinero, C.; Rubio, B.; González-Fernández, C.; Martínez, B. and García-Cachán, M.D.

Estación Tecnológica de la Carne. Instituto Tecnológico Agrario de Castilla y León. C/ Filiberto Villalobos s/n. 37770 Guijuelo (Salamanca). Spain

Background

Spanish "Cecina" is a salted, dried, and smoked beef meat product manufactured traditionally in the province of Leon (north-western Spain). It is an intermediate moisture product meat, made from three possible different anatomical retail cuts: "babilla" (composed of by *M. rectus femoris* and *vastus lateralis*, *vastus. medialis* and *vastus intermedius*), "tapa" (M. s*emimembranosus*, *sartorius*, g*racilis*, *adductor*, *pectineus*, *quadratus femoralis* and the external extra pelvic portion of M. *obturatorius externus*) and "contra" (*M. semitendinosus* and g*luteobiceps*). The preparation method is similar to that used in dry-cured ham manufacture. The final product has a typical red colour, smoked flavour and a characteristic slight salty taste. "Cecina" is highly prized in Spain and has recently been exported to the rest of Europe. Despite this, few studies have been carried out on the "Cecina de Leon".

Objectives

The objective of this research was to evaluate physicochemical and sensory characteristics of the three different types of "Cecina de Leon" ("babilla", "tapa" and "contra").

Materials and methods

Ten pieces of "babilla", ten of "tapa" and ten of "contra", provided by Protected Geographical Indication (PGI) "Cecina de Leon" were analyzed. All samples were vacuum packed and refrigerated at -4ºC until analyses. The analytical determinations were carried out in triplicate and the results expressed as dry matter.

The samples were subjected to the following analyses: pH, water activity (a_w), moisture, protein, fat and ash content. These physicochemical parameters were determined following the Official Methods of Analysis (BOE 29/8/1979) and the ISO recommended methods (ISO R-1442, ISO R-937, ISO R-1443, and ISO R-936 respectively). The following analyses were also performed: total carbohydrates (Luff-Schoorl method), hydroxyproline (Bonnet and Kopp, 1984), nitrate (brucine method), nitrite (ISO 2918) and NaCl content (Carpentier-Volhard method).

Fatty acid composition was carried out on total of fat extract according Bligh and Dyer (1959) after methyl-derivatization (Morrison and Smith, 1964). Gas chromatographic analysis was performed with a Perkin-Elmer Auto syst-X.L equipped with an Omegawax 320 column. Results are presented as g/100g fatty acids (% by weight) of oleic acid, saturated, monounsaturated and polyunsaturated acids. Nutritional quality is described by the polyunsaturated:saturated ratio and ω_6:ω_3 ratio.

Surface colour of the pieces was measured using a reflectance spectrophotometer (Minolta CM-2002). Colour coordinates were determined in the CIE-LAB system and the results were expressed as lightness (L*), redness (a*) and yellowness (b*).

Instrumental Texture Profile Analysis (TPA) (Breene, 1975) was used to evaluate the instrumental texture. All the measurements were made using Texture Analyzer TA-XT2 (Stable Micro Systems Ltd.) with cylindrical probe. A uniaxial compression test was carried out using a cross-head speed of 1 mm/min and the level of compression was 50% of sample thickness. From the TPA curves hardness, springiness, chewiness and cohesiveness were the parameters obtained.

Sensory evaluation was carried out on "Cecina" slices by an trained 8-member sensory panel. The parameters studied were: external appearance (colour homogeneity, colour intensity, marbling, intermuscular fat and yellowness), odour intensity, texture (hardness, chewiness, juiciness, and pastiness) and flavour (flavour intensity and after taste). The sensory attributes were scored using 5-points hedonic scales, 5 denoted extremely high and 1 denoted extremely low.

Statistical analysis of data was carried out by one-way analysis of variance, and means were separated by Tukey honest significant difference test using at 5% level (Statistica software package).

Results and discussion

The chemical composition and physicochemical parameters of the three types of "Cecina" are shown in Table 1. No differences ($p>0.05$) were observed in pH and a_w. The values of a_w (0.882-0.903) are characteristic of an intermediate moisture meat product, which give microbial stability and, hence, help to preserve meat. In relation to the proximate composition, except for moisture content, "contra" was significantly different ($p<0.05$) from "babilla" and "tapa". The results obtained for protein, fat, ash and hydroxyproline contents in "babilla" and "tapa" were basically in line with data published by Gutierrez et al. (1998) for "tapa". The small differences ($p<0.05$) existing in moisture content between "babilla" (52.4%) and the other pieces, "tapa" and contra", could be attributed to its lower size since for the same ripening time the water loss is higher. Although "Cecina de León" is characterized by a high protein and low fat content, "contra" presented a high ($p<0.05$) fat content (28.6% dry matter) resulting in a low ($p<0.05$) protein, carbohydrate and ash contents. Differences in histochemical composition between muscles could explain the differences found in fat content between retail cuts used (Hunt and Hedrick, 1977; Renerre, 1984; Kirchoefer et al., 2002). In this sense, some muscles included in "contra" (M. *gluteobiceps* and *semitendinosus*, overall its inner part) are characterized by a higher percentage of red fibbers, with greater fat contents, than those included in "tapa" (M. s*emimembranosus* and *gracilis*).

Table 1.-Chemical composition and physicochemical parameters (mean ± S.D.) of "babilla" (n=10), "tapa" (n=10) and "contra" (n=10).

DM: dry matter; n.d.: not detected.

Regarding fatty acid composition, "babilla" showed a lower ($p<0.05$) content than "tapa" and "contra" in oleic acid (35.9% vs. 40.6 and 42.9% respectively), and in consequence in monounsaturated and unsaturated fatty acids. "Babilla" also presented the higher polyunsaturated fatty acids contents, however no differences ($p>0.05$) between pieces were found for this parameter. The amount of saturated fatty acids was significantly different ($p<0.05$) in "babilla" and "contra". The ratio between polyunsaturated and saturated fatty acids was below to that recommended for human diet (>0.4). The highest ($p<0.05$) ω_6/ω_3 was found in "tapa" (6.2), "babilla" and "contra" presented a more favourable balance (3.5) between ω_6 and ω_3 polyunsaturated acid. A dietary ratio of 4 or 5:1 for ω_6/ω_3 polyunsaturated acids is desirable. Higher ratios are less desirable. The proportion is especially important in relation to the incidence of cardiovascular disease (Warriss, 2000).

Concerning the curing agents, the salt content was higher ($p<0.05$) in "tapa", significant differences ($p<0.05$) were also found in nitrite and nitrate content. These values are under their legally established limits (Directive 2001/5/CEE).

Results of colour measurement are shown in Table 2. No differences ($p>0.05$) in L* value were detected among the three pieces. "Babilla" had lower ($p<0.05$) a* and b*, as compared to those of "tapa" and "contra".

Table 2.- Values (mean ± S.D.) of colour parameters in "Cecina".

CIE –LAB coordinates	*"Babilla"*	*"Tapa"*	*"Contra"*
L* (lightness)	^{a} 30.0 ± 2.2	^{a} 29.3 ± 1.8	^{a} 31.7 ± 2.6
a* (redness)	^{a} 7.8 ± 2.5	^{b} 11.6 ± 3.0	^{b} 10.0 ± 2.3
b* (yellowness)	^{a} 1.9 ± 1.4	^{b} 5.7 ± 2.4	^{b} 5.8 ± 2.0

$^{a, b, c}$ Means with different letters indicate significant differences (Tukey test: $p<0.05$).

The values of texture descriptors are shown in Figure 1. No differences ($p>0.05$) were found in cohesiveness and springiness among the three type of "Cecina". On the contrary, "contra" exhibited higher ($p<0.05$) values, both in hardness and chewiness than "babilla" and "tapa". The hydroxyproline content has been previously fitted as indicator for hardness (Rodriguez-Lazaro *et al*., 2001). In this sense, "contra" was the piece that presented a higher ($p<0.05$) hydroxyproline content, this is explained by the higher hydroxyproline content in M. *semitendinosus* (included in "contra") than M. *semimembranosus* (included in "tapa") (Pedersen *et. al*., 1996).

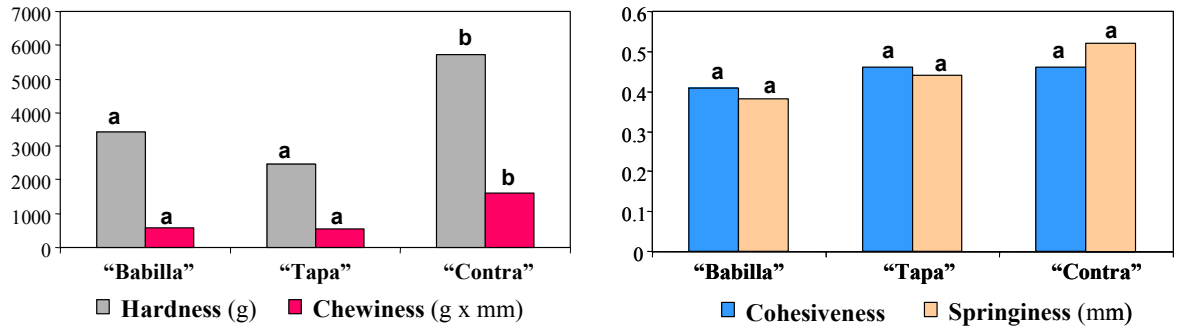

Figure 1.- Mean values of Instrumental Texture Profile Analysis (TPA). (^{abc} Columns with different letters indicate significant differences (Tukey test: $p<0.05$).

Flavour intensity	^{a} 3.0 ± 0.4	^{a} 3.1 ± 0.3	^{a} 3.1 ± 0.6
After taste	^{b} 3.8 ± 0.1	^{a} 2.6 ± 0.5	^{b} 3.1 ± 0.4

^{a,b,c} Means with different letters indicate significant differences (Tukey test: $p<0.05$).

Results of sensory analysis of "Cecina" are presented in Table 3. No differences ($p>0.05$) were found in colour (homogeneity and intensity), odour intensity and flavour intensity. Concerning fat, marbling was similar ($p>0.05$) between the evaluated pieces, however the presence of intermuscular fat was higher ($p<0.05$) in "contra" than "tapa", which presented the highest yellowness scores ($p<0.05$). On the other hand, the highest values ($p<0.05$) for hardness, pastiness and chewiness obtained in "contra" confirm the instrumental texture results. Finally, the judges considered that "tapa" was more juicy ($p<0.05$) than "babilla" and "contra" although its aftertaste was lower ($p<0.05$).

Conclusions

"Babilla" and "tapa" seem to be the most similar between the types of "Cecina" studied. Both pieces of "Cecina" presented a higher protein content and a lower fat content than "contra". However, "contra" showed the highest acid oleic percentage and a good favourable balance between ω_6 /ω_3 polyunsaturated acids. By the other hand, instrumental Texture Profile Analysis (TPA), as well as sensory evaluation, indicated that "contra" was the hardest piece of "Cecina" studied, but also it had higher chewiness than the other.
Further research is needed for a better understanding of the relationship between anatomical origin of raw meat and final meat product.

EFFECT OF DIFFERENT CONCENTRATIONS OF NATURAL COLORANTS ON THE COLOUR OF FRESH PORK SAUSAGES PACKAGED IN MODIFIED ATMOSPHERE

Luis Martínez, Irene Cilla, José Antonio Beltrán and Pedro Roncalés

Dept. of Animal Production and Food Science. Laboratory of Food Technology. Faculty of Veterinary Science. University of Zaragoza. C/ Miguel Servet, 177, 50013. Zaragoza, Spain. E-mail: roncales@posta.unizar.es Tel.: +34-976-761582 Fax: +34-976-761612.

Background

Colour is the most deleterious factor as regards the appearance of meat and meat products during storage. It is also the most influential on the consumer purchasing decision. The attractive bright cherry red colour of freshly cut or comminuted meat is used by consumers as an indication of freshness. The preferences of the consumers for natural colorants has been increasing during these last years, because "natural" is often associated with an image of healthy and good quality. Consumers tend to perceive synthetic colorants as undesirable and harmful, and some are considered to be responsible for allergic and intolerance reaction (Blenford, 1995). Stability has been a problem with the use of natural colorants which are often very sensitive to heat, light, acidity, air or water activity changes (Attoe and von Elbe, 1981; Carnevale et al., 1980; Von Elbe et al., 1974). The combined use of colorants and modified atmosphere packaging for meat represents a realistic and attractive strategy to increase the shelf life of fresh meat and fresh meat products. Monascus species produce red colorants through solid state fermentation and have been used as a general food colorant and medical agent for centuries (Went, 1895). Recently, these pigments were tested for their ability to colour different foods, including meat products (Fink-Gremmels and Leistner, 1989). The red beet root (*Beta vulgaris*) is a rich source of red pigments known as betalains (Mabry and Dreiding, 1968).

Objectives

To study the effects of natural pigments of mould *Monascus purpureus* and red beet root juice, compared to betanin (E-162), on the shelf-life of fresh pork sausages packaged in modified atmosphere, in order to select the most appropriate natural colorant for improving their quality.

Materials and methods

Preparation of samples. Four pork forelegs were obtained at 48 h post slaughter from a local supplier (MARBE, Zaragoza, Spain), trimmed of external fat, and ground using an industrial grinder machine. Minced meat was divided in nine batches, which were mixed with NaCl (to a final concentration of 2%) and with either: 1) Control (no colorants), 2) *Monascus purpureus* (0.05%), 3) *Monascus purpureus* (0.1%), 4) *Monascus purpureus* (0.2%), 5) Red beet root juice (0.5 ml / kg meat) , 6) Red beet root juice (1 ml / kg meat), 7) E-162 (0.03%), 8) E-162 (0.05%), 9) E-162 (0.07%). The fresh sausages were stuffed into collagen casings, Colfan F (Viscofan S.A., Caseda, Spain), placed on polypropylene trays, introduced in a pouch made of a polyethylene and polyamide and filled with 80% O2 + 20% CO2 gas mixture. Sausages were stored for 16 days at 2 ± 1°C in the dark.

Red beet juice preparation. Fresh red beet roots (*Beta vulgaris*) were purchased from a commercial store. Samples were washed, dried and cut into cubes of about 1cm x 1cm, which were boiled for 5 min for blanching (Han et al, 1998). After rapid cooling, beet juice was extracted with a standard kitchen food processor. The crude juice was boiled at 100ºC for 1 min. After rapid cooling, it was filtered stepwise (MN 640w, Machinery Nagel GmbH & Co. KG, Düren, Alemania). The clear beet juice was stored at refrigeration until use.

Colour measurement. Meat colour was measured at the sausage surface using a reflectance spectrophotometer (Minolta CM-2002; Osaka, Japan), 30 min after of opening the packing. CIE L*, a*, b* (CIE, 1978) parameters were recorded. The h* value and C* were calculated $h^* = \tan^{-1}(b^*/a^*)$ and $C^* = ((a^*)^2+(b^{*2}))^{0.5}$. The spectra curves were determined over the range of 400-700 nm at 10 nm intervals with Minolta CM-2002. Each value was the mean of 30 determinations.

Statistical analyses. The significance of differences among samples at each day of storage was determined by analysis of variance using the least square difference method of the General Linear Model procedure of

SPSS (SPSS 11.5, 2002). Differences were considered significant at the $p<0.05$ level. Data were also analysed using canonical discriminant analysis (CDA) multivariate statistical method of SPSS (SPSS 11.5, 2002).

Results and discussion

The evolution of different colour parameters is shown in Table 1. Lightness. The use of colorants caused a decrease of L* values in all treatments ($p<0.05$) throughout the whole study. All samples with colorants added were darker than control fresh pork sausages, the higher the concentration the lower the lightness. Bloukas et al. (1999) found that betanin level significantly affected lightness, the higher the betanin level the lower the L* values. Stuempel (1997) also reported lower L* values for frankfurter-type sausages with higher betanin levels; Pipek et al. (1996) found that Monascus extract caused a decrease of brightness in sausages and frankfurters.

Redness. Samples with natural colorant added had higher a* values ($p<0.05$) than control sausages, the higher the concentration the higher the redness. Sayas-Barberá et al. (1987) also found a relationship with a* values and Monascus concentrations. Pipek et al. (1996) found that Monascus extract caused an increase of a* values. The behaviour of red beet root might be explained by betanin degradation by air and light. Bloukas et al. (1999) found that redness of frankfurters steadily increased with the betanin level; similar results were reported by Stuempel (1997).

Yellowness. Samples did not present variations in b* values along the 16 days of storage ($p>0.05$). Neither Klettner (1993), Pipek et al. (1996) nor Sayas-Barberá et al. (1987) found relevant variations in b* values. However, Bloukas (1999) found that use of betanin in frankfurters increased b* values.

a*/b* ratio. Changes of this ratio were very similar to those of a* values.

Chroma. All samples showed a slight increase of C* values at 4th day of storage; after that values decreased ($p<0.05$) along all the storage period. E-162 (0.07%) showed the higher chroma values, near 19, during the first 8 days after that they suffered a very significant decrease. Only Monascus 0.05% presented lower values throughout the experiment ($p<0.05$). Decrease or increase in C* has been associated to increase or decrease in h*, respectively. The typical pink-red colour of fresh pork meat minced is related to low h* and high C* values this colour changed to oxidized brown-grey meat surface (high h* and low C* values).

Hue. As the colour attribute hue increased, the shade of colour changed from red to brown, a gradual rise of hue angle indicated increasing metmyoglobin during storage (Isdell et al., 1999). Changes in hue angles confirmed the results obtained by measuring only a* values. Sayas-Barberá et al. (1987) found that the hue value decreased significantly by using above 40 ppm of Monascus.

Reflectance spectra of control fresh pork sausages and meat with *Monascus purpureus* (0.05%), E-162 (0.05%) and red beet root (1ml) are shown in Fig. 1. The reflectance spectrum of meat with red beet root was very similar to that of the fresh sausage used as control. The use of E-162 gave rise to a spectrum similar to the control, but was lower between 440 and 540 nm and from 590 nm to 700 nm. The spectrum of Monascus was the most different, presenting the lowest reflectance values. Palombo and Wijngaards (1990) pointed out that the shift of the spectrum towards higher reflectance values was due to a remarkable increase of L*, a decrease of h* and a decrease of C* values.

Canonical discriminant analysis is shown in Fig. 2. The two fist canonical functions accounted for 96.2% of variability of fresh pork sausages, therefore, they are a valuable tool for discriminating the different treatments. The most different treatments were Monascus (negative region) and control (positive region); red beet root at different concentrations had an intermediate behaviour between Monascus and the control samples.

Conclusions

The use of natural food colorant improved some colour characteristics of the fresh pork sausages. All samples with *Monascus purpureus*, betanin (E-162) and red beet root presented lower L*, b* and h* values

than control sausages, and higher a*, a*/b* and C* values than control. If red colour is used by consumers as freshness indicator and as willingness of purchasing, the use of natural red colorant enhanced the shelf life of this product. Reflectance spectrum of sausages with red beet root was very similar to control; so this colorant appeared to be most suitable for improving the natural colour of fresh pork sausage.

pH, WATER ACTIVITY, AND PROXIMATE COMPOSITION OF *MORCILLA DE LEÓN*, A TRADITIONAL EUROPEAN BLOOD SAUSAGE

Cabeza, E.[1], Zumalacárregui, J.M. [2], Antiduelo, A. [2], Mateo, J. [2]
[1]Department of Food Microbiology, Faculty of Basics Sciences, University of Pamplona, Colombia
[2]Department of Hygiene and Food Technology, Faculty of Veterinary Science, University of León, C.P. 24071, León, Spain, dhtjmo@unileon.es

Background

Among the diverse types of meat products in the world, there are some typical products which are elaborated with blood; these are named as "blood sausages". These sausages have rarely been studied, being found some bibliographic references in Germany (Souci, *et al*., 1989; Stiebing, 1990), Spain (Antiduelo, 2002; Santos *et al*., 2003) and Portugal (Roseiro *et al*., 1998) and some countries from Latin American (Bunger *et al*., 1992, Adesiyun *et al*., 1996). Blood sausages are made (besides blood) with ingredients such as fat, offal, onion, cereals, spices, etc., existing a great diversity of ingredients as well as ways of processing and preparation. The *Morcilla de León* is a typical product from Castilla and León (Spain), being onion (65%–75%), pork and/or beef fat (10%–20%), pork and/or beef blood (10%–20%), rice (2%–5%), salt (1%–1.5%) and spices the main ingredients in its composition (Antiduelo, 2002). Process usually consists on precooking the mixed of ingredients, which are then stuffed into a pork casing and cooked in hot water (80-100ºC). Finally, *Morcilla de León* is consumed fried or boiled.

Objectives

This study is aimed to contribute to *Morcilla de León* typification, a typical regional Spanish sausage, by studying its proximate composition and comparing results from this blood sausage with other results from different blood sausages in the World.

Materials and methods

Samples of blood sausages were purchased from the retail market coming from nine different meat industries which were located in León City and other smaller towns nearby. Once acquired, the samples were immediately transported to laboratory in refrigerated conditions. There, samples were homogenised and the following analysis were accomplished. pH was measured in fresh sample by duplicating according to the official method for meats (Presidencia del Gobierno, 1979). Water activity (a_w) was measured by a dewdrop point method with an Aqualab CX-2 (Decagon Devices, Washington, USA). Moisture was determined according to ISO (1973). Fat content of the dehydrated sample was measured by extraction with petroleum ether according to AOAC (1999a). Total protein was determined by the Kjeldahl method according to AOAC (1999b), by using 6.25 as conversion factor. Ash content was measured by incineration sample at 550ºC, according to Presidencia del Gobierno (1979). Finally, digestible carbohydrates extraction was carried out with 52% perchloric acid following the Presidencia del Gobierno (1982) method and quantification was made with the method described by Dubois *et al*. (1956). Relative analyses on composition were determined by duplicate and data were expressed as percentage on fresh and dry matter.

Results and discussion

pH and a_w values for *Morcilla de León* are shown at table 1, in which it is indicated that the pH averages c.a. 6 and the a_w averages 0.97. These parameters, which depend mainly on used ingredients in the sausage, i.e. onion, blood, fat and salt, were similar to those found by Santos *et al.* (2003) in the '*Morcilla de Burgos'*, another typical blood sausage from Spain made mainly with onion, rice, blood and fat. Due to the high pH and a_w of the sausage and the absence of preservatives in the formula, *Morcilla de León* is susceptible to early spoilage, its shelf-life depends on the initial microbial population of the mixture, heat treatment intensity in the boiling stage, handling conditions after boiling, and storage temperature. Anyway, during chilled storage a pH decrease (c.a. 0.5) has normally been observed which could be attributed to microbial growth (non published data).

Proximate composition of *Morcilla de León* is shown at tables 2 and 3. Regarding to moisture content, it was also similar to that of *Morcilla de Burgos* (Santos *et al*., 2003) but 11% lower than blood sausage from Chile (Bunger *et al*., 1992) and 21% and 25% higher than the moisture of *Morcela de Assar* from Portugal (Roseiro *et al*., 1998) and German '*Blutwurst'* (Souci *et al*., 1990), respectively. The reason for this variability could be explained by the differences in the types and amounts of ingredients used in the formulation of each kind of blood sausages. Furthermore, fat is probably the most variable proximate component in meat products. The fat content on dry matter found in different blood sausages has had a range between 28% of Morcilla de Burgos to 70% of Blutwurst (Souci, *et al.*, 1990, Bunger *et al.*, 1992, Roseiro *et al*., 1998, Santos *et al.*, 2003,), and the fat content on dry matter of *Morcilla de León* was into an intermediate place. In the same way, protein percentage on dry matter of *Morcilla de León* was slightly higher than those found in *Morcilla de Burgos,* and lower than those of other blood sausages.
Digestible carbohydrates in the *Morcilla de León*– fraction constituted basically by starch and soluble sugars – were 27% of the dry matter. This percentage was rather lower than in *Morcilla de Burgos* –51% on dry matter– because more rice (20% to 35% of rice) is added to make the last sausage (Santos *et al*., 2003) while the amount of rice or bread that is added to the *Morcilla de León* is about up to 10% (Antiduelo, 2002). The amount of cereals or other vegetables used for making other blood sausages such as Blutwurst, Chilean blood sausage or *Morcela de Assar* is even less and due to it its results of digestible carbohydrate. The presence of more than 1% of fiber in the *Morcilla de León* as well as in other blood sausage (Bunger et al., 1992; Santos et al., 2003) is also due to the addition of vegetables as ingredients, such as the onion, which, as it was said before, is the principal ingredient of *Morcilla de León* (c.a. 70%). Fiber content of cooked onion is approximately 1.5% (USDA, 2003). Finally, ash content of *Morcilla de León* was in the higher part of the range observed for blood sausages (4.3% a 8.4% on dry matter) (Roseiro *et al*., 1998, Santos *et al.*, 2003, Bunger *et al.*, 1992, Souci, *et al.*, 1990).
Table 4 contains the correlations between moisture, fat, ash and protein contents of *Morcilla de León* expressed as dry matter. Only the correlation digestible carbohydrates *vs.* fat –the two most abundant components– was statistically significant ($p<0.05$).

Conclusions

'Morcilla de León' is a cooked product subject to easy microbial spoilage which needs chilled storage. It represents a nutritional source of fat, carbohydrates, fiber and protein –mainly from blood–; nonetheless it has less protein than meat and most of meat products.

THE INFLUENCE OF WINE COMPONENTS ON THE TENDERNESS AND HISTOLOGICAL STRUCTURE OF COOKED MEAT

Ayako Mega, Tomiko Mitsuhashi*, Mariko Tajima**

Dept. of Home Economics, Faculty of Education & Human science, Yamanashi Univ. *Junior college, Nihon Univ. **Faculty of Education, Kagoshima Univ.

Background

Marinating in wine have long been used as a mean of reducing toughness and consequently to improve tenderness of beef muscles. In the case of typical German cuisine "Sauer Brauten", beef round meat was soaked in red wine for 2-3days and subsequently was cooked. Some authors reported that the tenderizing effect of wine was related to various components of wine (organic acids, sugar, polyphenol and alcohol [1), 2), 3), 4)]. However more studies are necessary to examine the relationship between the components of wine and meat tenderness.

Keywords: Wine, marinating, cooked meat tenderness, histological structure

Objectives

The aim of this study was to find the effect of various components of red and white wine on the meat tenderness and histological structure.

Materials and methods

Beef round meat was obtained from commercial source. After the fat and tendon (perimycium) were removed, the meat was cut into pieces weighing about 150g (2cm thick). Each piece of meat was put into plastic bag(Asahi Kasei H N type) and then soaked in each solution(water, white wine, red wine, 0-50mg Tannin, 0-0.6%tartarir acid, 0-2%glucose, 0-20%ethylalcohol) for 5 hours. These samples were heated at 100□ for 30min in the water bath. Thereafter five 1.27cm diameter cores, taken parallel to the muscle fiber, were removed from one piece per sample. Cores were sheared with Warner-Blatzler Meat Shear Model 2000. Shear force Values were recorded as kg force/1.27 cm sample. Samples for histological observation of meat structure were frozen in the freezer and cut into thin vertical sections. Observations were performed using an optical microscope (Nikon optiphoto).

Results and discussion

Shear force value of cooked meat

Figure 1 shows the mean and individual shear force values obtained for cooked meat marinating in water, red wine and white wine. There were no significant differences between red wine, white wine and water (control).

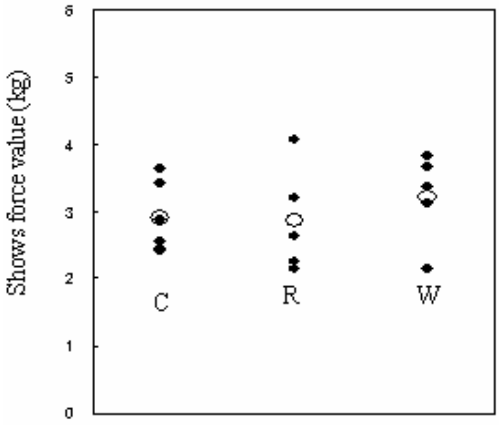

Fig.1

Figure 1 shows the shear force value of cooked meat marinated in C: water, R: red wine, W: white wine

Figure 2-a,b,c,d showed the shear value of cooked meat marinating in tannin, tartaric acid, glucose and ethyl alcohol, respectively.
As, shown in Figure 2-a, the concentration of tannin increased from 0 to 50 mg%, the shear force value of cooked meat increased from 2.4 kg to 3.9kg (correlation coefficient=0.67). There was a similar trend for the increase of glucose concentration (Figure 2-c). Whereas Figure 2-b indicated that there was the excellent correlation (-0.95) between decreased tenderness and increased tartaric acid concentration from 0 to 0.6%. A similar trend was observed in increasing of ethyl alcohol concentration (Figure 2-d).

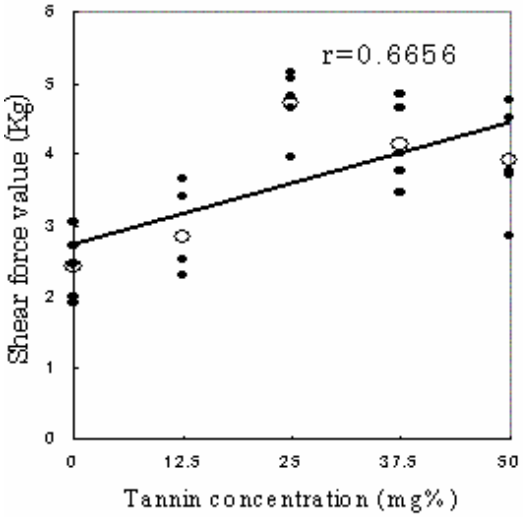

Fig.2-a

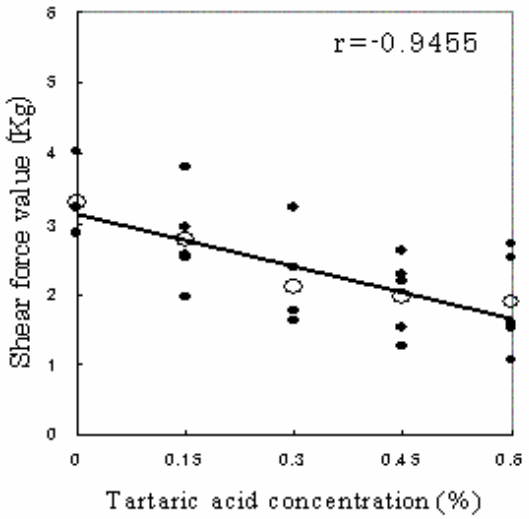

Fig.2-b

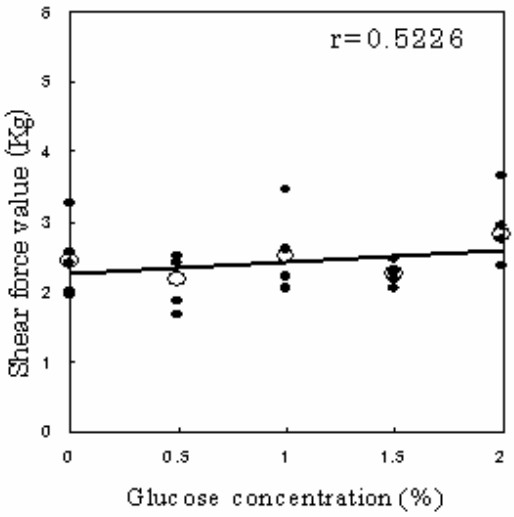

Fig.2-c

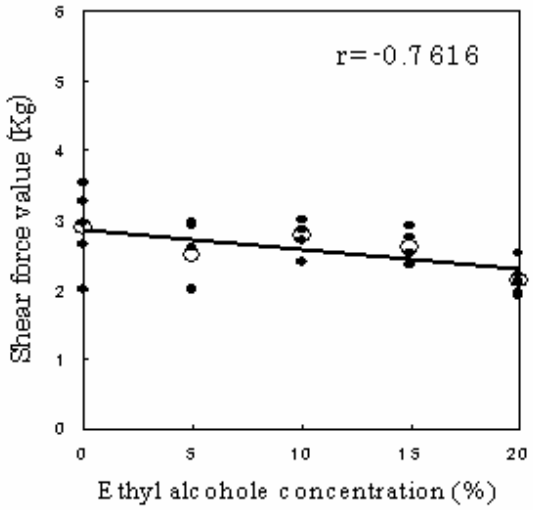

Fig.2-d

Figure 2 compares the shear force value of cooked meat marinated in (a) tannin, (b) tartaric acid, (c) glucose, (d) ethyl alcohol.

Structure of cooked meat

Figure 3-a,b,c,d,e showed the structure of marinated meat in water, tannin, tartaric acid, glucose and ethyl alcohol. The marinating in tannin leads to the remarkable shrinking of muscle fiber, simultaneously, that appearance also observed for marinating in glucose. Whereas in the case of marinating in tartaric acid and in ethyl alcohol no shrinkage occurred, but appeared horizontal cracks in muscle fiber structure.

Fig.3-a Water

Fig.3-b Tannin

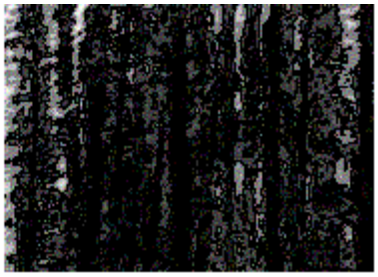

Fig.3-c Tartaric acid

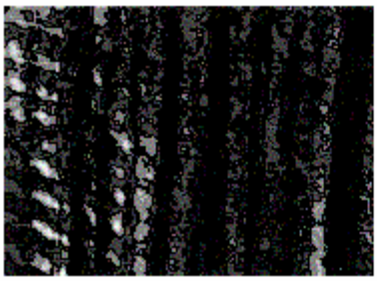

Fig.3-d Glucose

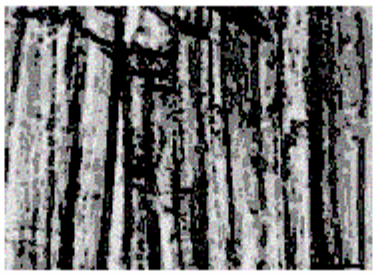

Fig.3-e Ethyl alcohol

Figure 3 showed the microstructure of cooked meat marinated in (a) water, (b) tannin, (c) tartaric acid, (d) glucose, (e) ethyl alcohol.

Conclusions

There were no significant differences in shear force value obtained for cooked beet round meat marinating in red wine, white wine and water. Marinating in tartaric acid was most effective to tenderizing of meat. When the meat soaked in Tannin, the shear force value of cooked meat increased as concentration of tannin increased. This treatment leads to the remarkable shrinking of muscle fiber.
These results indicate that the excellent correlation between increased toughness of cooked meat associated with shrinking of muscle fiber.

QUALITY OF LOW-FAT MEATBALLS CONTAINING LEGUME FLOURS AS EXTENDERS

Meltem Serdaroglu, Gülen Yildiz-Turp, Kiyalbek Abdoimov
Ege University , Engineering Faculty , Food Engineering Department
35100, Bornova-İzmir-TURKEY
gulen@food.ege.edu.tr

Background

Ground meat is used for the production of a variety of traditional meat products such as meatballs, kebabs and döner in Turkey. The meat is mixed with spices and extenders then formed and cooked. Various extenders and binders such as egg, flours and breadcrumbs are used in ground meat formulations to bind the meat particles. Legumes are economic source of protein and also various minerals. In recent years legumes have been investigated regarding to their potential use in developing functional foods. Inclusion of legumes in the daily diet has many physiological effects in controlling and preventing various metabolic diseases such as mellitus, coronary heart disease and colon cancer (Tharanathan and Mahadevamma, 2003).

Beef sausages extended with common bean flour had higher water holding capacity, lower cooking loss and lower protein content (Dzudie et al. 2002). Modi et al. (2003) investigated the effect of Bengal gram, green gram and black gram flours in meatballs, and gram flour in burgers. Beef patties extended with soy flour and samh flour had lower water activity and moisture content but protein content was not affected by the addition of extenders (Elgasim and Al-Wessali, 2000).

Objectives

The objective of this research was to evaluate the effects of legume flours (blackeye bean, chickpea and lentil) and rusk on proximate composition, fatty acid composition and lipid oxidation of low-fat meatballs.

Materials and methods

Beef as boneless rounds was obtained from the local butcher in Izmir, Turkey. All subcutaneous fat and inter-muscular fat was removed from the muscles and used as the fat source. Lean and fat were ground through a 3 mm plate grinder. Legumes; blackeye bean (*Vigna unguiculata,*23.5% protein, 1.5% fat), chickpea (*Cicer arietinum,* 20.6% protein, 4.5% fat), lentil (*Lens culinary*, 23,5% protein, 1.2% fat) and rusk (12,4 protein, 4.5 fat) used in this study were obtained from a local market. Each legume was soaked (ratio of 1:2 legume to water) for 12 hours and cooked for 1.5 hours in boiling water. Cooked legumes were dried separately in electric oven (100ºC) for two hours and grind in a mill. Similarly rusk was also prepared in the same mill to obtain a fine structure and all above the flours were used as extenders. The minced beef was then mixed with 10% (g/100g) extender, 7% beef fat, 0.3% onion powder, (0.8% spice mix) and 2% salt. Batches of 2 kg of each formulation were mixed with food processor and processed into meatballs (1cm thick and 80 mm diameter) by using a metal shaper.

Moisture and ash content of each meatball were measured by using AOAC procedures. Fat content was determined by chloroform-methanol extraction according to Flynn and Bramblett (1975). Protein content was determined according to Anonymous (1979). Lipids were extracted from 10 g samples with chloroform : methanol (2:1 v/v) (Folch et al.1957) and methylated (Anonymous, 1987). Fatty acid methyl esters (FAME) were analyzed using a gas chromatography (HP5890) fitted with a fused silica capillary column (DB-23, 30 mx 0.25 mm id., 0.25 µm film thickness, J.W.Scientific). The column temperature programmed 100ºC to 220 ºC in 4 ºC/min and 15 min at 220ºC. The injector temperature was set at 220ºC and the detector (FID) temperature was set at 220 ºC. The carrier gas was hydrogen at a flow rate of 1 ml/min. The fatty acids were identified by comparision of the retention times of the sample with those of standards.

Meatball samples were frozen at -18°C for 3 months in polypropylene boxes with lids. On 0 th day and 1st, 2nd and 3rd months of frozen storage , samples were thawed at 4°C and oxidative rancidity of meatballs was determined by thiobarbuturic acid test (TBA) according to Tarladgis et al. (1960). Data were subjected to one-way analysis of ANOVA (Minitab, 2003).

Results and discussion

Mean values for proximate composition of uncooked and cooked meatballs are given in Table 1. For uncooked and cooked samples the moisture, fat and ash contents in the formulations of different extenders were almost the same ($p>0.05$). Uncooked meatballs had a fat content ranging from 8.5 to 9.1%, cooked meatballs had a fat content ranging from 7.9 to 8.8%. Incorporation of legume flours increased protein contents of meatballs ($p<0.05$). Extended with BBF and CF slightly increased the ash content of raw meatballs. Meatballs formulated with rye bran had higher ash content than all meat control (Yılmaz, 2004).

Cooking slightly decreased moisture and increased protein content of meatballs. The protein content ranged from 18.8 to 21.1% for uncooked meatballs, from 19.3 to 23.5% for cooked meatballs. Fat and protein contents of meatballs were within the limits of Turkish Uncooked Meatball Standard (TSE, 1992). Extended with BC resulted lowest (18.8% uncooked, 19.3% cooked) protein content. Several researchers have found that protein content of comminuted meat products increased with the addition of soy proteins (Tömek et al. 1988), cowpea flour (Prinyawiwatkul et al. 1997).

Table 5 shows the changes in TBA values. On 0^{th} day, no differences were observed between the TBA values of meatball samples. In other investigation periods meatballs with BBF and CF had similar TBA values and these values were lower than the TBA values of meatballs with LF and meatballs with R. Antioxidative properties of some fruits and vegetables have been showed in various meat products (Ulu, 2004; Mansour and Khalil, 2000). At the end of the storage period all meatballs had TBA values in consumable limits and were 2.11 mg ma/kg for BBF, 1.99 mg ma/kg for CF and 2.88 mg ma/kg, 2.55 mg ma/kg for LF and R treatments respectively. Ulu (2004) concluded that 0.2% soya protein isolate was effective retarding lipid oxidation in cooked meatballs.

Unsaturated fatty acids were in similar amounts in all formulations. Our results are similar to those determined by Yılmaz (2004), Yılmaz and Dağlıoğlu (2003) for unsaturated and saturated fatty acids. Meatballs extended with BBF and CF had similar concentrations of total saturated and unsaturated saturated fatty acids. Meatballs with LF and R had similar concentrations of total saturated and unsaturated fatty acids. There were significant differences between the amounts of total polyunsaturated fatty acids of meatball samples; samples with rusk had the highest amount of total polyunsaturated fatty acids.

Conclusions

This study suggests that legume flours (blackeye bean, chickpea and lentil) can be successfully used in meatball formulations as extenders. Protein content of meatballs increased with the addition of legume flours. Legume flours are potential source of non-meat protein for meatballs. Blackeye bean flour and chickpea flour slightly retarded oxidative changes during frozen storage. There is significant difference among the meatball samples in respect to fatty acid composition.

Background

Conjugated linoleic acid (CLA) refers to a group of fatty acids comprised of different positional (placement of the C=C double bonds along the carbon chain) and geometrical (configuration around the C=C double bonds) isomers of linoleic acid (cis-9(Z), cis-12(Z) C18:2). Conjugated fatty acids are predominantly found in the fats and tissues of ruminants (C18:2 and C18:3) with a few plant (C18:3) and marine (C18:4, C20:4, C22:6) sources also known (Parodi, 1977; Chin et al., 1992; Cahoon et al., 1999; Hamberg, 1992). Typically over 80% of the CLA in dairy products is composed of a single isomer, cis-9(Z), trans-11(E) C18:2 (Sehat et al., 1998). Much interest has been generated for CLA in recent years due to the demonstration of a number of health-promoting biological activities in animals, including anticarcinogenic, antiatherogenic, antidiabetogenic, and immunomodulatory effects. In this regard CLA may be a very important functional food ingredient that food industries will need to take advantage of in future developments if the same health benefits are shown to occur in humans.

Objectives

To demonstrate how natural ingredients increase the CLA content in ruminants through dietary intervention and the use of the adipose fat depot as a functional ingredient enriched in CLA for the production of other food products such as burgers.

Materials and methods

Sixty Charolais crossbred heifers (mean initial bodyweight = 333kg, s.d. 39.90) were blocked by initial bodyweight and, within block, were randomly assigned to one of four dietary treatments (n = 15): 1) indoor, silage/concentrates (control, SC); 2) unsupplemented grazing (G); 3) restricted grazing plus 2kg/head/day of linseed oil-enriched meal (LSG) and 4) restricted grazing plus 2 kg/head/day of sunflower oil-enriched meal (SFG). Concentrates and grass allowances were monitored at three-week intervals during a 5-month experimental period to achieve similar carcass weights across the treatments. Animals were slaughtered at a commercial facility, carcasses were chilled for 48 h at 4°C, and the *M. semimembranosus* (SM) and subcutaneous adipose tissue (SC) were excised from each carcass.

The fatty acids (FAs) were extracted and saponified from tissue samples in 6mL 5M KOH in methanol/water (50:50) at 60ºC for 1 hour and methylated using trimethylsilyl-diazomethane in methanol:toluene (2:1 %v/v) at 40ºC for 10 min based on a modified method by Elmore *et al*. (1999). Separation of fatty acid methyl esters (FAMEs) was performed on a Varian CX3400 GC, using a BPX-70 column (120m x 0.25mm i.d., 0.2□m film thickness, SGE, Australia) with a programmed temperature ramp. Injector and detector were set at 270°C and 300°C respectively. The carrier gas was hydrogen set to a flow rate of 1.6ml/min, measured at the initial temperature and using a split ratio of 50:1. FAMEs were identified according to similar peak retention times using standards (Sigma Chemical Co. Ltd., Poole, U.K.), and quantified according to the use of an internal standard ($C_{23:0}$ methyl ester) with its addition prior to saponification. The data was analysed as a randomized block design using MiniTab 14.

Adipose tissue was evaluated for its content of beneficial fatty acids, and, its suitability as an enriched source of CLA that could be used in product development. Beef burgers were produced from the *M. semimembranosus* and the CLA-enriched fat. Fatty acid analysis and sensory evaluation was carried out on these burgers to determine the effect if any on flavour and textural quality attributes

Results and discussion

Fatty Acid Results:

A processed meat product was produced and made available for CLA and fatty acid determinations. The *M. semimembranosous* was used in conjunction with carcass fat to produce beef burgers. Burgers were compared with respect to the initial dietary treatments (table 1). Of interest is the following: 1. the fatty acid content of burgers is quite different to the lean muscle (because of the high percentage of adipose tissue present in the burgers) – long chain polyunsaturates are less abundant (C20:4, C20:5, C22:5, C22:6) but a relatively high amount of C18:1 trans-11 (TVA) and CLA is present; 2. quite marked treatment affects are observed illustrating the production of burgers high in certain fatty acids such as CLA (table 1), diets rich in linoleic acid such as the sunflower oil supplemented diet drive the synthesis of CLA cis-9, trans-11 and C18:1 trans-11 (trans vacenic acid). The results also illustrate a large difference compared to conventional indoor silage-based diets (the content of CLA in silage - control Vs sunflower oil supplemented diet differs by more than 400%!, figure1).

Of the four different dietary treatments the linseed diet contained the most polyunsaturates (PUFA), followed by the sunflower diet and pasture diet with the silage diet containing the least amount of PUFA. For the total saturated fatty acids (SFA) the positions were reversed with the control diet containing the most SFA, followed by the pasture diet and sunflower diet while the linseed diet contained the least amount of SFA. The P:S ratio was highest for the linseed diet and lowest for the silage diet. The n-6: n-3 ratio was lowest for the pasture based diet, followed by the linseed, then silage and finally sunflower oil diets.

Sensory Evaluation:

An inhouse, trained panel of 20 people from different backgrounds was established to access the following sensory attributes: texture (hardness, softness), juiciness, and flavour quality. In addition they were also asked to give an overall acceptability score for the various samples. Samples were graded on a categorical scale from 1 to 6, were 1 is generally least favoured, to 6 the most preferred. In general, higher preference scores were associated with the pasture and oil-supplemented diets. Significant differences ($P< 0.05$) were observed between the silage and the pasture and oil-supplemented diets. It must be stressed however, that these results do not imply that meat from the silage based diet tasted bad or was unacceptable, merely that the panellists showed a trend favouring burgers from the other dietary treatments.

Conclusions

Supplementing grazing animals with plant oil-enriched concentrates resulted in a further beneficial effect on the fatty acid composition of muscle and fat compared to grazing alone. Sunflower oil was more effective in increasing the concentration of CLA and TVA, but had a negative effect on the n-6:n-3 ratio, while linseed oil supplementation had a less pronounced effect on the CLA concentration than sunflower oil.

Beef burgers enriched in CLA were successfully produced and sensory evaluation indicated that there was no detrimental effect on burger flavour and other sensory qualities. In fact, many sensory attributes are improved by pasture and oil supplementation (based on burger sensory analysis).

The results clearly show the suitability of fatty tissue from oil-supplemented diets to be a particularly rich source of CLA. An interesting feature here is the difference in the qualitative fatty acid profile and the relative abundance of individual fatty acids when comparing adipose tissue and lean muscle tissue. The differences presumably reflect the two distinct biological roles these tissues play with respect to their lipid profiles. Adipose tissue is a predominantly storage depot of fat, while muscle adjusts its content of fatty acids (predominantly the phospholipids fraction) to suit the functioning of its membrane systems (calcium ion storage and electrical impulse conduction).

EFFECTS OF *POLYGONUM HYDROPIPER* L. EXTRACTS ON THE QUALITY OF CHILLED BEEF STEAK

Noriham, A.[a], Babji, A.S.[b] and Nulkirah, M. [b]

[a]Food Technology Department, Faculty of Applied Sciences, Universiti Teknologi MARA, Shah Alam, Selangor, Malaysia.

[b]School of Chemical Sciences and Food Technology, Faculty of Science and Technology, Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia

Abstract

This study was undertaken to examine the effects of *Polygonum hydropiper* L. extracts on the quality of Australian and Indian beef sirloin steaks. The use of 2000ppm extracts were observed to reduce lipid oxidation during 18 days chilled storage while pH values decreased during storage time in both types of meat, treated (K1 & K2) and untreated (S1 & S2). The application of *Polygonum hydropiper* L. extracts also resulted in the lower hardness values. No significant differences were observed in the L (lightness) value , however there was a decrease in a (redness) value for all samples . As for b (yellowness) value not much difference were detected except for Australian untreated beefsteak which increased drastically after 18 days of chilled storage.

Keywords: *Polygonum hydropiper;* extracts; beef steak; chilled

Introduction

Buffalo meat (Indian beef) are being imported in large volume by Malaysia while higher quality beef cuts are imported in smaller volume from Australia. Steaks from sirloin, striploin and ribeye muscles are generally tender and are quality cuts preferred by the consumers. However restaurants and hotels serving steaks are reluctant to use Indian fillets, referring to poor quality such as toughness, chewiness, low sensory acceptance and poor microbial quality related to meat imported from India. It is with this unconfirmed factors that this study research into the effects of plant extracts to improve certain quality attributes related to the consumers perception of Indian beef. Australian beef fillets are well received by local consumers as well as foreigners who associate beef from Australia as superior and of high quality.

Materials and methods

Preparation of beef steaks

Frozen (-18^{o}C) *longisimmus dorsi* muscles in the form of striploin or sirloin were purchased from a local importer (Lucky Frozen Sdn. Bhd.) in Kuala Lumpur, Malaysia. Beef were cut into pieces and marinated with salt (1.5%) and pepper (2%) for control, namely K1 (untreated Indian beefsteak) and K2 (untreated Australian beefsteak). 2000ppm of *Polygonum hydropiper* L. extracts were applied topically to steaks by dry rubbing the external surface of the steaks on both side for sample S1 (Indian beefsteak) and S2 (Australian beefsteak). The samples were stored at 5 $\pm$ 1^{o}C for 18 days.

pH determination

Duplicate beef samples were periodically removed from storage and homogenized in distilled deionized water (1:10 dilution). Homogenates were filtered through a Whatman No. 1 filter paper to obtain clear filtrate for pH measurement.

Colour measurement

Surface colour of sirloin steaks was determined for L (lightness), a (redness) and b (yellowness) using a Minolta Chromameter CR-100.

Texture Analysis

Textural characteristics of sirloin steaks were analyzed using a Warner-Bratzler shear machine.

Lipid Oxidation Analysis

Thiobarbituric acid numbers (TBA) was determined following the distillation method described by Tarladgis et al (1960) with little modification by Rhee (1978).

Statistical Analysis

The data were analyzed using the Statistical Analysis Systems (SAS) program version 6.12 (SAS 1995). Treatments showing significant differences ($p<0.05$) were subjected to the Duncan's Multiple Range Test.

Results and discussion

Fig 1 shows the pH values for the beef steaks stored at chilled temperature for 18 days. There was a significant decrease in pH values for all samples after chilled storage for 18 days. However there were no significant difference in pH values between the treated and untreated (control) samples for both types of meat. The lower pH values for all samples during the chilled storage could be due to production of free fatty acids from the phospholipids fraction and the separation of free fatty acid from the triacylglycerol (Rhee et al. 1977). The pH of fresh meat can be influenced by the presence of bacteria and may reflect the relative differentiation between the presence of gram positive or gram negative bacteria. Organic acids, produced by gram positive bacteria, decreased the pH of meats, whereas amines produced by gram negative bacteria increase pH (Lefebvre et al., 1994).

Colour changes in beef steaks during chilled storage were shown in Figures 2, 3 and 4.
There were not much changes in the lightness of the samples except for untreated Australian beef steak which increase after 18 days of chilled storage. Values for redness were found to decrease significantly after 18 days of storage in all samples. A loss of surface redness in all samples can be attributed to decrease in dissolved oxygen, due in part to the utilization of oxygen by psychrotrophic bacteria, and the participation in oxidative reactions such as lipid oxidation (Peter & David, 2002). As for yellowness values no significant difference were found in all samples except for K2 yellowness which increased drastically during storage.

Figure 5 showed the results for texture (gF) for the four samples. Warner-Bratzler shear measurement showed an increase in values indicating increase in toughness of all samples. This could be attributed to the moisture loss during the chilled storage.There was significant difference in toughness between the control K1 and K2 whereby K1 was tougher than K2. For samples treated with *Polygonum hydropiper* L. extracts (S1 & S2) the toughness was significantly lower than the control (K1 & K2). Lipid soluble antioxidant from plant extracts can maintain integrity of muscle fibres and reduce moisture loss (Mitsumoto et al., 1995).
Rancidity of meat products are indicated by an increase in the content of malonaldehyde normally measured by TBA method. In this study there was a significant increase in TBA values in all samples as a result of the 18 days chilled storage (Fig. 6). However the values of treated samples (S1 & S2) were significantly lower than the controls (K1 & K2) though K1 showed higher values than K2. Taylor (1987) suggested prooxidants such as iron and copper from water and spices to contribute to increase in rancidity of meat products. Besides, the process of cutting and mixing during preparation of samples also increased oxidation in meat. Lower TBA values in treated samples for both types of meat indicated that *Polygonum hydropiper* L. extract was effective in inhibiting the formation of malonaldehyde, thus delaying lipid oxidation of the chilled beef steaks. The extracts was known to contain ten flavonoid compounds that possess strong antioxidative activity (Zhao et al., 2003).

Conclusions

The addition of *Polygonum hydropiper* L. extracts to the Australian and Indian beef steaks was found to improve the quality attributes such as texture and oxidative changes. The toughness was reduced when compared to the untreated samples for both types of meat. The oxidative process increased at a slower rate when compared to the untreated samples after 18 days of chilled storage at 5^{o}C.

EFFECT OF PHOSPHATE, ASCORBIC ACID AND α-TOCOPHEROL WITH THE CONTINUOUS NON-VACUUM OR VACUUM TUMBLING PROCESS ON LIPID OXIDATION OF PRECOOKED ROAST BEEF

Jen-hua Cheng[1] and Herbert Wood Ockerman[2]

[1]Department of Nutrition and Health Science, ToKo University, Taiwan
[2]Department of Animal Sciences, The Ohio State University, USA

Background

Lipids can be oxidized by enzymatic and nonenzymatic reactions and there are many mechanisms to explain these complex reactions in meat. However, autoxidation is a continuous free-radical chain reaction and is the most important mechanism of lipid oxidation in meat (Pearson *et al*., 1983).
Synergistic antioxidants are the compounds used to improve the function of primary antioxidant and improve lipid stability in food. The functions of synergists are to regenerate the primary antioxidants, to react with oxygen (oxygen scavengers), and to chelate prooxidants (chelators) such as iron and copper (Rajalakshmi and Narasimhan, 1996). Phosphate chelates irons which act as catalysts for lipid oxidation. The antioxidative ability of vitamin E is that it acts as a free radical scavenger and a singlet oxygen quencher (Yang and Min, 1993). Ascorbic acid stabilizes lipid oxidation is due to its functions as an oxygen scavenger (Jadhav *et al*., 1996), and it is used to regenerate activity of primary antioxidants and to inactivate prooxidants (Bauernfient and Pinkert, 1970).
There are two major types of tumbling that includes vacuum and non-vacuum processing. According to tumbling schedules, Ockerman *et al*. (1978) indicated that continuous tumbling is a constant mechanical action during a short period of time from 1 to 3 hours; however, intermittent tumbling is where the tumbler works for 10-15 minutes followed by a rest period each hour for an 18-24 hours period.

Objectives

The objective of this experiment was to test if continuous vacuum or non-vacuum tumbling decreases lipid oxidation of precooked roast beef under a short tumbling period (3 hour of tumbling) after injection.

Materials and methods

Raw beef bottom rounds, which were approximately 7 days post-mortem, were purchased from a local supermarket in Columbus, Ohio. The beef round primal cuts were trimmed of visible fat and connective tissue. The water-soluble antioxidants, such as sodium tripolyphosphate and ascorbic acid, were dissolved in distilled water. The α-tocopherol, a fat soluble antioxidant, was dissolved in propylene glycol. All beef bottom rounds were cut into uniform roasts (8 x 8 x 8 dimensions). The tumbling was a continous schedule` for 3 hrs. A non-vacuum tumbler and a vacuum (Hobart, Model HVM 30, Troy, Ohio) of 15 in (381mm) Hg were drawn and the tumbler was rotated at 12 rpm in a 4°C cooler.
Moisture content (Oven Dry Method; Ockerman, 1985) was measured in a drying oven at 100°C for 18 hours. A Corning pH meter (Model 7) measured the pH values of the samples. A modified extraction of the TBARS method was used to analyze lipid oxidation (Pensel, 1990). The shear values of cooked roast beef were evaluated using a 2.54 cm core by the Warner-Bratzler (G.K. Electric Mfg. Co., Kansas) instrument (Ockerman, 1985). Total iron was followed the ferrozine assay from Stookey, 1970 and Clark *et al*, 1997. Total pigment test was measured by the modified method from Ockerman (1985). Heme iron was calculated by the modified technique of Clark et al. (1997); the iron content is calculated with the factor of 0.0882 μg/μg hematin (Merck, 1989).

Heme iron (ppm; μg/g) = total pigment (ppm; μg/g) x 0.0882
Nonheme iron of sample = Total iron content – Heme iron content

Total aerobic, psychrotrophic, and thermophilic bacteria tests were utilized to detect contamination of various bacteria in precooked roast beef. Total aerobic plate count was evaluated using aerobic plate count (APC; Difco Laboratory, Detroit, MI) agar at an incubation temperature of 25°C for 4 days (Speck, 1984). Psychrotrophic bacteria were tested using APC agar at 4°C for 10 days and also "thermophiles" were determined on APC agar at 35°C for 48 hours. The number of bacteria was converted to $\log_{10}$ colony forming units per gram ($\log_{10}$CFU/g).

The control treatment was a non-injected roast beef.
PAT (phosphate, ascorbic acid and tocopherol) was a roast beef injected (based on cooked meat weight) with sodium tripolyphosphate (0.5%), ascorbic acid (550ppm) and α-tocopherol (200ppm).
PATT(phosphate, ascorbic acid, tocopherol and nonvacuum tumbling) was a 3 hr non-vacuum tumbled roast beef injected (based on cooked meat weight) with sodium tripolyphosphate (0.5%), ascorbic acid (550ppm) and α-tocopherol (200ppm).
PATV (phosphate, ascorbic acid, tocopherol and vacuum tumbling) was a 3 hr-vacuum tumbled roast beef injected (based on cooked meat weight) with sodium tripolyphosphate (0.5%), ascorbic acid (550ppm) and α-tocopherol (200ppm).

Results and discussion

There was a significant difference due to treatment for yield. The non-injected (control) roast beef had significantly lower cooking yield than injected treatments probably due to no added phosphate in the control; however, injected roast beef with or without tumbling had the same cooking yield (Table 1). There was no significant difference between the vacuum tumbled roast beef and the non-vacuum tumbled samples. Basically, nontumbling, continuous non-vacuum, or vacuum tumbling (3 hr) with three antioxidants (tocopherol, ascorbic acid and sodium tripolyphosphate) increased cooking yield, but there was a non-significant difference when non-vacuum was compared with vacuum tumbling.
There was no significant difference of psychrotrophs, mesophile or thermophile among treatments (Table 1). For cooked roast beef, the numbers for total plate counts were relative low.
For moisture, there was no significant treatment-time interaction for the roast beef samples. The control, noninjected treatment, had significantly lower moisture due to non-liquid injection compared to other treatments that all had the same values (Table 2). Increase in water-holding capacity with phosphate is due to the unfolding of the three dimensional protein network by the high ionic strength that causes the muscle to swell and the protein to solublize and to retain water before heating (Torley *et al*., 2000). During refrigerated storage, the moisture content was decreased significantly over time as would be expected.
For TBARS, there was a significant interaction due to treatment and storage time. The control (non-injected roast beef) had significantly higher TBARS value than other treatments at all measurement days (Table 3). During refrigerated storage, samples with three antioxidants maintained stable lipid oxidation up to day 14. However, the control significantly increased its TBARS value at day 14 compared to day 0. There was no significant difference of TBARS values among non-tumbled, non-vacuum tumbled and vacuum tumbled samples. Vacuum is used to retard oxygen that attacks muscle but did not significantly decrease lipid oxidation in this study. The reason could be it only prevents oxygen that contacts the surface of whole muscle while tumbling. Also, vacuum tumbling could cause more disruption of the cell membrane of muscle compared to non-vacuum tumbling.
For pH, there was no significant two-way interaction (treatment x storage time). The control had significantly lower pH value compared to other treatments (Table 2). It appears that the 0.5% sodium tripolyphosphate increased pH values in roast beef (Table 2). The antioxidative functions of alkaline phosphates are to increase the pH and ionic strength and tie up some prooxidants (Trout and Schmidt, 1984). There was no significant difference between non-tumbled, non-vacuum and vacuum tumbling treatments in pH values. There was no consistent change in pH values during the storage period
For shear values, there was no significant treatment x storage day interaction. The control and non-tumbled treatments had significantly higher shear values (tougher) when compared to non-vacuum and vacuum tumbled samples (Table 2). The increased tenderness is a primary function of the tumbling process along with increasing uniformity (Krause *et al*., 1978). The tumbling process did increase tenderness of precooked roast beef during 14-day refrigerated storage. The shear values of all samples had significantly ($p<0.05$) higher values at day 14 than day 0.
There was no significant treatment x storage day interaction and main effects (treatment and time) of total iron (Table 2). For heme iron, there was a treatment-time interaction for roast beef. There was no significant difference of heme iron among treatments at day 0 (Table 4). The vacuum tumbled treatment had the lowest heme iron at day 2, but it was the same as the control. There was no significant difference of heme iron among treatments at day 7 and 14. However, there was no treatment x storage day interaction for nonheme iron. The nonheme iron contents of the control had a significantly higher value than that of non-vacuum tumbled roast beef (Table 2). At day 7 and 14, nonheme iron content significantly increased comparing to those at 0, 2 and 4. According to this result, nonheme iron content was increased during storage.

Conclusions

There was no significant difference among non-tumbled, non-vacuum tumbled and vacuum tumbled samples for lipid oxidation. The vacuum tumbling only prevented oxygen from coming in contact with the surface of whole muscle; therefore, it was not significant in decreasing lipid oxidation compared to non-vacuum tumbling.

EFFECT OF ANTIOXIDANTS ON COLOR CHANGE AND LIPID OXIDATION OF SLICED ROAST BEEF

Okayama, T.[1], Iwanaga, S.[1], Kamisoyama, H.[1], Numata, M.[2], Sakata, R.[3] and Muguruma, M.[4]

[3]School of Veterinary Medicine, Azabu University, Sagamihara 229-8501, Japan, [4]Faculty of Agriculture, University of Miyazaki, Miyazaki 889-2192, Japan

Background

Roast beef is a meat product which has gained a lot of popularity in recent years. Its predominately bright red centre is one of its important characteristics. However, the reddening effect does not remain throughout the centre of the meat but fades as the meat is sliced. As a consequence, the marketing of sliced roast beef is very difficult.

Objectives

This research was conducted to elucidate the effect of antioxidants (rosemary + sage extract, grape seed polyphenol, vitamin E, water-soluble astaxanthin, astaxanthin oil, water-soluble catechin, oil-soluble catechin, butylated hydroxy toluene (BHT), oil-soluble rosemary extract + V.E, water-soluble rosemary extract) on color change and lipid oxidation of sliced roast beef.

Materials and methods

Sample : A commercial roast beef (manufactured by ITOHAM FOODS Inc., Japan) was used for the experiments. Topside grass-fed chilled Aussie beef was used for model roast beef as a raw material.
Antioxidants : We selected ten antioxidants with expected strong antioxidant effects. These were as follows : 1) rosemary + sage extract (Stabiloton WS, RAPS Japan Co., Ltd.), 2) grape seed polyphenol (Gravinol, Kikkoman Co., Ltd.), 3) vitamin E (E-mix, Eisai, Co., Ltd.), 4) water-soluble astaxanthin (Astareal, Fuji Chem. Co., Ltd.), 5) astaxanthin oil (Astareal oil, Fuji Chem. Co., Ltd.), 6) water-soluble catechin (Sunkatol W-5, Taiyo Kagaku Co., Ltd.), 7) oil-soluble catechin (Sunkatol No.1, Taiyo Kagaku Co., Ltd.), 8) butylated hydroxy toluene (BHT ; Sustane emulsion, Nikki-Universal, Co., Ltd.), 9) oil soluble rosemary extract + V.E (RM-21E, Mitsubishi-kagaku Foods Co., Ltd.), 10) water-soluble rosemary extract (RM-21A, Mitsubishi-kagaku Foods Co., Ltd.).
Model roast beef preparation : The preparation of model roast beef was as follows : after cutting and trimming of raw material, and then salting with salt and spices (2g/100g meat), and the surface of raw beef material was burnt by a Bunsen burner. The sample placed into polyethylene bag and cooked to an internal temperature of 57°C, for 43 min in a water bath and cooled.
Analysis : Judgements with the naked eye, the sense of smell, and panel test were carried out as far as possible to sliced roast beef sample. The percentage of metmyoglobin (MetMb) formation was measured by the procedure of Trout (1990). Lipid oxidation was determined by the reaction of malonaldehyde with thiobarbituric acid (TBA) as described Siu and Draper (1974) modified of the “filtration method” of Tarladgis *et al*. (1964). The absorbance value measured by the procedure was expressed as TBA reactive substances (TBARS).

Results and discussion

At first this experiment was undertaken for obtaining information on the changes in MetMb formation and TBARS of sliced roast beef during storage. Sliced roast beef about 3 mm thick was placed at 15 cm (about 3.400 Lux.) from the 15W white fluorescent lamp in refrigerator. A comparison to imitate the lighting used by supermarket displays in storage units was hard to accomplish. The changes in MetMb formation and TBARS of sliced roast beef during storage was shown in Fig. 1. The percentage of MetMb formation during storage increased with each additional storage day. The samples after 2 and 3 days storage reached a MetMb level of 38% and 51%, respectively. The TBARS value of samples increased linearly during storage. These

results indicated that the MetMb formation and TBARS value increased under these storage conditions. And the same condition was adopted to get the remarkable difference of sliced roast beef sample during storage.
Screening tests 1 and 2 were carried out to ten kinds of antioxidants. Screening test 1 was as follows : 1% antioxidants were applied to surface of sliced roast beef, and MetMb formation was determined after 3 days storage. Fig. 2 showed the effect of antioxidants on MetMb formation of sliced roast beef after 3 days storage. Grape seed polyphenol and water-soluble rosemary extract treatment samples exhibited a MetMb level under 30% after 3 days storage. Screening test 2 was as follows : The surface of sliced roast beef under the same condition of screening 1 were judged with the naked eye. Table 1 showed that rosemary + sage extract and vitamin E was acceptable but the water-soluble rosemary extract was much better. It was then agreed that the water-soluble rosemary extract (WSRE) from ten different antioxidants was chosen as a result of these screening tests.
Recently, there were several reports [Ahn *et al*. (2002), Coronade *et al*. (2002), Djeane *et al*. (2003), Tanabe *et al*. (2002), Yu *et al*. (2002)] concerning the oxidation effect of rosemary extract on the oxidation stability of meat and meat products. Yu *et al*. (2002) have already reported that rosemary extract acts as an inhibitor of lipid oxidation and color change in cooked turkey products during refrigerated storage. However, WSRE have not been evaluated for their effects to prevent color change and lipid oxidation of sliced roast beef.
The following experiment was conducted to determine the potential benefits of WSRE on color change and lipid oxidation of roast beef. Model roast beef was prepared by dry or wet salting containing 1% WSRE. After slicing, sample was stored under the same condition as previously stated above. Fig. 3 showed the effect of dry- and wet-salting on MetMb formation of sliced roast beef during storage. The percentage of MetMb formation in dry salted sliced roast beef was slightly higher than that in wet sample after 1 day of storage. But after 3 days of storage, the dry salted sample had a much lower level than that of the wet salted sample. The dry salting method was then used in subsequent experiments for roast beef preparation. Fig. 4 showed the effect of salting time on MetMb formation and TBARS value of roast beef. Model roast beef prepared for 0, 1, 3 and 5 days salting containing 1% WSRE, and after slicing, samples were stored under the above mentioned conditions. After 1 day storage, the percentage of MetMb formation of the sample 3 days salting was higher than those of 0, 1 and 5 salting days. But, after 3 days storage, the sample of 3 and 5 days salting were low level of MetMb formation than those of 0 and 1 day salting samples. The TBARS value of samples salting 3 and 5 days were slightly lower than those of 0 and 1 day salting samples.

From separate experiment, the color of sliced roast beef salted sample containing 1% WSRE for 3 days was much better than those of samples added 1% WSRE just after cooking by judgement of naked eye (data not shown).

More detail investigations are necessary to clarify the effect of WSRE on color change and lipid oxidation of sliced roast beef.

Conclusions

The effect of antioxidants on color change and lipid oxidation of sliced roast beef was investigated. The water-soluble rosemary extract was chosen as a result of the screeing tests. Changes were measured in metmyoglobin formation and thiobarbituric acid-reactive substances of roast beef samples containing 1% water-soluble rosemary extract. It was suggested that the water-soluble rosemary extract showed protection of color change and lipid oxidation of sliced roast beef.

Acknowledgements

We gratefully thank Ms. Atuko Sone in our lab., Kobe Univ., who carried out the experiments in this study. We would like to thank Mr. Toru Ito, ITOHAM FOODS Inc., for donating the beef sample. We are also deeply grateful to Mr. Roy Shrigley for his useful comments in reading this paper.

IMPROVEMENT OF PROPERTIES OF PRODUCTS MADE FROM PSE MEAT BY ADDITION OF SODIUM CASEINATE AND MTGASE

Michał Olkiewicz[1], Edward Pospiech[1,2], Bożena Grześ[2], Barbara Kłossowska[1]

[1]Meat and Fat Research Institute, ul. Jubilerska 4, 04-190 Warszawa,
[2]Institute of Meat Technology, Agricultural University, ul. Wojska Polskiego 31,60-624 Poznań

Background

PSE meat is characterized by its lowered culinary and processing value. The quality of products manufactured from this meat is worse in comparison with those made from normal meat which are characterized by a lack of appropriate consistency and juiciness, a deterioration of texture, weak binding ability of meat and excessive quantity of thermal loss. One of the common practices aiming to assure high quality of processed meat is the application of certain substances (e.g. phosphates, carbonates) or the incorporation of protein ingredients in the product formulation. The second group of substances includes a variety of isolated proteins, which have been used as functional ingredients in ground or whole muscle foods, of which milk, beside soy proteins, is employed most widely (Pietrasik & Li-Chan 2002, Ramírez-Suárez , Xiong 2003). In recent years, trans-glutaminase (E.C. 2.3.2.13), as a functional additive, has raised much interest (Hammer 1998, Kuraishi et al. 1998). This enzyme promotes polymerization of proteins through intermolecular ε-(γ-glutamyl)lysine cross-links, which form stable covalent cross-bonds between the particles of proteins and peptides and cause modifications in their structure (Kurt & Rogers 1984). It may have an effect on the change in the water-holding capacity of the muscle tissue and improve the texture of the final product.

Objectives

The purpose of the present study was to examine the effectiveness of microbial transglutaminase (MTGase) as a catalyst for the interaction of sodium caseinate and proteins of the PSE muscle under processing conditions. Our hypothesis was that MTGase would induce polymerization and, therefore, properties of products manufactured from PSE muscles might be similar to those made from normal muscles.

Materials and methods

The experimental material used in this study comprised the following ham muscles: *m. semimembranosus* and *m. biceps femoris* which were selected in two quality groups: - normal (RFN) and watery (PSE) meat according to typical critical values used in other studies. They were used for the production of a model ham. Four variants of the model pork ham were produced. The differentiating factors included the type of meat (RFN or PSE) (first two variants – the ham made from RFN meat – first variant that made from PSE meat – second variant). In the case of the PSE and RFN model ham (first and second variants), they were produced with additives, which contained curing brine. In the next variant (third one – PSE1), the MTGase preparation was added to the curing brine and, in the last treatment (fourth variant – PSE2), additionally, 2.0% sodium caseinate preparation was added. Muscles, after coarse mincing, were cured and tumbled. The composition of brine was the following: water – 86.88%, salt – 11.3%, sugar – 1.10%, sodium ascorbate – 0.22%, sodium glutamate – 0.22%, protein hydrolysate – 0.22% and sodium nitrate – 0.055%. The brine was used in the quantity of 30% in relation to the weight of meat. Before tumbling, commercial preparations of microbiological transglutaminase containing 0.5% of the active enzyme ("Active WM"), suspended in maltodextrin as a carrier and / or 2.0 % sodium caseinate preparation were added. Meat was tumbled at the lower pressure in three cycles for 24 hours. Afterwards, some of the meat mass was taken for the analysis of the protein fraction and the remainder was canned and pasteurized until the temperature of 72°C was reached in the centre of the can. The investigation of raw meat comprised determinations of the pH value and electrical conductivity of meat, measurements of its basic composition (total protein, water and fat content), the amount of centrifugal drip from the raw meat and from meat after tumbling, free water content

determined by the filter paper method, by Makała & Olkiewicz (2001), electrophoretic separation of proteins from the fraction of washed myofibrils and the centrifugal drip according to the method of Fritz et al. (1989) with the later modification of Pospiech et al. (2000). This modification consisted in the use of an 8M urea addition in the separating layer of gel. The analyses performed on the final product comprised the estimation of the amount of thermal drip from ham, measurement of slice strength using the UTM Zwick apparatus, model 1445 MOPS (Tyszkiewicz & Olkiewicz 1991) and determinations of rheological characteristics of meat using the CASRA method (Continuously Stress-Relax Analysis) (Tyszkiewicz & Olkiewicz 1997). The experiment was performed in three replications. The statistical evaluation of the results was conducted using the Statgraphic for Windows program ver. 3.1.

Results and discussion

The PSE meat, in comparison with the normal meat, was characterized by a significantly lower pH value and significantly higher electrical conductivity (Table 1). The total water content in the PSE meat was lower than in the normal meat – on average by 1.3%. On the other hand, the free water content was almost double in the PSE meat. The significantly higher content of total protein and higher fat content in the PSE meat were probably caused by the dripping of water from this meat causing a relative increase in the content of the remaining components.

TABLE 1. Characteristics of pork meat

Muscle characteristic	RFN	PSE	*LSD*
water content (%)	75.6	74.3	*1.9*
protein content (%)	19.8 [a]	21.7 [b]	*1.6*
fat content (%)	2.6	2.8	*1.1*
pH	5.89 [b]	5.56 [a]	*0.22*
electrical conductivity [mS]	8.0 [a]	15.3 [b]	*7.3*
amount of centrifugal drip (%)	5.6 [a]	9.0 [b]	*2.2*
free water content (%)	13.9[a]	22.6 [b]	*4.6*

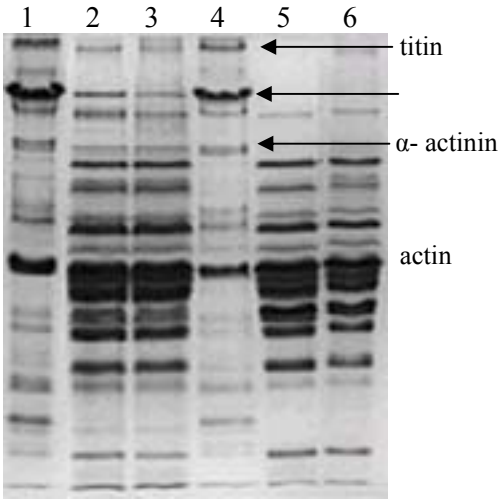

Fig. 1. Protein separation of the washed myofibrils fraction and the fraction of centrifugal drips obtained from diverse quality meat. Band: 1 – washed myofibrils from watery meat, 2 – centrifugal drips from watery meat with 0.1% „Activa WM" preparation (PSE1), 3 – centrifugal drips from watery meat with 2% sodium caseinate preparation (PSE2), 4 – washed myofibrils from meat of normal quality (RFN), 5 – centrifugal drips from watery meat (PSE), 6 – centrifugal drips from meat of normal quality (RFN)

The separations of proteins isolated from the PSE meat were characterized by a somewhat higher number of bands as compared with those from the normal quality meat. In the first case, 30-36 bands were obtained, while in the second – 27 to 30 bands. This may have been connected with more rapid changes of proteins occurring in the PSE meat directly after slaughter - especially in the range below 42 kDa. It is known that in the case of PSE meat, the extraction of proteins is weaker (Fischer et al., 1979; Joo et al., 1999) and the bands of high-molecular proteins (above 200 kDa) are considerably more pronounced. The percentage of native titin (T1) was somewhat higher in the case of myofibrils from the PSE meat as compared with the RFN meat. Double amounts of titin-degraded products were found in normal meat in comparison with the PSE meat. This confirms the more rapid degradation of cytoskeletal proteins in the first type of material. The slower degradation of the cytoskeletal proteins in watery muscles is a typical picture, found not only in pig meat (Boles 1992) but also in turkey meat (Pospiech et al. 1997). It is much easier to observe the liberation of myofibrillar proteins from muscle tissue based on the analysis of the centrifugal drip from the meat (Grześ et al., 1996; Pospiech et al., 2000). If the presence of proteins, which, as a rule, should not be present in the drip, is confirmed, this may be the evidence of protein degradation and their shifting from the muscle fibers to the ambient environment. Observations obtained in this study showed that samples of centrifugal drip from the PSE meat, as compared to the drip from the RFN meat, contained less titin (T1) and products of its degradation (T2) and heavy myosin chains (ca. 200 kDa). These differences may have resulted from the

increased liberation of myosin from the myofibrillar structure and the quicker degradation of the cytoskeletal proteins in the normal meat. According to other authors (Grześ et al., 1996; Pospiech et al., 2001; Taylor et al., 1995), these differences may constitute evidence of better tenderness and water-binding capacity of the normal meat. The use of additives in the PSE meat showed that the electrophoretic separation of proteins of the centrifugal drip was distinctly different from the separation of proteins of the centrifugal drips from the RFN or PSE meat only. In these drips (samples PSE1 and PSE2) were found proteins, which did not appear in the drips from PSE and RFN meat, or were present in them in smaller quantities (Fig. 1). The content of proteins with the molecular weight of 3700 kDa (probably mainly the T1) increased by more than 10 times. The quantity of proteins with the molecular weight of 2400 kDa and 105 kDa was 2-3 times higher than in the PSE and RFN meat drips. The above changes could probably be attributed to the effect of the influence of MTGase and to interactions of sodium caseinate and proteins of PSE muscle under processing conditions. Transglutaminase probably induced their polymerization and, therefore, improved properties of products made from the PSE meat. The data presented in Table 2 indicate a significant improvement of the slice strength in the samples from the PSE meat with the addition of the enzyme. The same observations also concern other reological properties of the model hams i.e. their plasticity, elasticity and fluidity. When evaluating the effect of MTGase on the water-binding capacity (WBC) of the PSE meat, it should be stressed that the process observed as the liberation of proteins and generation of new aggregates, including aggregates with MTGase, affected unfavorably WBC. After the addition of the enzyme, the drip increased, when compared to the sample without this additive, on average by 5.6%. This could be attributed to the participation of MTGase in the formation of a strong covalent cross linking between the particles of proteins and peptides, which caused such a strengthening of protein structures that an additional, mechanical squeezing of water from the product, containing the PSE meat, took place. The addition of sodium caseinate to the meat caused the appearance of one band more in the electrophoretic picture, which was not present in the previous separations. This was a band with the molecular weight of more than 3700 kDa. The studies of Fritz et al. (1992) and Grześ (2000) showed that proteins of such weight might constitute products of aggregation. In the case of both cited studies, titin was present in the composition of the aggregates. Additionally, the study of Grześ (2000) demonstrated that the aggregates also contained myosin. The role of these aggregates in the formation of functional properties of meat and its structure is not fully explained. The studies of Grześ (2000) and Fritz et al. (1992) showed that, together with the prolongation of the tumbling and heating, the incidence of aggregates was more intensive. These results indicate that milk proteins may stimulate the generation of aggregates because the percentage content of this band in the separation of proteins was almost twice as high compared to the remaining samples. The addition of caseinate also caused a 50% decrease of the band responding to T1, almost tripled the increase of the content of the 2400 kDa band and increased, by more than half, the proteins with the molecular weight of 200 kDa. The changes observed in the proteins resulting from the addition of sodium caseinate to the PSE meat favorably affected WBC, which is confirmed by the comparison of the size of the thermal drip. The addition of sodium caseinate to the PSE ham decreased the thermal drip by 3.7% in comparison with the PSE ham manufactured without the caseinate. Whether the water was retained by the generated protein aggregates, or bound by the caseinate alone, requires further studies. The retention of a great quantity of water in the hams caused a lowering of the strength of slices. Plasticity, elasticity and fluidity were worse (table. 2). The conducted study suggests that the addition of any of the employed functional additives individually did not decrease the unfavorable consequences of the PSE meat to any satisfactory degree and only their application together with MTGase resulted in a positive effect.

Table 2. Binding ability and reological characteristics of model hams made of RFN and PSE meat

Type of the sample	Binding ability		Reological characteristics		
	slice strength ($N\ cm^{-2}$)	thermal loss (%)	plasticity ($x\ 10^5\ N\ m^{-2}$)	elasticity ($x10^{-6}\ m^2\ N^{-1}$)	fluidity ($x10^{-8}\ m^2\ N^{-1}\ s^{-1}$)
RFN	$2.65^{c} \pm 0.21$	$11.3^{a} \pm 0.7$	$6.87^{ab} \pm 0.47$	$6.10^{ab} \pm 0.88$	$4.34^{a} \pm 0.17$
PSE	$1.50^{a} \pm 0.04$	$19.1^{c} \pm 0.8$	$6.55^{a} \pm 0.84$	$6.63^{b} \pm 0.82$	$5.05^{a} \pm 0.59$
PSE 1	$1.80^{b} \pm 0.07$	$24.7^{d} \pm 1.7$	$7.72^{bc} \pm 0.50$	$5.56^{ab} \pm 0.26$	$5.56^{b} \pm 0.26$
PSE 2	$1.34^{a} \pm 0.07$	$15.4^{b} \pm 1.39$	$6.46^{a} \pm 0.21$	$5.65^{ab} \pm 0.19$	$4.73^{a} \pm 0.30$
LSD	0.22	2.4	0.96	1.12	1.12

a, b, – means in rows with different superscript are significantly different at $P<0.05$; LSD – Least Significant Difference, RFN – raw meat of normal quality, PSE – raw watery meat, PSE1 – raw watery meat after tumbling with 0.1 % „Activa WM" preparation, PSE2 – raw watery meat after tumbling with 2.0 % sodium caseinate preparation.

Conclusions

1. Transglutaminase, when added to the PSE meat, affected significantly the improvement of consistency. At the same time, the water binding capacity of the product deteriorated.
2. Sodium caseinate, when added to the PSE meat together with MTGase, intensified the aggregation of proteins and improved water binding significantly but, at the same time, a weakening of the structure and consistency of the final product was observed.

COLOUR PHOTOGRAPHS TO ESTIMATE HETEROCYCLIC AMINE INTAKE FROM PORK OF DIFFERENT RN GENOTYPES

Viktoria Olsson, Kerstin Skog*), Kerstin Lundström and Margaretha Jägerstad

Background

The Maillard reaction is important to obtain an appetizing surface browning of meat during frying and roasting; however, it also induces the formation of several carcinogenic/mutagenic heterocyclic amines (HCAs) (Jägerstad *et al.*, 1983). Cooked meat and fish are important sources of exposure to HCAs, as are pan residues when used to prepare gravy. The most abundant HCAs in cooked foods include 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) and 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx) (Skog *et al.*, 1998). The formation of HCAs depends on cooking conditions, especially temperature and time, the concentration of precursors, such as free amino acids, creatine/ine and sugar in the food as well as the occurrence of certain modulators, e.g. pro/antioxidants (Skog *et al.*, 1998).

Although eight HCAs have been judged as probable human carcinogens and one as a possible carcinogen (group 2B and 2A respectively, according to (IARC, 1993)) it is difficult to evaluate their impact in the aethiology of human cancer. The most serious drawbacks in epidemiological studies include difficulties in estimating the exposure, for example the intake of HCAs in a population because of large ranges in the reported level of HCAs in cooked food, differences in estimated consumption (e.g. portion size, frequency), as well as difficulties in taking various cooking practices into consideration (Augustsson & Steineck, 2000). One common way to indirectly assess HCA intake is through food frequency questionnaires, sometimes complemented with colour photographs so that the degree of doneness can be estimated (Augustsson *et al.*, 1999; Sinha *et al.*, 1999). It has been suggested that visual aids, such as photographs, will improve exposure assessment in epidemiological investigations of HCA intake (Keating *et al.*, 2000). However, the relationship between cooking conditions (temperature and time), degree of surface browning and concentration of HCAs as judged from colour photographs has limitations. We have shown that pig meat of different genotypes (the dominant RN^- mutation) through a marked variation in glycogen levels, may give rise not only to varying concentrations of HCAs but also degree of browning when fried under identical conditions (Olsson *et al.*, 2002). In that study, a subjective scoring of surface browning correlated negatively with the level of HCA. Thus, the degree of surface browning may be a poor indicator of HCA content, and meat with similar surface browning could contribute very differently to the daily intake of HCAs. Because the colour of the crust is an important factor for judging doneness of the domestically cocked pig meat, we wanted to investigate how these findings affected the estimated intake of HCAs from pork chops.

Pig meat is the most popular type of meat in Sweden and the estimated frequency of carriers of the RN^- allele may be as high as 60-70% in the Swedish slaughter pig population. The *RN* mutation affects several of the precursors for the formation of HCAs, and due to hyperaccumulation of glycogen in glycolytic muscles, meat from carriers of the RN^- allele exhibits markedly higher glycogen levels than the normal meat of non-carriers (Lundström *et al.*, 1996). Further, we have found that the level of creatine and some free amino acids in the meat are affected by the *RN* genotype of the pigs (Olsson *et al.*, 2002).

Objectives

The overall aim of the present study was to contribute to an improvement of HCA exposure assessment. Pork chops from different *RN* genotypes were fried at three different temperatures, photographed, whereupon crust colour was recorded and the crusts analysed for HCAs. The results were combined with a simple questionnaire to study dietary practice and preferences, and a monthly intake of mutagenic HCAs through fried pork chops was estimated (Olsson *et al.*, 2004).

Materials and methods

Two *M. longissimus dorsi* (LD) muscles of pig, weighing approximately 2.5 kg each, were selected from the commercial cutting line at the slaughterhouse in Uppsala, Sweden. Genotyping (carrier (*RN⁻/rn+)* or non-carrier (*rn+/rn+)* of the *RN⁻* allele) was performed following the procedure reported by Milan *et al.* (2000). The contents of free amino acids (FAA), dipeptides, residual glycogen, creatine and creatinine in the meat were analysed as described before (Olsson *et al.*, 2002). The *RN⁻/rn+* and *rn+/rn+* samples were vacuum-packed, stored at +4ºC for 4 days and thereafter used in the frying experiment.

The deboned meat was fried as intact 2-cm-thick chops. Before frying, the edges of the chops were slightly cut to avoid an uneven curving during frying and the meat was tempered until the mean internal temperature was 18.7 ± 1ºC. Three *RN⁻/rn+* chops at a time, followed by three *rn+/rn+* chops were fried at low (160ºC), medium (180ºC) and high (200ºC) temperatures in a cast iron pan on an ordinary household stove with a ceramic top. The chops were fried in 10 g of a commercial vegetable frying fat for 3 min per side and then the chops were left to cool to room temperature, weighed and photographed. Cooking loss was calculated as the percentage change in chop weight before and after frying.

The concentration of HCAs in the crust was analysed using a Blue chitin solid-phase extraction method. In short, the freeze-dried crust was homogenised in NaOH, mixed with diatomaceous earth and packed into a cartridge. The HCAs were extracted with ethyl acetate. The eluate was evaporated to dryness, dissolved in NaOH and applied on a Blue Chitin column. The HCAs were eluted with MeOH/ NH4OH (9:1 v/v), evaporated to dryness, dissolved in MeOH, and then analysed using LC/MS (LCQDECA ion-trap mass spectrometer, with Xcalibur software, Thermo Finnigan, San José, CA, USA), using the electrospray as ion source (Bång *et al.*, 2002). The recoveries ranged between 30-80% depending of type of HCA and recovery corrections were made before presenting the results.

In the questionnaire, the questions were aimed to provide data on consumption habits and household cooking practices for pig meat with special emphasis on the loin (pork chops), *M. longissimus dorsi* (LD). For general questions on the consumption of pig meat the respondents were asked only to consider lean meat and not mixed or further processed products such as cooked ham, sausages or bacon. Six colour photographs showing the surface colour and the interior colour of fried pork chops were presented to the respondents who were asked to indicate which of the photographs corresponded best to their normal frying practices. The six photographs represented *RN⁻/rn+* and *rn+/rn+* meat, fried at three different temperatures described previously. The questionnaire was distributed to a total of 151 people (60 men and 91 women) in Uppsala, Sweden, at three different occasions during the summer of 2002. For the analysis of the questionnaire, the respondents were divided into four age groups: 1 = 15-20, 2 = 21-40, 3 = 41-60, and 4 = 61 years and upwards.

Results and discussion

Three initial pan temperatures, 160, 180 or 200º C were chosen to mimic various domestic frying practices. After frying pork chops from one carrier and one non-carrier of the *RN⁻* allele at these different temperatures, we found the mutagenic HCAs, MeIQx, PhIP and IQx, in low concentrations in the crust. The level of mutagenic HCAs was almost ten times higher in *rn+/rn+* meat fried at 200ºC compared to the *RN⁻/rn+* chops (0.49 vs. 4.13 ng/g cooked meat). IQx was detected only in the *RN⁻/rn+* crust whereas the comutagens, harman and norharman, were detected in the crust of the *rn+/rn+* chops but not in the *RN⁻/rn+* meat. The *rn+/rn+* meat, fried at an initial pan temperature of 200ºC gave more than 20 times the amount of mutagenic HCAs compared to that fried at 160ºC, 4.13 compared to 0.18 ng/g cooked meat. PhIP was the main HCA formed. In a study by Augustsson *et al.* (1997) a 20-fold increase of PhIP levels was typically seen when increasing the frying temperature for several meat dishes from 175ºC to 225º C, and a general temperature dependency of the formation of HCAs has been repeatedly reported (e.g. Skog *et al.*, 1995).

Based on colour photographs, the respondents reported that they preferred fried chops with medium crust colour, rejecting the very pale crust of the non-carrier of the *RN⁻* allele fried at low temperatures as well as the dark brown of the carrier fried at medium/high temperature. Most respondents chose fried chops from the non-carrier, which, based on information given in a questionnaire, would result in an markedly higher average contribution to the monthly HCA intake of 359 ± 402 ng (mean ± SD) compared to 35 ± 60

ng/month for consumers who preferred the *RN⁻/rn+* chops. Overall, the total monthly intake of mutagenic HCAs derived from consuming pork chops was moderate, on average 256 ng, ranging from 0 to 1982 ng/month (Table 1). A mean intake of 256 ng/month would mean a limited daily contribution of about 9 ng from fried pork chops, well in agreement with an earlier Swedish study which estimated a daily contribution of 10.1 ng/day from fried pork chops and gravy (Voskuil *et al.*, 1999). This intake rate should be related to the assessed total daily intake of 200 and 120 ng HCAs for Swedish men and women, respectively (Augustsson *et al.*, 1997). Besides the Swedish study, data on the specific contribution of pork to the intake of HCAs are sparse. According to estimates by Layton *et al.* (1995) the intake of HCAs originating from pork would be 51 ng/day for a man or woman weighing 70 kg. The corresponding figures for beef and chicken would be 542 and 173 ng/day, respectively. The estimated daily intake in this study was however high, 1820 ng/day compared to 160 ng/day in another Swedish study (Augustsson *et al.*, 1997).

Conclusions

To estimate total HCA intake, epidemiologists try to identify markers for the factors cooking time and temperature. Doneness of meat and crust browning have been put forward as a reasonable indirect measurement of mutagenic activity (Steineck *et al.*, 1993; Sinha *et al.*, 1999). However, our data show that care should be taken when using colour photographs to determine cooking preferences for assessment of HCA intake because background factors, such as the occurrence of the *RN⁻* allele in pigs, may influence the results. The *RN* genotype of pigs affects both colour formation and HCA content and thereby makes crust colour inappropriate for estimation of HCA content in cooked pig meat carrying the *RN⁻* allele.

The study involves respondents from a small regional area in Sweden and a relatively homogenous population group. Thus, it is not appropriate to extrapolate its findings to general exposure of HCAs in the Swedish society. However, it does contribute to better knowledge about the level and formation of HCA in domestically prepared pork chops as well as understanding of the complexity of using different exposure indicators, such as the degree of surface browning, in the assessment of HCA intake through diet. The study shows that the raw material composition is important and that small adjustments in the domestic cooking practices may help reduce the formation and intake of HCAs.

Background

Semitendinosus beef muscles injected with salt solutions -sodium chloride (SC) and sodium tripolyphosphate (STPP)- and cooked by the *sous vide* system (research carried out by our group), showed that both salts -alone or in combination- successfully reduced cooking weight losses (Sanchez, *et al*. 2004). The best results were obtained with the following salts combinations (0.25 g STPP + 1.20 g SC, and 0.25 g STPP + 0.70 g SC, per 100 g tissue), reducing cooking weight losses to almost 0%. Salt incorporation modified both, pH and Hunter Lab *a* parameter. Sample pH increased as STTP concentration increased. Hunter Lab *a* parameter was affected by both, salts and temperature. The optimum cooking temperature (CT) range was 60-65 ºC, this temperature range modified structural components of the muscle inducing disintegration of filaments and lateral and longitudinal shrinkage of myofibrils. The magnitude of the alterations depends on CT. The combination of STPP and SC salts and a CT of 65ºC produced the best gel-like structure that preserves cellular structures and increases water holding capacity (Gonzalez *et al.* 2004). Even though the micro and ultra structural studies described certain mechanisms involved in salts and CT effects on these muscles, it was important to evaluate biochemical parameters in order to confirm or further explain these effects on the final quality of the product.

Objectives

To determine tissue salts concentrations and evaluate its distribution and analyse collagen, salt soluble and total protein content, and protein patterns in cooking juice after the application of both, salts injection and *sous vide* cooking, on *Semitendinosus* muscles. To evaluate myofibrillar protein patterns in non-cooked samples.

Materials and methods

Beef *Semitendinosus* muscles were excised from steers carcasses and collected at a beef packaging plant 48 h after slaughter. Fat free muscles (pH average: 5.49 ± 0.26) were injected (10%w/w, hand operated brine pump) with appropriate salt solutions to obtain the final tissue concentrations of STPP and SC indicated in tables I and II. Injected and non-injected samples were then submitted to *sous vide* cooking procedure, temperatures applied were 55, 58, 65, 72 and 75 ºC (Sanchez *et al*. 2004). Tissue phosphate extraction was carried out as in Sanchez, *et al*. (2004) and the determination was accomplished utilizing a Sigma Diagnostics Kit based on the Fiske-Soubarrow reaction. Sodium Chloride quantification was performed following the directions of Ockerman (1985). Total collagen was evaluated following the procedure reported by Hill (1966). Salt soluble protein extraction was carried out as in Saffle & Galbreath (1981), and protein quantification was completed by the Bradford methodology (1976). Total protein content was achieved by the Kjeldahl method (AOAC 1994). Purified myofibrils were isolated following the method described by Molina & Toldrá (1992), and the SDS-PAGE was performed following the procedure of Laemmli (1970). Molecular weight (MW) and relative quantity of protein bands in the gels were analysed with a Bio Rad GS-800 Calibrated Densitometer.

Results and discussion

Table I shows the average and standard deviation (SD) for each salt actual value (experimentally obtained values) expressed as g/ 100 g dried tissue, and the comparison to the nominal one (theoretically injected value). It can be seen that until 0.25% STPP, the nominal and actual values were close similar, and at higher STPP concentrations lower amount of the salt was retained inside the muscle. Instead, SC was almost totally

retained at all concentrations utilized. This result made evident that the procedure selected to incorporate the salts was appropriate.

Figure 1 depicts the slice sampling performed to study salts distribution. Table II illustrates the significant differences of STPP and SC actual values for each slice sampling. It can be seen that the higher the STPP concentration is, the higher is the difference between values of the centre (site of the injection) and the peripheral positions, indicating a restricted diffusion of this large molecule inside the muscular tissue. However, at the same STPP concentration injected, the presence of SC improved STPP distribution, probably accelerating its diffusion by establishing a competence between both ions (increases effective diffusion coefficient). In the case of SC, this table shows that at the lower SC concentration the salt is evenly distributed nevertheless when the salt concentration is increased to ≥ 0.7 (g/100 g tissue) the distribution became less homogeneous. However, when STPP concentration increased it improved SC distribution as was previously described. The overall result indicated that salts distribution was not as homogeneous as we expected. Consequently further investigations related to the present issue were conducted applying multi-needle injection and tumbling (massaging) procedures to improve salts distribution.

There were not significant differences ($p>0.05$) in total collagen concentration due to the different salt treatments and CTs including 72 ºC (data not shown), indicating that this parameter was not affected by the incorporation of the salts and/or by changes in CT between 55-72 ºC. On the other hand at 75ºC, the total amount of collagen in the tissue consistently diminished (no significant differences were found among salt treatments), probably due to the solubilization/gelatinization of the collagen that occurs at temperatures between 75-85 ºC, with the potential loss of this protein in the cooking-juices.

Fig. 2 shows the salt soluble protein content for each salt treatment at the different CTs grouped as Low CT (55 ºC to 58 ºC), Medium CT (65ºC) and High CT (72ºC to 75ºC) expressed as mg/100 g of dried tissue. Non significant differences were found among salt treatments for each temperature range ($p> 0.05$). Instead, when CT increased the salt soluble protein concentrations in the tissue decreased ($p < 0.05$). This tissue reduction was probably due to a greater protein solubilization induced by the higher temperatures, and the consequent loss of the solubilised protein in the cooking-juices.

Non changes in the total protein content of the tissue (data not shown) were found among salt treatments or comparing the different CTs, it seems that the small but significant changes detected in the tissue concentration of the salt soluble proteins were not evidenced in the total protein content of the tissue.

Supernatants (final wash) of the myofibril extraction of non-cooked samples (figs. 3 & 4), and of cooking-juices (65 ºC, data not shown) coming from salt-treated and control samples, were analysed for type and quantity of proteins. These figures depict the protein patterns of the 10% and 7.5% SDS-PAGE of the same sample. It can be seen that three major bands in the range of 43-45 kD, 105 kD and 200 kD appeared in the 5th line (0.25% STPP + 0.70% SC), which 2 to 3 times higher concentration compared to the other salt treatments and the control. Densitometry analysis showed that the MW of these major bands are in accordance to the actine (42-43 kD), α-actinine (100-103 kD), and Heavy Chain Myosin (200 kD) bands. It appeared that these proteins were much more solubilized by this combination of salts. However, when higher SC concentration (0.25% STPP + 1.2%SC) was applied, it seems that a salting out effect reduced protein solubilization. In the protein pattern of the cooking-juices (data not shown), it was also detected an increment in proteins concentration, mainly in those of lower MW, corroborating partially previous results. Again, it appears that 0.7% SC is the more suitable concentration to increase protein solubilization, and the combination of both salts improved this solubilization. The differences found between supernatant (non-cooked) and cooking-juice was probably due to the CT applied, which also increased protein solubilization disregarding of the salt concentration used. As well, the appearance of smaller MW bands could be related to the temperature-induced degradation. The presence of these solubilised proteins could be responsible for the gel-like structure described previously by this group (Sanchez, *et al.* 2004, Gonzalez, *et al*. 2004), where the strongest gel-like structure formed and the lowest cooking weight loss was obtained with the salt combination of 0.25% STPP + 0.70% SC and 65 ºC cooking temperature.

Conclusions

Salts incorporated were not evenly distributed in the muscle suggesting the use of another methodologies to improve incorporation and distribution.

Salt addition (particularly 0.25% STPP + 0.70% SC) induced protein solubilization in the fresh tissue, this result supports the formation of a gel-like structure at 65 ºC that reduce cooking weight loss reported in previous work of the group.

No other biochemical changes were observed with the different salt combinations.

INDONESIAN BAKSO MEATBALL PROPERTIES WITH POSTMORTEM MEAT TIME AND TAPIOCA STARCH CONCENTRATIONS

Rahardiyan, D.[1] and McMillin, K.W.[2]

Background

Food is an integral part of human society, providing nourishment and cultural enjoyment. Worldwide, more emphasis is being placed on convenient and traditional foods. Meatballs are a convenient meat product for preparation in the home or by commercial eating establishments. Meatballs and fishballs are especially popular in Asia. In Indonesia, meatballs known as bakso are made from prerigor meat or meat before completion of rigor mortis (Purnomo, 1990). The meat is ground and emulsified with salt, tapioca starch, and garlic. The batter is formed into small balls and cooked by steaming, boiling, or deep-frying, depending on the cuisine. Bakso is commonly served with boiled chicken stock or soup and distributed from pushcarts at street corners (Pandisurya, 1983), with consumer preference for tougher, but more elastic, bakso (Yuliati, 1999). Commercial production of bakso has been difficult for Indonesian meat processors because sufficient quantities of prerigor or early postmortem meat materials are not readily available. The use of raw chilled or frozen postrigor meat would provide for consistent supplies of adequate raw materials.

Objectives

The purpose of this research was to evaluate the properties of bakso after substitution of postrigor meat for early postmortem meat in bakso and to determine the appropriate level of tapioca starch for production of bakso with postrigor meat.

Materials and Methods

Local 2 to 4 year old Ongole crossbred grass-fed cattle were slaughtered at RPH Pegirian (Pegirian Slaughter House, Surabaya, East Java, Indonesia). Meat collection was approximately 3 hours in total for deboning of *Semimembranosus* and *Semitendinosus* muscles from carcasses and about 1 hour transportation to the PT. Eloda Mitra meat plant (Sidoarjo, East Java, Indonesia) in a refrigerated truck. The 160 kg of collected meat was chilled immediately after collection (10°C) and randomly assigned to early postmortem and postrigor groups of 80 kg. Early postmortem meat was ground for immediate usage for bakso. Postrigor meat was held chilled at 10°C for approximately 24 hours until processing into bakso. Early postmortem ground meat pH was 5.30-5.79, while the postrigor ground meat had pH of 5.06-5.59. Added ingredients were tapioca starch (National® 7, National Starch and Chemical, Singapore) at 5, 10, or 15% of total formulation, 0.6% sodium tripolyphosphate (STPP, $Na_5P_3O_{10}$, Albert & Wilson Phosphate Groups, Indonesia), 1.6% salt (NaCl) from local markets, 0.6% regular cane sugar obtained from local markets, and 0.8% monosodium glutamate (MSG, PT. Ajinomoto, Indonesia). The meat block was decreased proportionally to increased starch levels. Bakso was manufactured using the equipment, facilities, formulation, and processing procedures of PT. Eloda Mitra.

Ground meat was chopped in a bowl chopper (K.G. Wetter, Germany) for 20 minutes. Salt, STPP, and tapioca starch were added to the early postmortem or postrigor meat batches with crushed ice at 5% to maintain 15°C batter temperature. Batter was formed mechanically into 14 g balls with a meatball former (Chuang Zong Baller, Taiwan). The balls were boiled at 100°C for 20 minutes in an open boiler (PT. Mastrada, Indonesia) or until balls were floating in the boiling water. Cooked bakso balls were drained on perforated aluminum trays to remove excess water (outer surface appeared dry) before packing into limited-low-density polyethylene bags (25 x 160mm, 0.15 mm thick, Top Printing Indonesia Co., Indonesia) with 20 balls/bag for vacuum packaging (Henkelman H-800 Double Chamber, Netherlands) and frozen at -20°C. Each experiment was replicated 3 times.

Bakso balls were stored frozen at -20°C and thawed at room temperature (32°C) for 20 to 30 minutes before analyses. Moisture and fat were determined by methods 950.46 and 960.39 (AOAC, 1990), respectively, at Laboratorium Sentral Pangan (Central Food Lab, University of Brawijaya, Malang, East Java, Indonesia). Texture analysis was with a Lloyd Machine Model Universal Testing Instrument according to Hidayati (2002) and Yuliati (1999) at Pusat Antar Universitas Pangan dan Gizi (Center Inter-University Food and Nutrition, Gajah Mada University, Yogyakarta, Indonesia). The Lloyd Universal Testing machine was warmed up for 10 minutes before reading elasticity, gel strength, and shear force readings with an upper cycle limit of 4-mm, lower cycle limit of 3-mm, compression mode, and 60-mm/min test speed, 20-mm/min chart speed. Sample width was set to 10-mm, depth to 10-mm and gauge length to 10-mm. The bakso sample was a cube of 10 x 10 x 10-mm placed under the slice shear force probe for measurement of texture as minutes/gram for elasticity and newtons for gel strength (hardness) and shear force values. Samples for scanning electron microscope procedure were prepared according to Hidayati (2002) and Yuliati (1999) at UPT Mikroskopi Elektron (University of Airlangga, Surabaya, East Java, Indonesia). Bakso samples were sliced 2 to 3-mm thick with a razor blade, fixed with 2% glutaraldehyde in a phosphate buffer of 7.3 pH, and dried with critical point drying (Sumdri-780 Sample Drying, USA) for 72 hours before placing on a brass plate holder. Samples were coated with 24 carat gold with an ion sputter-fine coater (JEOL-GLE4X, JEOL Technic Co. Ltd., Japan) for 1.5 min, achieving an approximate thickness of 0.25-mm. The coated sample was observed under a scanning electron microscope unit (JEOL GSM-T100 Scanning Electron Microscope, JEOL Technic Co. Ltd., Japan) at 1500X magnification. Statistical analyses were performed by General Linear Model procedures for a completely randomized design (SAS, 1998), with main effects of postmortem condition, tapioca starch concentration, replication, and interactions, and least mean squares differences in analyses of variance at probability value of less than 0.05.

Results and Discussion

Replications in this experiment were different ($p<0.05$) for fat content and shear force, most likely due to animal source, but perhaps due to differences in homogenization of different batches. Moisture, fat, elasticity, and gel strength were not different ($p>0.05$) in bakso from postrigor meat or early postmortem meat. Shear force was higher ($p<0.05$) in bakso from early postmortem beef (21.4 N) than postrigor beef (20.6 N). The bakso met the Indonesian National Standards (70% moisture, less than 2% fat, Board of Nasional Standardization, 1995) with 72 to 75% moisture content and 0.2% fat. Moisture, fat, elasticity, and gel strength did not differ ($p>0.05$) with level of tapioca starch, but trends for increased texture with increased starch were observed. Shear force increased ($p<0.05$) with increased starch. SEM micrographs of bakso from early postmortem and postrigor meat with 5, 10, and 15% tapioca starch illustrated spongy three dimensional structures. The myofibrillar proteins appeared as interconnecting thin protein strands that formed a net-like matrix. The tapioca granules were observed as dense spherical granule aggregates, aw was also reported by Yuliati (1999) in canned bakso. The dense, aggregate, and non-swelled appearance of tapioca starch granules may be an effect of the high vacuum of the scanning electron microscope column (Hood et al., 1974). Micrographs of bakso from postrigor meat showed slightly less complex protein networking and pores appeared to have more large voids than in bakso from early postmortem meat. Bakso from postrigor meat had a spongy structure with less protein network development than bakso from early postmortem meat that appeared to have more extensive matrix development and more and smaller void spaces.

Sufficient proteins were extracted during comminution with 1.6% salt to result in stable batters (Barbut, 1995) and added phosphates reduce processing yield losses and stabilize emulsion structure (Eilert et al., 1996). Starch granule swelling and gelatinization contribute to emulsion stability, viscosity or elasticity, and prevention of syneresis during refrigeration, frozen storage, or thawing (Hood *et al*., 1974). Hidayati (2002) studied the effects of sodium tripolyphosphate and sodium alginate on the rheological properties of bakso and obtained elasticity ranging from 0.5183 to 0.540 min/gram while hardness (gel strength) of bakso ranged between 24.237 to 59.410N. The texture in those studies was relatively uniform, which was also observed with the present results. Sensory panelists indicated that tougher bakso with more elastic properties was more desirable (Yuliati, 1999).

Conclusions

Use of postrigor meat in bakso production gave only slightly different textural properties than early postmortem meat. Bakso with 15% starch had the highest elasticity, which is sought as a bakso rheological trait. Postrigor meat with inclusion of 15% tapioca starch could be used to produce bakso with sufficient textural traits for commercial mass production. This will allow improved raw material procurement and increased efficiencies for bakso processors.

DESCRIPTIVE EMPIRICAL MODEL OF INSTRUMENTAL HARDNESS CHANGES IN DRY-CURED *SEMIMEMBRANOSUS* AND *BICEPS FEMORIS* MUSCLES AS A FUNCTION OF WATER CONTENT, NACL AND PH

J. Ruiz-Ramírez, J. Arnau, L.Guerrero, P. Gou

Institut de Recerca i Tecnologia Agroalimentàries (IRTA). Centre de Tecnologia de la Carn, Granja Camps i Armet s/n, 17121 Monells, Girona, Spain

Background

The dry-cured ham process involves a long drying period that produces a gradient in hardness in the product. Extreme superficial hardness could cause the crust formation, which is one of the most important problems in cured meat products. This problem is related to a high drying rate on the outer part while in the inner part there is a high moisture content. The diffusion rate of water from the inner zone does not compensate the high dehydration rate on the surface and consequently the surface hardens and forms a crust (Flores, 2001). The experimental relationship between hardness and water content has been reported by various authors (e.g. Virgili *et al*., 1995; Ruiz-Ramírez *et al*., 2003) but until now no attempt has been made to describe the effect of NaCl and pH on this relationship. According to Ruiz-Ramírez *et al*. (2003), the hardness-water content relationship can be described by an exponential model.

The effect of pH and NaCl content on the texture of dry-cured meat products have been examined in previous studies. Arnau *et al*. (1998) and Guerrero *et al*. (1999) established higher hardness for normal or low pH hams than for high pH hams. Whereas, Magraner *et al*. (2003) associated high pH levels with harder dry-cured hams. Low NaCl content was related with pastiness and softness in dry-cured ham (Arnau, 1991), while high NaCl content increases the shear force in dried fish products (Iseya *et al*., 1998).

Objectives

The aim of this study was to model the relationship between water content and hardness of dry-cured meat products considering the NaCl and pH effects.

Materials and methods

The experiment was undertaken using 18 hams. Half of the hams had a pH<5.7 and the rest a pH>6.2. The pH was measured on *Semimbranosus* (SM) muscle at 24-h post mortem (pH_{SM}) with a combined electrode (Ingold 406, Ingold, Urdof, Switzerland) attached to a portable pH-meter (Crison 507, Crison Instruments S. A, Barcelona, Spain). SM and *Biceps femoris* (BF) muscles were separated from the hams and manually rubbed with a dry salt-cured mixture of 0.5 g of KNO_3, 0.3 g of $NaNO_2$ and depending on treatment with 20, 50 and 80 g of NaCl per kg of muscle (8.19%, 16.67% and 21.29%) on a dry matter basis (DM) respectively. These muscles were individually packaged in bags of polyamide and polyethylene (SACOLIVA® permeability: 2.6 g H_20/m^2/day at 23 ºC/85%RH) and were horizontally placed in trays in a room at 2±2 ºC for 45 days. Thereafter nine samples from each muscle (N=324) were shaped as a parallelepiped (4x2x2 cm). The rest of the muscles were ground and packaged in metallic bags (SACOLIVA® permeability: < 1 mg H_20/m2/day, to 23 ºC/85%HR), and stored at 2±2 ºC until its posterior physicochemical analysis. Each parallelepiped was weighed in an analytical balance of 0.01 mg of precision (Mettler PE 300) and was dried in a drying tunnel at 3±2 ºC, 57.5±2.5% RH and 1m/s air speed, until desired levels of drying were reached. Levels of drying used corresponded to the range of water content 28,5- 59.7%. The dried samples were individually packed in plastic bags (20 µm polyamide / 70 µm polyethylene; water vapor permeability: 2.0 g/m^2/24h; SACOLIVA S.L.®, Castellar del Vallès, Barcelona) with a 70% nitrogen atmosphere and kept at 15±2ºC for a minimum of 30 days to allow homogenization of NaCl and water throughout the sample.

A texture Analyzer (Universal MTS Alliance model. RT/5, SEM, Barcelona, Spain) was used to determine hardness. Before carrying out texture analyses nitrogen-packed samples were kept for one hour at room temperature. The cores of the dry-cured loin slices were accurately carved with a scalpel into 10 x 10 x 10 mm (length x width x height) and triplicates were obtained. The samples were compressed to 50% of their original height. Force-time curves were recorded at crosshead speed of 1 mm/s. Hardness was defined by maximum peak force during the compression cycle.

The parallelepiped samples used for texture analysis were immediately cut up and water content was determined by drying at 103±2ºC until reaching constant weight (AOAC, 1990). Water content of the samples was expressed on a dry mater basis (DM) (X = kg H_2O / kg DM).
Sodium chloride content was determined by the Volhard method (ISO 1841-1: 1996), water content (AOAC, 1990) and pH (measured with a xerolyt penetration electrode Crison) were determined in the rest of the ground muscle.
Statistical analysis: All the statistical analyses were carried out with the SAS statistical package (SAS Institute, 1999). The relationships between hardness and water content on a dry mater basis (X) were studied through a non-linear regression analysis (PROC NLIN). The following model was used:

$$Y = aX^b \quad \textbf{(1)}$$

Where Y is the predicted hardness, a and b are the model parameters and X= water content on a dry mater basis.

Results and discussion

Figure 1 shows the relationship between hardness and water content (X) for all dry-cured samples. Experimental data indicate that for a range of X between 0.8 and 1.3 the hardness remains practically unchanged while for X<0.6 the hardness increases substantially. This substantial increase occurs at different values of X according to the product, i.e.: 0.8 in dry-cured loin (Ruiz-Ramírez, submitted) and 0.6 in dry-cured ham (Ruiz-Ramírez *et al*., 2003). In the present study, the substantial increase of the hardness is similar to the one observed in dry-cured ham. The different anatomical origin of the samples can explain the difference between ham and loin. Figure 2 (a) shows the predicted hardness by muscle. The BF and SM muscles presented similar hardness at each water content. Figure 2 (b) shows the predicted hardness according to pH measured in the muscle SM (pH_{SM}). The samples from hams with low pH_{SM} presented greater hardness than those from hams with high pH at X values from 0.6 to 1.3. But when X diminished below 0.6 the differences between samples from hams with different pH_{SM} were not significant (P>0.05). Nevertheless, at X>0.7, which corresponds to the inner part of the dry-cured ham, the samples from hams with low pH_{SM} presented greater hardness. The lowering of the meat pH closer to the isoelectric point of myosin, increases intermolecular linkages between negatively and positively charged groups, which would explain the greater hardness in the muscles with low pH. This result agrees with those reported by Arnau *et al*. (1998) and Guerrero *et al.* (1999), who found a higher hardness for low pH hams than for high pH hams at X values around 1.7.
The NaCl content also influenced the hardness of the muscles (Figure 3a and 3b). The muscles with higher NaCl content presented higher hardness for samples from hams with low pH_{SM}. These results are probably due to the fact that when high NaCl contents are used there is a compaction of myofibrillar structure (Shomer *et al*., 1987), which would increase the hardness. Similarly, Iseya (1998) found a higher hardness when the NaCl content was increased in dried fish products. The NaCl effect was different depending on the pH_{SM}. The NaCl effect was more evident in samples from hams with low pH_{SM} than in those from hams with high pH_{SM}, which presented similar hardness for NaCl content of 2% and 5% and higher for 8% in the range of X between 0.6 and 1.3. But when X diminished below 0.6 the significant differences between samples from hams with different NaCl content disappeared.
The behavior observed for the NaCl content was similar to that observed for pH, in the sense that when the X values diminished below 0.6, the differences among NaCl contents were lower. These results show that at X values below 0.6, which were achieved in the surface layer of dry-cured meats products, the hardness is more influenced by the water content than by NaCl or pH.
The estimates of parameters, the residual standard deviation (RMSE) and coefficient of determination (r^2) of the equation (1) obtained from the non-linear regression analysis for all dry-cured samples (general model), by muscle, pH_{SM} and NaCl content are showed in Table 1. The lowest RMSE for the model was for samples from hams with high pH_{SM} and 5% of NaCl and for samples from hams with low pH_{SM} and 2% NaCl content.

Conclusions

An exponential model was found appropriate for describing the relationship between hardness and water content (X). The hardness of the muscles was affected by the pH_{SM} and the NaCl content. As the NaCl content increases the hardness increases, especially at pH_{SM}<5.7. At X values lower than 0.6 the hardness is more influenced by water content than by NaCl content or pH.

Background

Lipid oxidation causes a rancid off-flavour and off-odour in meat. Numerous factors affect lipid oxidation including light, oxygen concentration, temperature, presence of anti- and pro-oxidants, degree of unsaturation of the fatty acids and the presence of enzymes (Skibsted *et al*., 1998). Lipid oxidation is normally not considered to be a limiting factor for shelf life of aerobic packed chill stored meat, as lipid oxidation occurs at a slower rate than discoloration or microbial growth (Zhao *et al*., 1994).

Meat colour is the primary attribute of fresh meat that affects consumer purchase decision. Consumers expect a uniform appearance within a group of similar ground beef products (i.e. patties with the same fat percentage) and relate any colour differences within similar products to deficiencies in product quality (Faustman & Cassens, 1990; Hood, 1990). Thus, any process that negatively affects the colour of fresh ground beef can lead to lower consumer appeal and marketability.

For cooked meat, thermal processes can promote lipid oxidation by disrupting cell membranes and releasing pro-oxidants, thereby inducing ‘‘warmed-over flavour’’ (WOF) during refrigerated storage and subsequent reheating (Sato and Hegarty, 1971). With the rapidly increasing consumer demand for precooked convenience meat items, a proper control of oxidation is of particular importance. One of the ways to minimize lipid oxidation and WOF in cooked meats is to use antioxidants.

There has been in the last years an increasing interest in borage (*Borago officinalis* L.), especially of its seed oil, by medical and nutritional research groups, due to the presence of high levels of γ-linolenic acid. Wettasinghe and Shahidi (1999) showed that borage meal exerted a concentration-dependent antioxidant activity in a meat model system. Borage extracts have demonstrated excellent antioxidant properties; the ability to retard lipid oxidation was attributable to the ability of its phenolic constituents to quench reactive oxygen species. Wettansinghe *et al*. (2001) reported that rosmarinic, syringic and sinapic acids are the major phenolic compounds present in the ethanolic extract of borage meal. It has been demonstrated that natural antioxidants rosemary extract, oregano extract and borage meal were highly effective in inhibiting lipid oxidation (TBARS formation) in beef patties packaged in modified atmosphere and stored in the dark at 2±1°C; in fact, borage meal suppressed totally TBARS formation (Sanchez-Escalante *et al*., 2003). The antioxidant activity of borage meal has been not studied in cooked meat products.

Objective

The purpose of this study is to determine antioxidant capacity of borage meal in fresh and cooked beef patties formulated with different content of fat and packaged in modified atmosphere and over-wrapped, respectively.

Materials and methods

Preparation of borage meal. Borage seeds were obtained from Spain. Seeds were cleaned, washed and dried, and after were stored vacuum packaged in polyethylene/polyamide pouches at 2-4°C until used. Borage seeds were ground in a mortar. The meal was defatted by shaking ground seeds with hexane (1:5 w/v, 5 min, three times). Dried and defatted borage meal was sifted with sieves of decreasing sizes (l.0, 0.5 and 0.2 mm) to eliminate the remaining husk and reduce the particle size of the meal.

Fresh patties and atmospheres. Meat was obtained fresh (3 day post-mortem) with a local producer, was excised from 2 beef carcasses, and minced using a conventional mincer through a plate with 4 mm holes. All two minced muscles were thoroughly mixed together in a single batch. Portions of uniform weight of the minced muscle (about 90 g) were mixed with salt (2%), borage (1%), and fat (10% for fresh patties and 10% and 20% for cooked patties). Also controls (no borage meal) were prepared with different fat levels. Fresh

beef patties were formed. One group was placed on styrofoam trays, for the study of fresh patties. Each tray with the round beef patty was introduced in a pouch made of a nylon and polyethylene laminate of water vapour and oxygen permeability 0.6 g/110 sq inch/24 hr and 3.5 cc / 100 sq inch / 24 hr 5-7 g/m^2/24 h at 23°C, respectively. The pouches were filled with a gas mixture of 80% O_2 + 20% CO_2, and sealed. Fresh patties were stored for 12 days at 2±1°C in the dark. Four packs were opened for subsequent analysis for each formulation every 3 days of storage; two of them were used for microbial sampling alone, while the 2 other were used firstly for colour instrumental analysis and thereafter for the determination of pH and TBARS.

Cooking and packaging. Meat patties were cooked on an open electric broiler by flipping every 3 min until the final internal temperature of 70 ºC (measured with a thermocouple) was reached. Samples were weighed before and after cooking to measure cooking losses. After cooling down to room temperature, meat patties were placed in styrene foam trays, over-wrapped in an oxygen permeable (6000–8000 cm^3/m^2/24 h at STP) cling film (Cryovac USA) and stored in a 2±1 ºC dark room for up to 12 days. Also a group of cooked meat patties were storage under light (1000 lux) at 2±1 ºC.

Colour measurement. Colour changes in the surface of fresh meat samples during storage were monitored by recording the CIE L*, a* and b* values using a Hunter Lab Colorimeter (D25 model). Measurement was achieved 30 min after package opening.

Lipid oxidation. Lipid oxidation in stored meat patties was also measured as thiobarbituric acid-reactive substances (TBARS) as described by Pfalzgraf *et al*. (1995).

Microbial analysis. Counts of aerobic psychrotrophic flora were determined in fresh and cooked patties in Plate Count Agar (Merck; Darmstadt, Germany) after incubation at 10°C for 7 days (Elliott *et al*., 1983). Counts were expressed as log cfu/g.

Statistical analysis. The significance of differences among samples at each day of storage was determined by analysis of variance (ANOVA) using the Least Square Difference method of the General Linear Model procedure of SPSS (SPSS 1995). Differences were considered significant at the $p<0.05$ level.

Results and discussion

Colour Measurement. Figure 1 shows that fresh beef patties with borage meal had ($p<0.05$) higher a* values, than those of controls with 10% of fat and without fat. The value of a* was influenced by the days of storage in each one of the treatments. The red colour diminished progressively along the storage in all the hamburgers, without caring the treatment neither the quantity of added fat. The control treatments, independently of the quantity of applied fat, showed significantly lower values ($p<0.05$) than the treatments with borage meal until day 9 of storage. It indicates that the borage meal is able to maintain high values of a* for more time. Red colour of borage samples was very intense instead to presence of meat pigments. These results were in agreement with Sánchez-Escalante *et al*. (2003) who reported that borage was effective in maintaining red colour for the first 10-12 days.

Lipid Oxidation. Figure 2 shows the changes in TBA value for fresh patties. Lipid oxidation increased rapidly with increasing time ($p<0.05$) in control samples. However, TBA values were kept to a minimum in samples containing borage meal. These results agree with the results of Wettasinghe and Shahidi (1999) and with Sánchez-Escalante *et al*. (2003), who found that borage meal possess antioxidant properties. With respect to cooked patties stored under darkness (Figure 3), our results show that the addition of borage meal is effective still after heating at 70ºC, since it delays the formation of TBARS; while control samples show an intense oxidation. Fat level did not affect antioxidant activity of borage meal; lipid oxidation was not increased with increasing time ($p<0.05$). Figure 4 show that lighting not increased lipid oxidation, thus borage meal was effective delaying TBARS formation, while controls developed an important lipid oxidation. The type of lighting significantly affected the shelf life of meat when is displayed for retail sale. The use of a lamp emitting radiation in the UV range (conventional supermarket fluorescent tube) is severely detrimental for the retail life of meat. TBARS values reveal that the retail life of beef meat is significantly more stable in the absence of UV light (Djenane *et al*., 2001).

Microbial Analysis. The results of counts of psychrotrophic aerobes (data not shown) in fresh and cooked patties show that the borage meal addition did not present an inhibitory effect on the growth of psychrothophic flora. Same behavior was already reported for Sánchez-Escalante *et al*. (2003) who observed that the borage meal has important antioxidant properties, but it does not have any antimicrobial effect in fresh beef patties.

Conclusions

Borage was very effective in preventing lipid oxidation, without dependence on the level of fat; thus the addition of borage meal resulted in a significant antioxidant activity in fresh and cooked beef patties, while it inhibited only partially metmyoglobin formation in fresh meat. All effects contributed to extending the shelf life of fresh and cooked beef patties. It is also important to consider that the smallest amount of UV radiation should be avoided in lighting devices for the retail display of meat.

PROTEOMIC CHARACTERISATION OF NORMAL AND PASTY SPANISH DRY-CURED HAMS

[1]Hortos Maria, [2]Santé-Lhoutellier Véronique , [1]Arnau Jacinto & [2]Monin Gabriel

[1]IRTA-Centre de Tecnologia de la Carn. Granja Camps i Armet, s/n. 17121-Monells, Spain
[2]INRA Meat Research Centre 63122 Saint Genès Champanelle, France

Background

Tenderness is an important quality trait of dry-cured ham for which changes in the solubility and integrity of the muscle structural proteins are considered to be the main mechanisms responsible for the tenderization of hams during dry-curing. Monin *et al*. (1997) pointed out that the hardness and chewiness of hams increase during the initial stages of processing due to a decrease in protein solubility and water content and subsequently which decreases as proteolysis progresses. However, intense proteolysis can induce textural defects that may reduce the acceptability to consumers.
The relationship between excessive proteolysis and defective texture was first reported in Italian dry-cured hams (Parolari *et al*. 1994, Virgili *et al.* 1995). However, although pastiness and softness have been related to increased proteolysis measured as amino acid and peptide contents (Parolari *et al.* 1988, Careri *et al*. 1993, Virgili *et al.* 1999), but the proteins implicated have not been identified. The endogenous lysosomal cathepsins of muscle are thought to be the enzymes mainly responsible in this process (Parolari *et al*. 1988, Schivazappa *et al.* 2002). However, several factors have been reported to affect proteolysis: genetic type, sex, age, meat pH and processing (salting, temperature and time) (Buscailhon *et al*. 1994, Arnau *et al*. 1998, Garcia-Garrido *et al*. 1999, Tabilo *et al*. 1999).

The development of new separation techniques, such as 2-D electrophoresis, enables the study of those mechanisms related to meat and meat products quality.

Objectives

The study was carried out to compare protein 2D electrophoretic patterns of pasty and soft dry-cured ham to those from normal hams to find markers related to textural defects. To achieve this, low molecular ionic strength extracts were used to find markers related to the defective texture of dry-cured hams.

Material and methods

The normal-texture dry-cured hams (control) processed with different processing times: short (6 months), medium (8-12 months) or long (18 months); were selected at a Spanish company. The defectiveness samples (3) were selected according to their textural characteristics: soft (1), pasty (1) and very pasty (2). The analyses were performed on the *Biceps femoris* muscle.

Protein extraction/fractionation

150 mg of muscle were added to 1.5 ml of extraction buffer (150 mM NaCl, 25 mM KCl, 3 mM $MgCl_2$ and 4 mM EDTA) in an Eppendorf tube containing a glass bead. Homogenisation was performed using a Retsch MM2 agitator (Retsch, Haan, Germany) for 30 min at 4°C. Homogenates were centrifuged at 10,000g for 10 min at 10°C. The supernatant was collected and protein content was measured using Bio-Rad Bradford Protein Assay kit.

2D electrophoresis

2D electrophoresis was performed on both normal and defective quality samples. Immobilised pH gradient (IPG) isoelectric focusing (IEF) was carried out in a Protean IEF cell (BioRad), using BioRad strip, 17 cm pH 4-7. 90 µg of soluble proteins were loaded onto the strips for analytical gels. Protein loading on strips, IEF and SDS-PAGE were performed according to Morzel *et al*. (2004). Gels, in duplicate, were silver stainned following the protocol of Yan *et al*. (2000). Gel images were acquired using GS-800 densitometer and analysed using the PDQuest software (Bio-Rad).

Results and discussion

Different 2DE patterns were detected between dry-cured ham quality, although the profiles were also clearly influenced by the total processing time.

Actually, differences in profile evolution of the spot intensity were detected between processing times. However, a noticable number of spots were characteristic for middle (n=21 spots) or long (n= 11 spots) processing times (Table 1). Moreover, the intensity of a significant number of spots was also higher in both the long and the middle processing times. Such evolution could be explained by a higher protein solubility development as the processing time increased. And the relative number of characteristic spots to the higher intensity spots, for both the long and medium processes, is probably related to the different solubilities and degradation patterns of those proteins implicated. A high protein solubility would increase the intensity and/or the number of spots, while more degradation would produce progressively a decrease of protein molecular weight. This is consistent with the different spot pattern observed in gels between the processing times. For the long processing time, spots were located either at the upper zone of the gel or at the lower zone and at a pH area about 5 or 6 (Fig 1). In contrast, for medium processing, the characteristic spots were above 30-40 kDa.

Furthermore, the lower protein solubility from the short processing time was also consistent with an absence of any characteristic spot. But we observed numerous spots having lower intensity, mainly distributed between around pH 6 – 6.5, showing a decrease in solubility of the molecules having a pI close the dry-cured ham pH.

	Processing time		
Process	Long	Medium	Short
Characteristic	11	21	-
Higher Intensity	24	7	4
Lower Intensity	1	11	15

Table 1. Number of selected spots

The characteristic spots of the softness profile were mainly detected in the middle (2104-2201--5112-5113-5210) and bottom (2013-7019) parts of the gel. However, the soft hams had a very similar spot pattern to the normal quality ham pattern. Also several spots were detected in both normal and soft dry-cured hams but were more intense from soft hams (5707-5715-5717-5718-6712-6713-6714-6716-6717-7716).

Both softness and pastiness patterns had common spots at the upper zone of the gels, on the anode (3624-4517) side. The softness and pastiness pattern did not show the several low molecular weight spots characteristic of normal hams (Fig 2). These results are in agreement with the intense proteolysis previously reported (Parolari *et al*. 1988), assuming that these spots (protein or fragment) result from proteolysis.

In the upper gel zone, several characteristic spots (3621-3622-3625-3626-3733-3734-4213-4624-4735-4736-4824-4825-5616) were apparent of the gel from the pastiness ham. Other spots (3735-3736-4627-4628) were present in the pasty ham while in the very pasty hams, they were less intense or absent. In the middle part of the gels, the 5205 spot exhibited a lower intensity in high pasty hams which could be due to a more intense proteolysis in very pasty samples. However, the intensity of the 4116 spot increased as pastiness increased and seemed to be related to the extent of defectiveness.

Conclusions

Different 2DE patterns were detected between dry-cured ham quality, although the profiles were also clearly influenced by the total processing time. The protein solubility increased as the processing time increased.
The decrease in the molecular weight of proteins depended to the processing time.
The pasty and soft texture of dry-cured hams had more spots with high molecular weight.
2-D electrophoresis was effective in characterizing the quality of dry-cured hams. In further work , spots of interest (either proteins or fragments) will be studied by Maldi-tof spectrometry.

PREDICTION OF INTER-MUSCULAR FAT IN THE FRESH PORK LEG

A. J. Stetzer[1], R. E. Klont[2], A. A. Sosnicki[2], F. K. McKeith[1]
[1]University of Illinois at Urbana – Champaign, Urbana, IL, 61801, USA, and [2]PIC USA, Franklin, KY

Background

Consumers continue to demand home-cooked taste as they purchase more ready-to-eat foods. Ham is a key raw material utilized for many of these foods because of ease of preparation and high flavor. The demand for center cut slices and spiral sliced hams has increased, however, one of the drawbacks of these products is the presence of inter-muscular fat commercially recognized as "Star fat" and seam fat. Thus, the pork industry has identified a need to measure and predict star fat to aid in selecting hams more suitable for center cut slices.

Objectives

The objective of this experiment was to quantify the relationship of linear carcass measurements to star fat in hams and to predict the amount of star fat in hams.

Material and methods

A total of 90 carcasses, 45 gilts (G) and 45 barrows (B), of the same genetic background were selected based on hot carcass weight (HCW) at ranges of 70.8 - 83.6 kg, 84.4 - 90.4 kg, and 90.9 - 98.9 kg (L, M and H groups, respectively). Linear carcass measurements were taken at 24 h post-mortem. Paired fresh pork legs (n = 178) were utilized in which the left side was processed into hams for center cut slice (Figure 1) area measurements and processing yields. Four to six center cut slices were removed per ham, and total area of lean, star fat, and bone was measured per slice by three evaluators. Right side fresh pork legs were utilized for fresh ham composition and cut yields. Three subcutaneous fat thickness points were measured on the right fresh pork leg. The initial fat depth measurement was evaluated perpendicular to the midpoint of the dorsal-ventral line of the ham, while subsequent measurements were taken at 45° angles dorsal and ventral) from the midpoint. Individual muscles or muscle groups were excised and weighed. Data were analyzed with the MIXED procedure of SAS (2000) with the model accounting for the effects of weight group and sex with significance determined at the level of $P < 0.05$. Regression analysis was conducted with the REG procedure (SAS, 2000) utilizing star fat weight as the independent variable whereas cubic (C), quadratic (Q), and linear (L) models were compared with the F test for lack of fit (Neter et al., 1990).

Results and discussion

Selection based on HCW resulted in a wide range of fat and lean measurements. Mean ham weights ranged from 8.09 - 12.07 kg, and last rib fat ranged from 0.76 - 3.05 cm. Ham weights also varied for the left side of 11.26, 10.64, and 9.82 kg and for the right side of 11.19, 10.53, and 9.66 kg (H, M, and L, respectively). Also, last rib fat differed for B (2.49 cm) and G (2.16 cm; $P < 0.05$). Star fat weight increased with the weight groups (0.08, 0.10 and 0.11 kg, respectively for L, M and H; $P < 0.05$). Linear fat measurements did not consistently predict star fat weight. Star fat area measurements had a correlation to seam fat weight (0.29). The three subcutaneous fat depth measurements taken at the midpoint, ventral and dorsal sites had moderate correlations of (0.17, 0.19 and 0.19, respectively) to star fat weight. However, these midpoint, ventral and dorsal fat depth measurements had higher correlations to seam fat (0.35, 0.29 and 0.28, respectively) and subcutaneous fat (0.76, 0.72 and 0.71, respectively). Both, seam and subcutaneous fat can explain a portion of the variation in star fat weight using cubic ($R^2 = 0.27$) and linear regressions ($R^2 = 0.30$). In addition, HCW can explain a portion of the variation in star fat weight using cubic regression ($R^2 = 0.27$).

Conclusions

By utilizing a few key variables, like HCW or ham weight, star fat weight could be minimized in ham production. HCW was the single best predictor of star fat. Selecting lower weight carcasses having less backfat would decrease seam fat occurrence in hams, thus making them more suitable for bone-in products. Future research will focus on better understanding of all carcass variables impacting the development of inter-muscular fat in the fresh pork leg according to the key genetic background/commercial lines of the pigs.

WATER LOSS FROM PORK DURING COOKING

– DOES PH DURING COOKING HAVE AN IMPACT?

K. Rosenvold, M. Baltzer and M.D. Aaslyng and S. Støier
Danish Meat Research Institute, PO Box 57, 4000 Roskilde, Denmark

Background

Eating quality of pork is a combination of appearance, flavour, tenderness and juiciness. The cooking procedure (centre temperature, heating time/temperature and heating method) has an impact on juiciness, and an increase of centre temperatures will decrease the juiciness (Bejerholm & Aaslyng, 2003). In a recent study (Aaslyng et al., 2003) as much as 50% of the variation in juiciness was explained by the variation in cooking loss in *Longissimus dorsi*. Both juiciness and cooking loss are affected by the pH_u and waterholding capacity (WHC) of the raw meat.

Aaslyng et al. (2003) also showed – in 10 different raw meat qualities – that while there was a large variation in cooking loss when measured at 60°C and 70°C, this difference was gone when the same samples were heated to 80°C. In addition, higher final cooking loss was registered in samples with low WHC and low pH_u. On the other hand, there was no difference in cooking loss when WHC and pH_u of the meat was medium or high. This indicated the presence of a threshold value for pH_u and/or WHC above which cooking loss is influenced neither by WHC nor pH_u.

Based on the above, it was speculated whether the observed differences in cooking loss were influenced by different pH courses in the meat during cooking. Hence, an experiment was carried out that followed the pH course and cooking loss during cooking of *L. dorsi* and *Biceps femoris* samples with high, normal and low pH_u.

Objectives

The objective of this study was to investigate a possible relation between the pH course and cooking loss during cooking of pork samples with high, normal and low pH_u.

Materials and methods

A total of 12 *L. dorsi* samples - four high, four normal and four low pH_u samples - and eight *B. femoris* samples – four high and four normal pH_u samples – were included in the experiment. The selection of samples was based exclusively on pH_u in commercial slaughter pigs. The samples were stored frozen and were defrosted for 20-24 hr at 4°C prior to cooking. Cooking procedure: Whole roasts in oven (convection oven) at 90°C. When the centre temperature in the samples reached 70°C, the oven temperature was increased to 105°C. The centre temperature, weight and pH were measured prior to cooking and at regular intervals during the cooking until a centre temperature of 90°C was reached. pH was measured using a Knick Portamess 910 pH meter with a Mettler Toledo Lot 406-m&-S7/25 until centre temperatures of approx. 55°C were reached, as the pH meter was unreliable above this temperature. The pH electrode was calibrated prior

Table 1 pH_u (measured prior to cooking) and final cooking loss (measured when the centre temperature had reached 90°C) in *L. dorsi* and *B. femoris* samples with high, normal or low pH_u[a].

	L. dorsi			*B. femoris*	
pH-group	high	normal	low	high	normal
pH_u	5.84 ± 0.04[a]	5.58 ± 0.04[b]	5.40 ± 0.03[c]	5.99 ± 0.03[a]	5.62 ± 0.03[b]
final cooking loss	36.7 ± 1.7[a]	39.5 ± 1.4[a]	47.8 ± 1.4[b]	43.9 ± 1.1[a]	45.6 ± 1.1[a]

[a] Least squares means and SEM are shown. Different letters for pHu and final cooking loss within muscle indicate significant differences ($p < 0.05$) between the high, normal and low pH-groups.

to each measurement in buffers equilibrated to the centre temperature ± 5°C of the sample at the specific measurement. Cooking loss was calculated on the basis of the measured sample weights.

The statistical analysis was carried out with the Statistical Analysis System, version 8.2 (SAS Institute, Cary, NC, USA). The MIXED procedure was applied when calculating the least square means and standard error of all the variables. A model including the fixed effects of pH group (high, normal, low) and centre temperature as well as their interaction, the repeated effect of centre temperature with sample as subject was applied for pH and accumulated cooking loss.

Results and discussion

pH_u (measured prior to cooking) of the three *L. dorsi* and the two *B. femoris* pH groups is listed in Table 1, showing that the pH values of the different pH groups were significantly different when the experiment was initiated.

The pH course during cooking is shown in Figure 1 for *L. dorsi* and in Figure 2 for *B. femoris*. During cooking, the pH courses of the high and normal pH_u samples were almost identical although taking place at different levels. In *L. dorsi,* pH fell approximately 0.3 pH units from 0°C until centre temperatures of 35-45°C were reached. When the centre temperature increased further, the pH slowly increased as well – approximately 0.2 pH units. In contrast, the pH fell less than 0.2 pH units in the low pH *L. dorsi* group, and the minimum pH was reached before the centre temperature reached 20°C. In *B. femoris*, pH fell approximately 0.2 pH units from 0°C until the centre temperatures reached 35-45°C. When the temperature increased further, pH in both pH groups increased again, with the highest increase in the normal pH_u group.

The final cooking loss (measured when the centre temperature had reached 90°C) is shown in Table 1. In *L. dorsi*, the final cooking loss in the low pH group was significantly higher than in the high and normal pH groups. There was no significant difference in final cooking loss between the high and normal pH group in either *L. dorsi* or *B. femoris*.

The accumulated cooking loss is shown in Figure 1 for *L. dorsi* and in Figure 2 for *B. femoris*, respectively. In *L. dorsi*, cooking loss

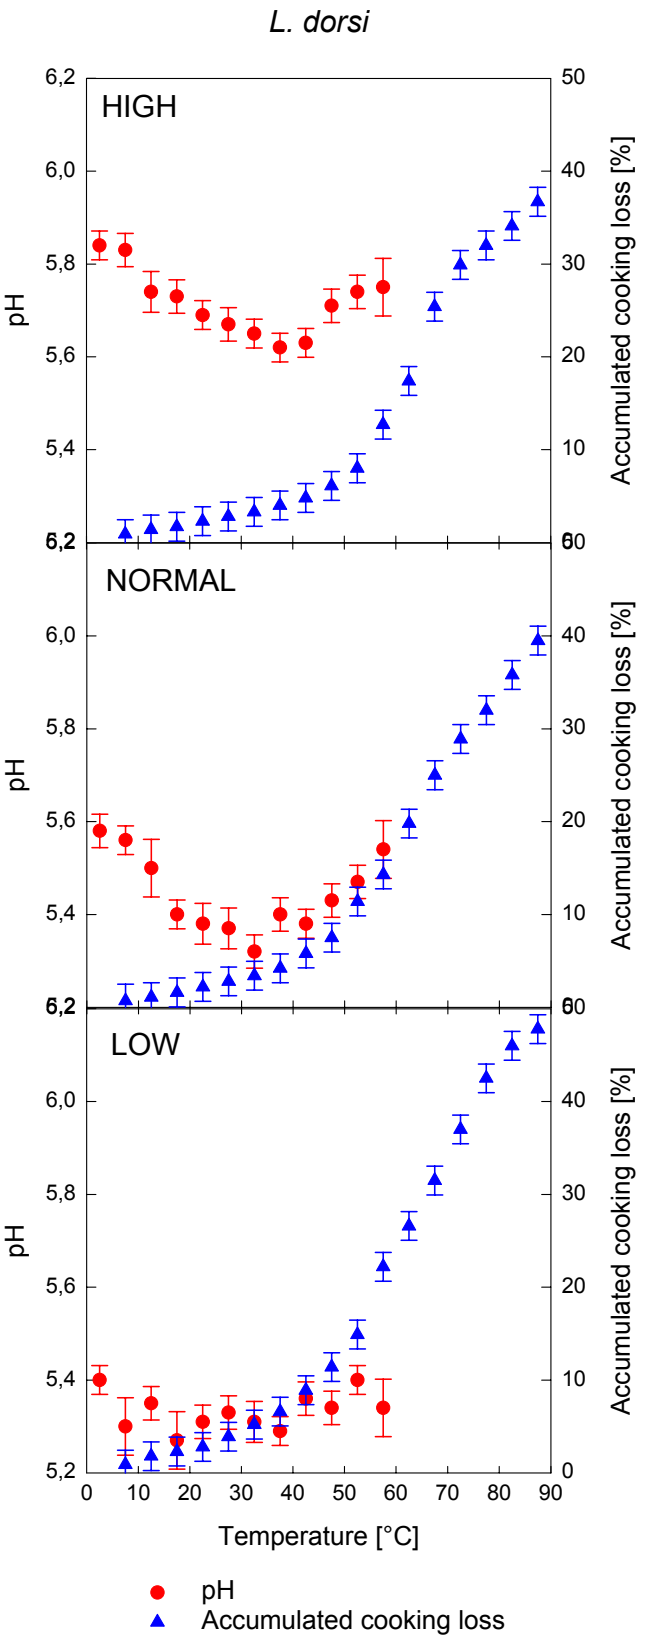

Figure 1 pH and accumulated cooking loss measured at centre temperature intervals of 5°C during cooking of *L. dorsi* samples of high, normal and low pH_u.

of the low pH group exceeded 1% cooking loss per 5°C temperature increase already at 30°C, and the highest cooking loss per 5°C temperature increase was observed in the temperature interval of 55-60°C. In contrast, the centre temperature in the normal and high pH groups was above 40°C and 45°C, respectively, before the cooking loss exceeded 1% per 5°C temperature increase and the highest cooking loss was observed in the temperature interval of 65-70°C for both groups. Thus, the water was lost at a lower temperature in the low pH group and the total cooking loss was higher.

The final cooking loss was higher in *B. femoris* than in *L. dorsi*, but below 40°C the cooking loss pattern observed in *B. femoris* was almost identical to that observed in *L. dorsi*, as the temperature was above 40°C before the cooking loss exceeded 1% per 5°C temperature increase and the highest cooking loss was observed in the interval of 65-70°C. However, in the temperature interval between 40°C and 65°C significantly more water was lost from the normal pH group compared to the high pH group and compared to the high and normal group of *L. dorsi*. From the high pH group water was lost at higher temperatures why the final cooking loss was not significantly different in the two groups.

The aim of this experiment was to study whether the pH course during cooking had an influence on when cooking loss takes place. As discussed above pH in the low pH group hardly changed during cooking while water was lost already at low temperatures. In the normal and high pH group, pH decreased when cooking was initiated and increased again when temperatures got above approximately 45°C. However, water was not lost to any considerable extent until the temperature got above approximately 40°C i.e. when pH had started to increase again. Hence, the pH course does not seem to have any direct influence on when water is lost during cooking.

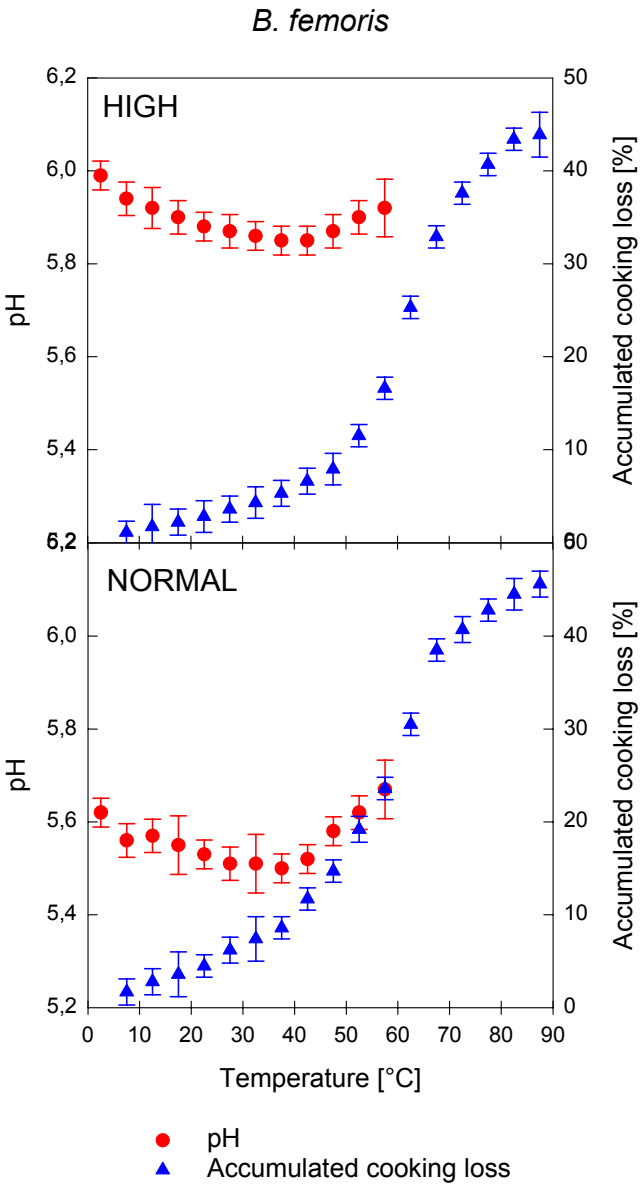

Figure 2, pH and accumulated cooking loss measured at centre temperature intervals of 5°C during cooking of *B. femoris* samples of high and normal pH_u.

The existence of a threshold value above which cooking loss is not influenced by WHC or pH has been suggested (Aaslyng et al., 2003). The final cooking loss was identical in the normal and high pH groups in *B. femoris*, but the water was lost at different temperatures in this muscle. In *L. dorsi* the water loss was almost identical in the two groups. This discrepancy between *L. dorsi* and *B. femoris* could be due to muscle differences, e.g. the final cooking loss being higher in *B. femoris* than in *L. dorsi*. However, the discrepancy may also be due to larger differences in pH_u between the two different pH groups in *B. femoris* compared to *L. dorsi* as well as considerably higher pH_u in the high pH group in *B. femoris* compared to the high pH group in *L. dorsi* (Table 1). These results indicate that pH_u does influence the water loss during cooking even at normal and high pH_u - although to a smaller extent than at low pH_u.

Conclusions

Final cooking loss in *L. dorsi* was higher in low pH_u samples compared with high and normal pH_u samples. In *B. femoris* there were no differences in final cooking loss between high and normal pH_u samples. However, there was no relationship between water loss during cooking and the changes in pH.

THE INFLUENCE OF PHYSICAL AND CHEMICAL PROPERTIES OF PORK FAT ON THE QUALITY OF HEAT TREATED MEAT PRODUCTS

Gitte Svenstrup, Lars Kristensen, Jens Risbo and Leif H. Skibsted

Department of Food Science, The Royal Veterinary and Agricultural University, Rolighedsvej 30, 1958 Frederiksberg, Copenhagen, Denmark.

Background

The influence of the fatty acid profile on the quality of fresh meat is well described (Eggert *et al.* 2001;Fiedler *et al.* 2003;Nguyen *et al.* 2003). However, knowledge about the influence of physical and chemical properties of fat in heat treated meat products is insufficient. Fat undergo solid-to-liquid phase transitions between ambient and body temperature. This reversible phase transition is highly desirable when fat is used as a functional ingredient in food providing properties such as structure, mouth feel, flavour delivery, and barriers to moisture migration. Vegetable and animal fat are polymorph, meaning they have several solid phases. Each solid phase has a certain melting point and consistency. This phenomenon has in detail been studied in cocoa butter where control of the crystallization process is essential for the eating quality of the chocolate (Schlichter-Aronhime and Garti 1988). All triglycerides have individually polymorphic properties depending on their fatty acid distribution and composition (Sato 2001). The triglycerid composition is different depending on the origin of the pork fat; leaf fat contains more saturated fatty acids than lard fat. Pork fat crystallization properties during production of heat treated meat products have only sparsely been studied and never systematically correlated to processing parameters and the sensory quality of the final meat products. This paper reports results from a fundamental study of lard/leaf fat crystallization and melting using Differential Scanning Calorimetry (DSC).

Objectives

The objectives of this study were to describe the physical properties of pork lard and leaf fat in pure form and as an ingredient in liver pâté.

Materials and methods

Two sources of pork fat were used in this study – lard and leaf fat. The physical and chemical properties of the fat were investigated in 3 different products: Pure fat extracted using chloroform by the method described by Folch *et al.* (1957) with minor modifications and raw unextracted fat as an ingredient in liver pâté. The ingredients in the liver pâté are listed in Table 1. The melting points for each product were determined with a DSC 820, Mettler Toledo (Schwerzenbach, Switzerland) based on the heat flux principle and cooled with liquid nitrogen. Experimental conditions were identical for all products: The samples were held at 80 °C for 30 minutes, cooled to (-20) °C with different cooling rates (0.5 °C/min, 1.0 °C/min, 5.0 °C/min, and 10 °C/min), and subsequently heated to 80 °C (heating rate: 1.0 °C/min and 5.0 °C/min).

Table 1 Liver pâté, list of ingredients.

Ingredients	Quantity	Ingredients	Quantity
Pork fat	37.04 %	Salt	0.93 %
Lard	30.35 %	Dried onions	0.56 %
Soup[1]	25.20 %	Glucose	0.19 %
Wheat fluor	3.09 %	White pepper	0.15 %
Dried milk	2.47 %	Thyme	0.03 %

[1] Soup is the designation of lard boiled in water.

Results and discussion

The melting curves of extracted lard and extracted leaf fat are not identical (Figure 1). This is probably due to differences in the fatty acid profile of the two fat sources. Leaf fat has the highest melting point at 48 °C while lard has the highest melting point at 39 °C, indicating that leaf fat is more saturated than lard fat. The number of melting points is almost similar for the two kinds of fat – 5 or 6 melting points were recorded depending on the cooling rate. In a study of particle size of lard fat, it was also found that lard fat have 6 crystal fractions at a cooling rate of 0.5 ºC/min (Wang and Lin 1995). From Figure 1 it can be seen that different cooling rates leads to different appearances of the curves. Consequently the cooling rate has an effect on fat crystallization in pork fat. The cooling rate was found to have an effect on both the lard and leaf fat. The peaks are more separated for slowly cooled fat than for fast cooled. This effect may be due to the fact that triglycerides have more time to embed in more stable crystal forms during slow cooling.

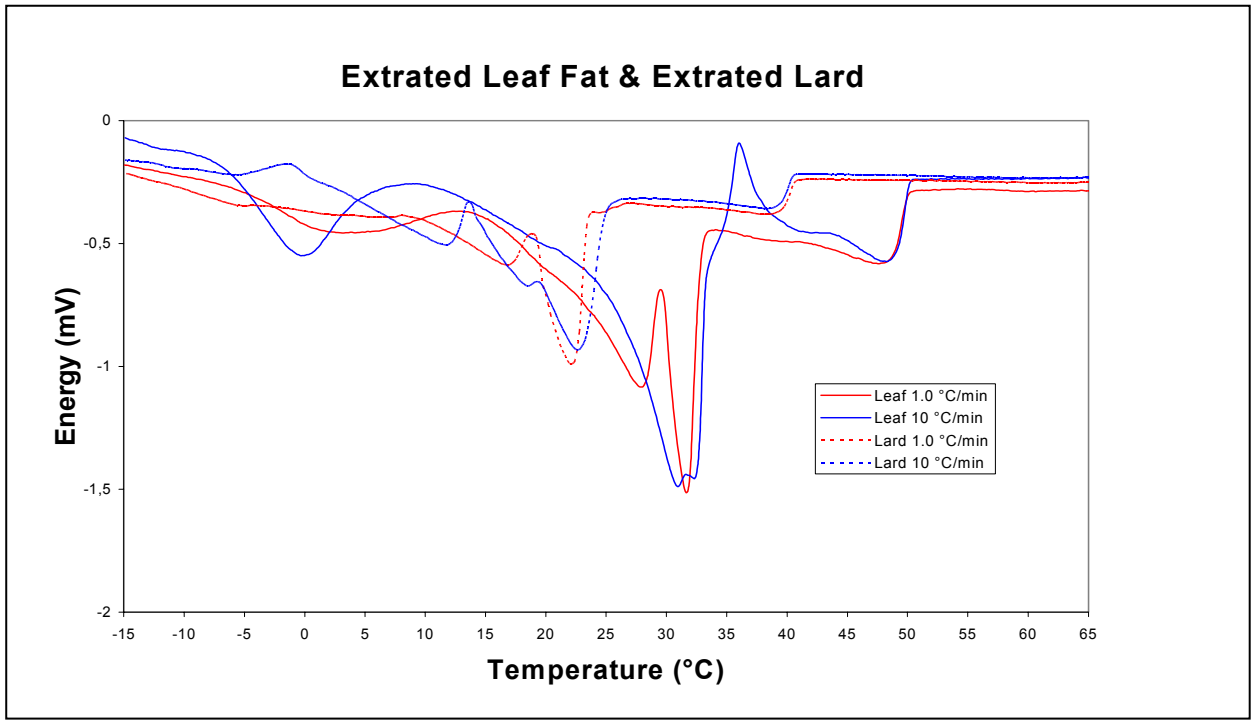

Figure 1 DSC melting curves of extracted lard and leaf fat. Heating rate: 1.0 °C/min. Inserted box indicates cooling rates.

The thermogram of the liver pâté in Figure 2 has the largest peak around 0 °C, due to water melting. The size of the peak indicates that liver pâté contains a significant amount of water. Due to the size of the water melting peak, central information about fat melting peaks might be hidden. Figure 2B is an enlarged version of the marked area in Figure 2A. From Figure 2B it is possible to see that the melting curves have several peaks. The slowest cooled sample has five exothermic peaks and the fastest cooled sample has four exothermic peaks indicating melting of fat crystals. This means that the cooling rate also has an effect on the melting properties of the liver pâté. It may thus be possible to produce liver pâtés with different lipid crystals, leading to varying consistence of the liver pâtés depending at the cooling rate. Future experiments will show if it is possible, by means of sensory experiments, to distinguish any differences in the mouth feel of differently cooled liver pâté.

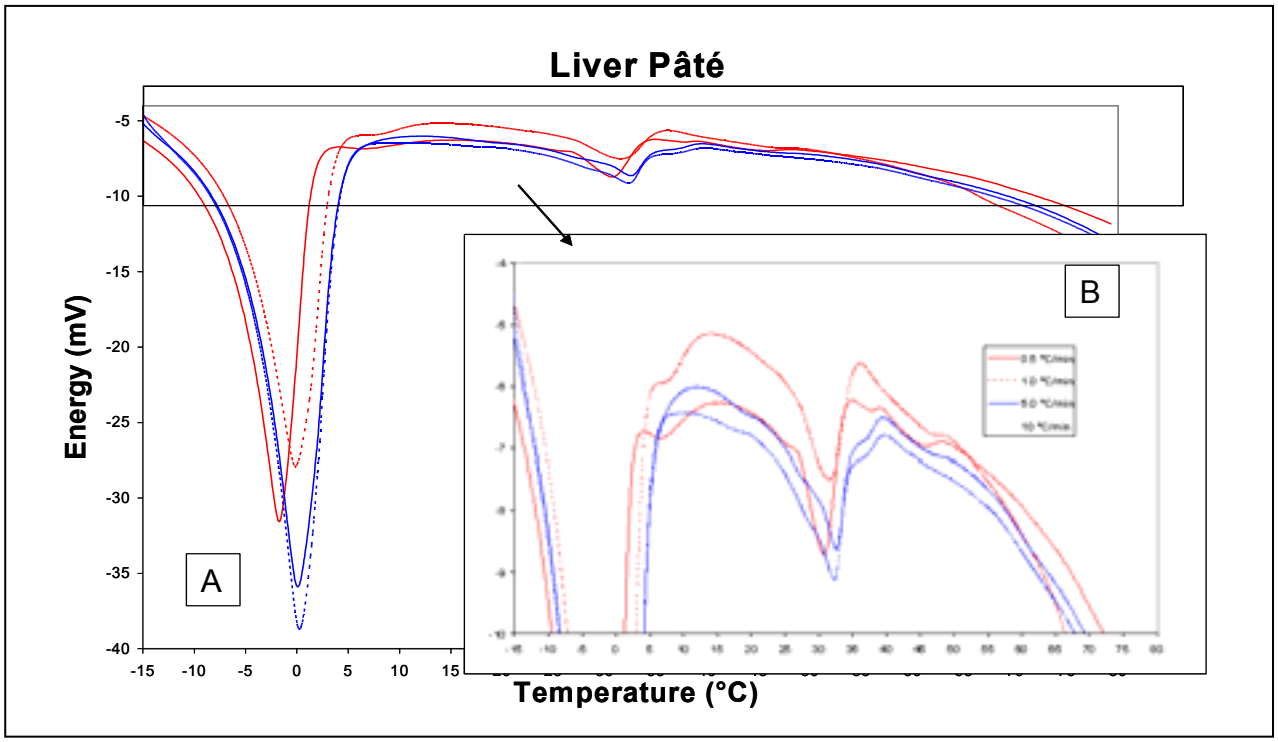

Figure 2 DSC melting curves of Liver pâté made of lard fat - heating rate 1.0 °C/min. B is an enlarged version of the marked area in A.

Conclusions

The cooling rate has a significant effect on the crystallization of both lard and leaf fat. The two sources of fat have 5-6 melting points depending on the cooling rate. The fat crystallization in liver pâté is also effected by the cooling rate. Consequently the cooling rate can most probably chance the physical properties of the liver pâté – i.e. it is possible to change the texture of the liver pâté by controlling the cooling rate after the liver pâté has been baked.

PHYSICAL AND SENSORY CHARACTERISTICS OF MARINATED CHICKEN DRUMSTICKS TREATED WITH THE LACTOPEROXIDASE SYSTEM AND THERMAL TREATMENT

Fa-Jui Tan[1] and Herbert W. Ockerman[2]
[1]Department of Diet and Restaurant Management, Chung-Shan Medical University, Taichung, 402 Taiwan
[2]Department of Animal Sciences, The Ohio State University, Columbus, OH 43210, USA

Background

Marination is a procedure of treating meat with an aqueous mixture of vinegar, salt and spices before cooking. Marination of poultry is practiced to improve product's physical and sensory attributes (Hashim *et al*., 1999; Lemos *et al*., 1999; Xiong and Kupski, 1999; Zheng *et al*., 2000). Thermal or heat treatment, which is one of the most common physical methods to reduce the load of microorganisms, has been widely applied to preserve foods for years. In addition, heating is also involved in many food processes, such as cooking, scalding, pasteurizing, drying, and etc. The lactoperoxidase system (LPS), which consists of lactoperoxidase (LP), thiocyanate (SCN^-), and hydrogen peroxide (H_2O_2), is an inhibitory system that is present naturally in bovine milk, and has been shown to be inhibitory against some microorganisms (Kamau *et al*., 1990; Earnshaw *et al*., 1990; Zapico *et al*., 1998). Even though LPS has been reported to have little effect on the sensory and physical characteristics of the treated milk and dairy products (Zapico *et al*., 1998; Martinez *et al*., 1988), limited information on the contribution of marination, thermal treatment, and LPS to the physical and sensory characteristics of treated poultry products is available.

Objectives

The objective of this study was to investigate the effects of adding LPS and thermal treatment on some physical and sensory characteristics of the marinated chicken drumsticks.

Materials and methods

A marinade that contains acetic acid (1%) and salt (3%) was developed as a standardized marinade. LPS consisted of 1 μg/ml of LP, 5.9 mM of KSCN and 2.5 mM of H_2O_2 (30%) and was added to the marinade for the LPS-added treatment. The pH of the marinade was then adjusted to 4. For the sensory evaluation, flavoring agents (0.3% black pepper and 0.15% garlic powder) were added into the standardized marinade solutions for the marinated treatments 1 through 4; whereas no flavoring agents were added to the treatments 5 and 6 samples. No flavoring agents were added in the marinade for all 6 treatments for the physical evaluation. For the samples without thermal treatment (treatments 1 and 3), drumsticks were marinated in plastic containers with the marinade solution so that all the drumsticks were covered completely by the marinade and stored at 4°C for 18 hr. Treatment 5 control samples were submerged in distilled water. No water or marinade solution was added to treatment 6 samples. For those samples with thermal-marinating treatment (treatments 2 and 4), drumsticks were placed inside a plastic bag with the heated marinade solutions, which was previously heated in a water bath. After holding at 58°C for 2 min, the marinade-drumstick mixes in the bags were cooled by immersing the bags in running tap water. When the marination mix was cooled to 25°C (approximately 10 min), the mixes were moved into plastic containers and then refrigerated at 4°C for 18 hours. Physical characteristics, including the pH values of the marinate solutions and drumsticks, marinade absorption, L*a*b* values of the skin and muscles, cooking loss, and yield were evaluated. The sensory panel evaluated the sensory characteristics of the marinated products. Descriptive analysis was conducted to evaluate the intensities of sensory characteristics of the raw and cooked samples. Attributes of skin color, muscle color, marinated chicken aroma, and off-aroma were evaluated for the raw samples. After cooking, the samples were cooled to room temperature and served. Attributes for skin color, muscle color, marinated chicken flavor, off-flavor, juiciness, and tenderness were evaluated for the cooked samples. The sensory evaluation was conducted using a 1 to 9 scale, with 1 representing the lowest intensity and 9 the highest intensity for all attributes except for color (1 = light color; 9 = dark color), juiciness (1 = not juicy; 9 = very juicy), and tenderness (1 = not tender; 9 = very tender). Three trials were conducted. Data were analyzed using SAS GLM with a 5% level of significance. Means were separated using Duncan's multiple range test.

Results and discussion

In this study, treatment 1 had no LPS added and no thermal treatment; treatment 2 had no LPS added but with thermal treatment; treatment 3 had LPS added but without thermal treatment; treatment 4 had both LPS added and thermal treatment; treatment 5 had distilled water (instead of the marinade solution) added; treatment 6 had no water and no marinade solution added. After marinating or cooking, there were no significant ($p>0.05$) differences of muscle pH detected among the 1 through 4 marinated treatments. After marinating, the marinade solution pH values for the marinated treatments 1 through 4 were significant ($p<0.05$) lower than the solution pH of the control with addition of distilled water samples (treatment 5) as expected. There was no significant ($p>0.05$) difference of marinade absorption, cooking loss, and yield for the marinated treatments 1 through 4 (Table 1).

Table 2 illustrates the color evaluation of marinade chicken drumsticks with or without thermal treatment and/or addition of LPS. After marinating, all the skin L* values of treatments 1 through 5 increased, whereas the control without addition of distilled water (treatment 6) remained approximately the same, which was significant ($p<0.05$) lower. After cooking, all the skin L* values of the samples for treatments 1 through 6 decreased without significant ($p>0.05$) differences. After marinating, treatment 3 and treatment 4 (LPS added), had significantly ($p<0.05$) lower skin a* values than treatment 1 and 2 (no LPS added). Similarly, after cooking, the skin a* values of treatment 3 and treatment 4 were significantly ($p<0.05$) lower than the values of treatment 1 and 2. This significant reduction of a* values of the LPS treated samples was probably due to the addition of hydrogen peroxide, which is one of the components of the LPS treatment, and is a strong oxidizing agent that is occasionally used as a bleaching agent in the food industry. After marinating, the skin b* values were without any significant differences ($p>0.05$) among all 6 treatments. After cooking, the skin b* increased without any significant differences ($p>0.05$). The significant changes of skin a* values of the LPS treated samples (treatments 3 and 4) in the current study did not agree with the report by Wolfson (1992). Wolfson (1992) investigated the LPS effect on some physical characteristics of LPS treated poultry. In that study, treated chicken legs and thighs were immersed in a 50°C bath containing the LPS (1μg/ml LP, 5.9 mM KSCN, and 2.5 mM H_2O_2) for 5 min, and then stored at 4°C, and no LPS was added for the control samples. Wolfson (1992) reported that there was no significant ($p<0.01$) difference for the Hunterlab color values (L, a, b) between the LPS treated chicken thigh skin and controls after 24 and 48 hours storage at 4°C. The possible reason of this disagreement between the two studies is probably that the LPS-treated time (18 hours in the current study) was much longer than the time of 5 min in Wolfson's study. After marinating, all the muscle L* values of the marinated treatments 1 through 4 increased and were significant ($p<0.05$) higher than the values of the two control samples (treatments 5 and 6). After marinating, treatments 3 and 4 (LPS added) had significantly ($p<0.05$) lower muscle a* values than the values of treatments 1 and 2 (no LPS added). Similarly, after cooking, the muscle a* values of treatments 3 and 4 (LPS added) were significantly ($p<0.05$) lower than the values of treatments 1 and 2 (no LPS added). After marinating, the muscle b* values of treatments 1 through 6 increased without significance ($p>0.05$). After cooking, there was no significant ($p>0.05$) difference for the muscle b* values for marinated treatments 1 through 4.

In this study, total color difference (ΔE^*_{ab}) is calculated as: Total color difference (ΔE^*_{ab}) = square root of $[(\Delta L^*)^2 + (\Delta a^*)^2 + [(\Delta b^*)^2]$, where L* = light and dark, a* = red and green, b* = yellow and blue, and Δ representing the difference between the two processing steps, and it is commonly applied to evaluate the color changes of samples at the two different processing steps in food science studies. There was no significant ($p>0.05$) difference for total color difference of skin between before and after marination for the marinated treatments 1 through 4 samples, but the control samples without distilled water added (treatment 6) had a significantly ($p<0.05$) lower total color differences for skin color. There was no significant ($p>0.05$) difference for total color difference for skin color between before and after cooking for the all six treatment samples. Similarly, no significant ($p>0.05$) difference for total color difference for skin between before marination and after cooking for the all 6 treatment samples was obtained. In the current study, the control samples with or without distilled water added (treatments 5 and 6) had significant ($p<0.05$) lower total color difference in muscle color, when compared with the samples of the marinated treatments 1 through 3. There was no significant ($p>0.05$) total color difference in muscle between before and after cooking, and between before marination and after cooking for all 6 treatment samples (Table 3).

Sensory evaluation of marinated chicken drumsticks with or without addition of LPS and/or thermal treatment is shown in Table 4. Based on a 1-9 scale, the marinated treatments 1 through 4 samples in this

study had lower sensory raw skin and muscle color scores without any significant differences ($p>0.05$) among the marinated treatments. The lightness of the skin and muscle colors for marinated treatments 1 through 4 when comparing to the samples of the control groups was probably due to the addition of acid.

The marinated treatments 1 through 4 samples had significant ($p<0.05$) higher marinated chicken aroma scores, when compared with the controls probably due to lack of flavoring agents added. Low (1.3-1.6 based on a 1-9 scale) and without significant ($p>0.05$) difference for the sensory off-aroma scores for the raw samples for all treatments 1 through 6 were obtained in this study (Table 3). After cooking, the sensory skin and muscle color scores of the marinated treatments 1 through 4 samples increased. Also, there was no significant ($p>0.05$) difference for the sensory cooked skin and muscle color scores of all treatments 1 through 6. The marinated treatments 1 through 4 samples had significant ($p<0.05$) higher marinated chicken flavor scores. Low (1.1-1.9 based on a 1-9 scale) and without significant ($p>0.05$) difference values were obtained for the sensory off-flavor scores of the cooked samples for all treatments. There was no significant ($p>0.05$) difference for the sensory juiciness score of all treatments 1 through 6. In addition, no significant ($p>0.05$) difference for the sensory tenderness scores of marinated treatments 1 through 4 was observed.

Conclusions

In conclusion, the treatment consisting of addition of LPS (1 µg/ml of LP, 5.9 mM of KSCN, and 2.5 mM of H_2O_2) and thermal treatment (58°C for 2 min) did not impair the physical and sensory characteristics for the marinated chicken drumsticks.

Background

Meat ball is quite popular for one-dish serving meal in Thailand. There are several ways of cooking meat ball i.e. deep fry, yum (spicy salad), roasting and even to be in recipe with noodle. If we look at the amount of produced meat balls in Thailand from year 2000 to 2003, the amount of pork balls was 843.36-1339.14 ton, chicken balls was 6923.72-4962.87 ton. There are basic three types of meat balls, i.e. pork ball, chicken ball and fish ball. Most of Thai people prefer to have meat ball with a high springiness and softness. To know the good quality of those meat balls, only the highly experienced person can tell. This is one restriction in processing of meat ball especially in SMEs (Small Medium Enterprises) since there is an instrumental limitation for checking and measuring the products. For a big manufacturer, the problem seems smaller since they can afford having a good quality control. Besides the taste of product, the texture of product is quite important factor to be judged for a good quality (e.g. no sponginess, smoothness, not too hard, etc.). This study wants to investigate the properties of some meat balls producing from some big and small factories by using the texture analyzer which is available in our laboratory and also using a simple method, e.g. folding test, to investigate those meat balls. We expect to find the correlation among those properties in order to encourage small factory to implement the simple method for checking the quality of meat ball.

Objectives

The purpose of this study is to investigate the physical properties of commercial meat balls (pork ball, chicken ball and fish ball) by using texture analyser and folding test and to look for their correlations.

Materials and methods

The materials are ten items of each type of meat balls (pork, chicken and fish) in the market of Thailand as shown in Table 1. We pick up some of the most popular and non popular meat balls in order to having a wide range of samples. The high price meat balls will be numbered from 1 to 4 while numbers 5-7 will be the medium price and numbers 8-10 will be the cheap ones. The texture analyzer model TA.TX2i was used to measure the physical properties. The conditions are as follows: TPA (Texture Profile Analysis), 75 mm of probe size, compression 30 % deformation, the pre-test speed and test speed at 1.0 mm/sec, post-test speed at 10.0 mm/sec. The properties such as hardness, fracturability, springiness and so on will be obtained from this instrument. To investigate the folding test, meat ball was sliced having thickness around 2-3 mm and then checked the cracking after folding one-half and one-fourth. The ranking of folding test score was 5 to 1 as shown in Table 2. Score 5 means meat ball having more softness and score 1 means meat ball having more hardness.

Results and discussion

When the texture analyzer (TPA) is used, several information can be obtained, i.e. hardness (g-force), fracturability (g-force), adhesiveness (g.sec), springiness, cohesiveness, gumminess and chewiness. Figure 1(a)-(c) shows the hardness and folding test scores of pork ball, chicken ball and fish ball, respectively.
Figure 1(a) shows pork ball having the hardness mainly range from 8000 -11000 g-force, and the folding test scores range from 3 to 5. We observe that the products having high scores (score 5) of folding test reveals the hardness from 8000 – 10000 g-force except two products, i.e., item 5 and item 9. This result may have occurred if the texture of that product was not smooth enough. When the hardness spot of product was touched by the probe, the high value of hardness can be found. We can say that folding test score 5 will be

found in the group of high price. Whereas, the score 3 and 4 will be found in the group of medium and low price which is implied that raw material for producing is in different quality.
Figure 1(b) shows the hardness and folding test score of chicken balls. They have the value of hardness around 5000 -8000 g-force and have the folding test scores around 3-5. There are some products having quite high hardness, i.e., items 1, 2 and 7. This may happen in the same manner with pork ball. However, we can conclude that the chicken ball at low and medium price have a low folding test score (score 3).
Figure 1(c) shows the hardness and folding test scores of fish balls. They are mainly around 2500-5000 g-force, and the folding test score around 4-5. The scores of folding test 3 will be not found here in fish ball. There is only item 4 which have a high value of hardness (around 8500 g-force). The other information can be plotted in the same manner, but they are not shown in here. For example, the springiness of pork ball, chicken ball and fish ball will be 0.761-0.850, 0.682-0.882, and 0.832-0.949, respectively. The cohesiveness of pork ball, chicken ball and fish ball will be around 0.344-0.472, 0.259-0.498 and 0.491-0.542, respectively. Figure 1(d) shows the correlation of hardness and folding test score of those meat balls. Since there is the fluctuation of data, the correlation was not fit so well (R^2 is quite low in three of meat balls). However, if we neglect the scattered data, we should have a better correlation. It is noticeable that there is no data at the low value of folding test score (1-2). This may imply that those commercial meat balls should not have such a low value. Since low score of folding test means too fragile and cracking can be found easily in the product. This kind of property should be avoided. Figures 2(a)-(d) show the result of other properties, i.e., fracturability, springiness, cohesiveness and gumminess versus the folding test score in order to look for the correlation among them. In Figure 2(a) shows fracturability and folding test score of three meat balls. The correlation of pork balls is quite fair since the value of R^2 is satisfactory ($R^2 = 0.81$), whereas correlation of chicken balls is poor ($R^2 = 0.54$) as well as of fish balls. As we can see the rest of all figures from (b)-(d), the correlation is quite poor. However, the correlation could not expand to the low range of folding test, i.e. score 1-2. Since in this range, when the product was fold one half, the cracking could be observed in the product which is undesirable property.

Conclusions

We can conclude that the folding test score of commercial pork balls is 3-5 (majority is 5), and hardness is 8184.95-15859.28 g-force. The springiness is 0.761-0.850. The folding test score of chicken ball is 3-5 (majority is 3), and hardness is 5217.65-12522.13 g-force, springiness is 0.682- 0.882. The folding test score of fish ball is 4-5 (majority is 5), hardness is 2401.88-8539.04 g-force, and springiness is 0.832-0.949. The correlation of folding test and their properties could not draw conclusion since R square value is quite poor.

Table 1 Name and price of some commercial meat balls in Thailand

Pork ball		Chicken ball		Fish ball	
name	Price (Baht/kg)	name	Price (Baht/kg)	name	Price (Baht/kg)
1. Sechaun	150	1. C.P.	100	1. TaeJew	153.5

Background

Inadequate cooking of food products and use of improper holding times are common causes of food-borne disease outbreaks (Walton and McCarthy, 1999). Many of these outbreaks result from undercooking at food service and retail outlets where time and temperature of processing do not need to be adequately documented. Because of the high correlation of these outbreaks with consumption of undercooked food products, the elimination of these microorganisms from processed foods has become a prime concern for consumers, the meat industry, and the regulatory agencies. Heat treatment is given to meat to produce a palatable product, to improve the shelflife, and to minimize the risk of food-borne illness. Consequently, optimum cooking is necessary to keep the maximum food qualities but minimize the risk of heat-labile pathogens.

A large number of researches have been conducted to track the previous heat treatment (end-point temperature, EPT) of meat products (Townsend and Blankenship 1989; Miller *et al*, 2003), however, similar studies on marine products are almost negligible. Moreover, seafood are common vehicles of food-borne diseases can be contaminated with pathogens during several stages of processing. Therefore it became more important to achieve optimum heat treatment to seafood. We are conducting a series of study to assess EPT of processed marine products since they have an ever-growing role in human food source (Uddin *et al*, 2000; 2002a). Near infrared (NIR) spectroscopy, a non-destructive rapid technique, which has been widely used in the food industry, is based on the electromagnetic absorption of organic compounds. We successfully applied this NIR technique to investigate the heating adequacy of heated fish and shellfish meats (Uddin *et al*, 2002b).

Objectives

The purpose of this study was to assess EPT of kamaboko gels since surimi-based fish-meat gels have been gaining popularity in recent years for their protein quality, law fat content, and convenience in consumption. Surimi-based most common finished product kamaboko gel was used as a model of fish-meat gels. A potential useful application of NIR reflectance spectroscopy would be the reliable, rapid and non-destructive determination in these regards.

Materials and methods

Preparation of kamaboko gel

Two types of surimi were used to prepared kamaboko gel. Frozen SA grade walleye pollack (*Theragra chalcogramma*) surimi (Maruha Co., Tokyo, Japan) was thawed overnight at 5ºC then chopped in a kitchen-cutter (Yamada FP-1S, Mitsubishi Co., Ltd, Tokyo, Japan). Horse mackerel (*Trachurus japonicus*) surimi was prepared according to the procedure of Konno *et al*. (2000). The final moisture content was adjusted to 80% by adding cold distilled water prior to add NaCl equivalent to 2.5% of the surimi weight. Kamaboko gel was prepared by pressing the salt-ground surimi into a polyvinylidene chloride casing measuring 48 mm in circumference and approximately 150 mm in length. Both ends of each tube casing were tied with cotton thread, and all of the proceeding operations were accomplished at 5ºC. The filled casing samples were incubated at 10ºC intervals between 30 and 90ºC for 30 min in water bath incubators then cooled immediately in ice-cold water and kept at 4ºC overnight before NIR spectroscopic measurement.

Internal temperture of kamaboko gels were monitored using a recorder (Thermodac EF 5020A, Eto Denki Co., Tokyo, Japan) with connected thermocouples. Thermocouples (copper-constantan) were inserted through the side edge of separate samples in to the geometric center. Sixteen individual kamaboko samples

were prepared for each selected temperature therefore 112 samples were made for each walleye pollack and horse mackerel surimi respectively.

NIR spectroscopy

Visible-NIR spectra were recorded at 2 nm intervals using a NIRSystems 6500 scanning monochromator instrument (NIRSystems, Silver Spring, MD). Kamaboko spectra (n = 224) were collected using a surface interactance fibre optic accessory. Within a 4 cm square probe face, 7 quartz windows (1 x 20 mm) are fitted; windows are alternatively light exit (n = 4) and collection (n = 3) ports. Prior to spectral acquisition, the surface of the kamaboko was wiped with a paper tissue to remove excess moisture. Before spectra of the Kamaboko gels were measured, a background spectrum was collected. Spectra were collected between 650 and 1100 nm; above this range, the fibre optic probe becomes a significant absorber of radiation and were stored in optical density units log (1/R), where R represents the percent of energy reflected. Only a single spectrum was taken from an individual sample therefore 56 spectra were use to developed a calibration and remaining 56 spectra were used for validation set in both of walleye pollack and horse mackerel kamaboko gels. Two linear regression methods Partial Lest Squares (PLS) and Multiple Linear Regression (MLR) were used to develop calibration and validation set.

Data analysis was performed by the Vision spectral analysis software package (Version 2.11. NIRSystems, Silver Spring, MD) and The Unscrambler software (version 8.05. CAMO, USA).

Results and discussion

Figure 1 illustrates the spectra collected from kamaboko gel prepared by walleye pollack surimi heated at different temperatures. The higher curve is for the sample heated at lower temperature, whereas the lower curve applies to the higher temperature. Kamaboko made from horse mackerel surimi also showed similar fenomenon (data not shown). In every spectrum, the log (1/R) peaks at any wavelength decreased with increasing EPT. Water absorbs strongly in specific wavelengths which is expected and usually exhibits a broad band because of H-bonding interactions with itself and with other components in the meat. In visible-NIR spectroscopy, the regions from 740–760 nm and 960–980 nm are related to O–H bond of the water in the sample (Osborne *et al*, 1993; Murray and Williams, 1990). Since protein conformations, protein water interactions, or their combination might depend on the variation of water content, the NIR reflectance spectra of a heated sample could be affected separately with a different heating process. The kamaboko gels in this study were heat-treated in a stirred-water bath. The water content was constant before and after heat treatment which allowed us to minimize the differences in water contents between samples heat-treated at different temperatures. Therefore, these changes of NIR reflectance spectra upon heat treatment could be related to the heating temperature.

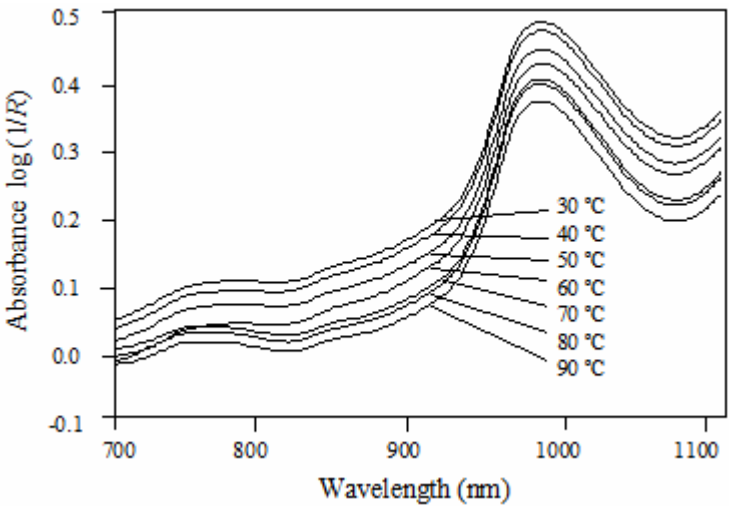

Fig. 1. Average reflectance spectra of kamaboko gels prepared from walleye pollack surimi.

Studies on thermal denaturation of muscle proteins indicate that the changes of meat proteins during cooking take place in a step-wise process (Findlay and Barbut, 1990). Moreover, food and feed substances of plant or animal origin are composed of constituents possessing functional groups such as C-H, O-H, N-H, S-H, and C=O which are selectively absorb NIR radiation. Therefore, if there is any linear relationship between NIR

spectral changes and heating temperature of meats, a calibration equation could be developed to track their previous heat treatment. It has been suggested that standard normal variance and de-trend (SNVD) transformation would remove multiplicative interference of scatter and particle size, baseline shift and curvilinearity. Consequently, derivative treatment reduces scattering effects and also increases resolution of spectrum peaks (Barnes *et al*, 1989; Ding and Xu, 1999). Therefore, to determine EPT of kamaboko gel, the spectra were subsequently scatter corrected using SNVD and 2nd-derivative treatments. Systematic differences in absorbance related to the heat treatment were observed at different wavelengths throughout the derivative treated spectra where the characteristic absorption peaks are more clearly separated. These differences are more visible between 800 and 930 nm region due to the main absorbance band of proteins (data not shown). Spectral changes upon heat treatment were related to the heating temperature which might be the reason for changes in the environment of the secondary structure due to the denaturation of proteins, and to changes in the state of water.

Table 1. Calibration and validation results obtained by MLR for assessing EPT of Kamaboko

Kamaboko sample	Wavelength selected (nm)				R	SEC (%)	SEP (%)	Bias (%)
	λ1	λ2	λ3	λ4				
Walleye pollack	910				0.81	5.07	5.41	-0.35
	910	848			0.94	3.22	3.95	-0.52
	910	848	822		0.97	1.88	1.73	-0.08
	910	848	822	938	0.98	1.76	1.71	-0.31
Horse mackerel	910				0.84	4.95	4.92	-0.26
	910	858			0.95	2.73	2.76	-0.06
	910	858	822		0.98	2.06	2.22	-0.28
	910	858	822	938	0.98	1.78	1.84	-0.07

R : Multiple correlation coefficient.
SEC: Standard error of calibration.
SEP: Bias corrected standard error of prediction.
Bias: The average of difference between actual value and NIR velue.

In order to predict EPT of kamaboko gels, the derivative-treated spectra were calculated. Spectral changes with heating temperatures were recorded by computer and analyzed by MLR and PLS regrassions. MLR analysis allowed us to select appropriate wavelengths related to specific known chemical bonds without interference. On the other hand, PLS regression has been widely applied recently because no selection of wavelengths is needed. However, even in PLS calibration, selection of the wavelength region was needed to make a good calibration equation, which was more complicated and time consuming. In MLR analysis, the wavelengths selected by a stepforward – stepreverse regression in this study to provide the calibration equations with the lowest standard error of calibration (SEC) and highest correlation coefficients of calibration (R) are given in Table 1. The first wavelength selection which most important and one of the major steps for MLR analysis 910 nm due to the absorbance of protein was selected by manually. The standard error of prediction (SEP) using 4 wavelengths were calculated to be less than 1.85%, suggesting that the calibrations developed are appropriate. Selected wavelengths for the prediction of EPT are extensively related to C-H, N-H and C=O groups (Murray and Williams, 1990; Osborne *et al*, 1993). It was suggested that the wavelengths selected by MLR could be used as a good indicator for selection of the wavelength region in PLS calibration (Saranwong *et al*, 2001). Therefore, the wavelength region selected by MLR was applied for PLS calibration which also gave better indication (Table 2).

Table 2. Calibration and validation results of PLS regression using whole spectrum and selected region obtained by MLR for assessing EPT

Kamaboko sample	Wavelength region	F	R	SEC (%)	SEP (%)	Bias (%)	RPD
Walleye pollack	650 - 1100	9	0.98	1.83	1.87	-0.21	2.63
	800 - 950	5	0.97	1.87	1.76	-0.07	3.07
Horse mackerel	650 - 1100	9	0.98	1.95	1.94	-0.13	2.25
	800 - 950	6	0.98	1.91	1.81	-0.11	2.49

F : The number of factor/variable used in the calibration equation.
RPD : The ratio of standard deviation of reference data in validation set to SEP.

Figure 2 depicts scatter plots of NIR predicted EPT against the actual heating temperatures obtained by MLR and PLS calculations of walleye pollack kamaboko gel. Similar results also observed from horse mackerel. A comparison of the NIR predicted EPT with known actual heating temperatures showed extreamely close detections. Both MLR and PLS could be used in making calibration equations with similar predictive eficiency. The R were better than 0.98 indicating a good model structure. Such a non-destructive, simple and reliable technique which is expected to assess EPT of processed products is essential in today's demand. In this study kamaboko was made from walleye pollack and horse mackerel surimi, however, it could be valid as a general technique for other species.

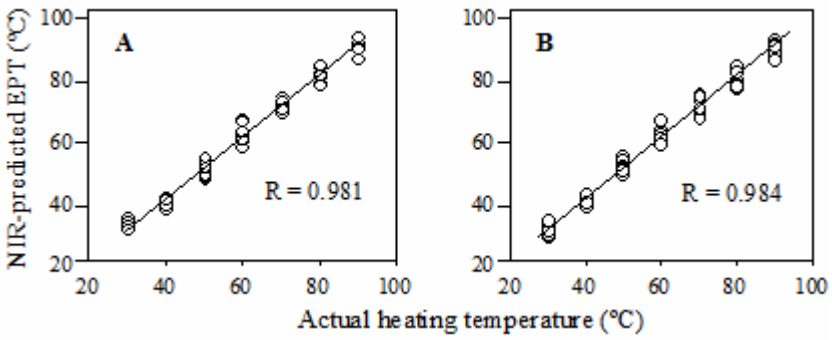

Fig. 2. NIR-predicted endpoint temperatures obtained by MLR (A) and PLS (B) of walleye pollack kamaboko gels plotted against the actual heating temperatures.

Conclusions

The results discussed above demonstrate the potential of visible-NIR reflectance spectroscopy for determining EPT of kamaboko gels in a rapid, reliable and non-destructive manner. Once perfected, this technique will have several advantages over other techniques, in that it will take the least time for analysis and will not require any consumables or supporting equipment.

Background

Due to concerns with obesity and related diseases, consumers are looking for no fat or low fat meat products. With excessive fat reduction, however, the products desire bland and dry and texture can be hard, resulting in less accepted products by consumers. Fat substituents based on proteins and carbohydrates have been widely used in meat industry to overcome the problems. Oat and oat bran have shown promise for increasing yield and juice retention in meat. In addition, the constituents have been used in diets to control hypertension, diabetes, and health disease.

Objectives

The objectives of this research were to evaluate how the addition of oatmeal affects the properties and acceptability of low fat sausages and to compare the effectiveness of incorporated oatmeal on sausages prepared with different types of meats such as beef, pork, and chicken.

Materials and methods

Sausage preparation : Beef, pork, and chicken were purchased from a local market and trimmed to reduce fat content before grinding though a 3mm plate. The moisture contents of all types of meats were adjusted to 60% and oatmeal was hydrated to provide 60% moisture content. This was done to ensure that any differences observed for added oatmeal would not be biased by differing moisture content. 10% hydrated oatmeal was added to each meat in a basis of total weight. The low fat content sausages were also prepared without addition of oatmeal. For each batch, meat, hydrated, and ingredient were mixed throughly using mixer. Alter mixing, the mixture were stuffed into artificial cellulose casing with diameter of about 30mm using a stuffer. The sausages were then held for 24hrs at 4℃ to allow for ingredient equilibrium. The sausage samples were cooked 30min in a steam chamber (SAA10, Absury, Germany) until the center temperature of the sausage reached 70℃.

Proximate analysis and cooking yield : Moisture, fat, and protein content were determined in triplicate for raw and cooked products using AOAC methods (AOAC, 1990). The weight of each sausage was measured before and after cooking to determine cooking yield, which was defined as the cooked weight divided by uncooked weight then multiply by 100.

TPA (texture profile analysis) : Before analysis, cooked sausages were equilibrated at room temperature (20ºC) for l hr. Sausages were cored into a cylinder with 1 cm diameter and cut with 1.5 cm height using a sharp edged knife. TPA was performed by compressing the sample between parallel plates in a Universal Testing Machine (Model 3343) to 70% of the original height in two consecutive cycles at a crosshead speed 100mm/min. From the resulting twice/deformation curves, the textural parameter of hardness, cohesiveness, springiness, brittleness, gummness, and chewiness were calculated.

Sensory evaluation : A 10-member trained sensory panel evaluated the low fat sausages for color, aroma, flavor, off-flavor, juiciness, tenderness, and overall acceptability. Sausages were served in random order to panelists. They evaluated each sample on 9 point hedonic scale (1=extremely, 9=extremely strong).

Statistical analysis : The data were analyzed using statistical analysis systems (SAS. 1999). To evaluate the differences among treatments, data were analyzed by analysis of variance (ANOVA) and Duncun's multiple range test.

Results and discussion

The proximate composition of sausage samples with or without oatmeal is shown in table 1. Fat contents in different sausages ranged from 3.94 to 5.22% and protein content ranged from 20.40 to 26.47%. In general, fat and protein contents for beef, pork, and chicken were slightly reduced by the addition of oatmeal ($P<0.05$). There was no significant difference in cooking yield among samples. This indicates that neither meat types nor addition of oatmeal affect cooking yield. Table 2 shown TPA of the sausages with different types of meats and with/or without oatmeal. Generally, there was significant difference in texture attributes such as hardness, cohesiveness, among sausages sample with different meat type ($P<0.05$). For examples, sausages from beef showed highest values in hardness, cohesiveness, chewiness, while chicken did lowest ones. On the other hand, brittleness, hardness, gummness and chewiness for all sausages decreased by addition of oatmeal while cohesiveness increased. The textural properties the sausage of prepared with beef were most affected by addition of oatmeal. Table 3 shown sensory evaluations of the sausages with different types of meats and with/or without oatmeal. There was significant difference in color, aroma, tenderness and acceptability among sausages prepared with different types of meats ($P<0.05$). Tenderness value was decreased by addition of oatmeal. Consequently, the addition of oatmeal improved textural attributes such as juiciness and tenderness, leading to better acceptability, compared to low fat content sausages.

Conclusions

Fat and protein contents of trimmed low fat sausages were further reduced by the addition of oatmeal. The oatmeal-added sausages improved textural properties such as juiciness, tenderness compared to low fat content sausages. This leads to better acceptability to trained sensory panels. The low fat sausage prepared with beef was most affected by the addition of oatmeal.

EFFECTS OF PROTEIN CONCENTRATION, PH, IONIC STRENGTH ON HEAT-INDUCED GELATION PROPERTIES OF MYOSIN FROM RABBIT SKELETAL MUSCLES

X. L. Xu, G. H. Zhou, H. B. Huang

Key laboratory of Agricultural and Animal Products Processing and Quality Control, Ministry of Agriculture, Nanjing Agricultural University, Nanjing 210095 P.R China

Background

The textural quality of reconstructed and comminuted meat depends on the functional properties of muscle proteins, especially the gelling, binding, emulsification of extracted proteins and water holding capacity (WHC) of the meat product (Boyer *et al* 1996b). Heat-induced gelation is the result of the nature and denatured muscle protein interactions, including inter-protein hydrogen, ionic linkage, hydrophobic interaction and so on. However, the equilibrium among protein-protein, protein-solvent and elements gravitation-repulsion are the most important factors in forming the fine three-dimensional gel matrix. Myosin accounts for about one-third of total muscle protein, 50%~55% of myofibril protein, morever, it has a lot of functional properties in determining the textural quality of meat products. Among these functional properties, wonderful gelling capacity of myosin has been aroused much attention from meat scientists (Siegel *et al* 1979, Boyer *et al* 1996a). Previous literatures indicated that a lot of factors such as protein concentration, pH, ionic strength, type of animal and muscle, extracting process of myosin, heating pattern, non-meat additives had significant effects on heat-induced gelation properties.

Objectives

The purpose of this study was to find out the effects of protein concentration, pH, ionic strength on the hardness, WHC and ultrastructure of heat-induced gelation of myosin from rabbit (New Jersey White rabbit) skeletal muscles (*Psoas major*, PM and *Semimenbranosus proprius*, SMp).

Materials and methods

Male rabbits with liveweight 2~3kg were obtained from Jiangsu Academy of Agriculture Science. After being fed with water only for about 18h, the rabbits were slaughtered and the PM and SMp muscles were used for extracting myosins. The extracting process referred to method of Nauss *et al* (1969), Hermansson *et al* (1986) and Wang *et al* (1994) with a little modification. Myosin concentration was measured by Biuret method (Gornall *et al* 1949) and the composition of each fraction was analyzed by SDS-PAGE on 10% slab gels according to Jun-yao Guo(2001). Myosin (15mg/ml) was held in 7ml plastic centrifugal tube (tubes were previously weighed as W_0 and the tube and protein weight was W_1), then was programmed heated from 20ºC to 65ºC at a rate of 1ºC/min and kept at 65ºC for 20min. Then gels were cooled to ambient temperature and held at 4ºC overnight .

Gel **hardness** (g) was measured with TA.XT2i Texture Analyzer (Stable Micro Systems Ltd, England). with P5 probe (5mm DIA CYLINDER STAINLESS). The test mode was TPA fracture.mac, and test speed was 0.5mm/sec. After centrifugation at 10,000×g, 4ºC, supernatant was decanted, the gel and tube was reweighed as W_2. The **WHC(**%) was calculated as $[(W_2-W_0)/(W_1-W_0)]\times100$. Each test was carried out with three repetitions. Duncan's Multiple-range test was used for ANOVA analysis with SAS8.2. For **SEM examination**, samples were prepared as described by Boyer *et al* (1996b) and observed with a 200 Hitachi Scanning Electron Microscopy (SEM, Hitachi Co Ltd, Japan) at an accelerating voltage of 20kv.

Results and discussion

Both the gel hardness and WHC linearly increased with the gradual increase of protein concentration (Figure 1A), and the differences were significant ($p<0.05$). Gels had maximum hardness of 15.18g for PM myosin , and 14.87g for SMp myosin at 15mmol/l. The maximum WHC was 66.85% for PM myosin and 51.89% for SMp myosin respectively. There was no difference in hardness between two types of myosin gels ($p>0.05$), however, when the myosin concentration was above 8mmol/l, PM myosin gels had higher WHC than SMp samples($p<0.05$).

pH played a significant role in the matrix formation and water retention of the myosin gels. Both the hardness and WHC varied with the increase of pH from 5.0 to 8.0 (Figure 1B). PM myosin gel had the highest hardness (20.79g) at pH6.0, while SMp myosin had a peak at pH5.5 (29.39g). WHC increased from pH 5.0, and reached maximum at pH6.0, and then decreased at higher pH. At the peak point, WHC was 82.99% for PM myosin gel which was higher than that of SMp myosin (67.27%)($p<0.05$).

Gel hardness decreased sharply when ionic strength increased from 0.2 to 0.6($p<0.05$) and decrased slowly at higher ionic strength (0.6~1.0) (Figure 1C). In gels at ionic strength 0.2, maximal hardness reached 45.60g and 44.61g for PM and SMp myosin respectively. In contrast, WHC decreased when ionic strength ranged from 0.2 to 0.4, and then increased gradually until ionic strength reached 1.0. PM myosin gel had maximal WHC (79.87%) at ionic strength 1.0, with no difference with that(74.56%) at ionic strength 0.2 ($p>0.05$). The similar profile in WHC occured for SMp myosin gel, which was 78.51% at ionic strength 1.0 compared to 76.69% at ionic stength 0.2. At all points, there was no difference between these two myosin gels.

Gel ultrastructure could be obtained by SEM only when myosin concentration was higher than 5mg/ml. PM myosin formed a looser network at concentration 5mg/ml than at 10,15 mg/ml (Figure 2B, Figure 3C). When heated, myosin molecules aggregated into cross-linkage with diameter 0.1~0.2μm(Figure 2A). The ultrastructure was a bit disorganized and pore size varied greatly from 0.2 to 1.3μm. Gel with 10mg/ml had a homogeneous granular structure exhibiting spherical corpuscles (diameter 0.1~0.2μm),uniform cavities(diameter~0.3μm), but the cross-linkages were shorter compared to those in 5mg/ml gel, which indicated more matrix formed in the course of heating.

Myosin formed a homogeneous network at 0.6mol/l KCl with spherical corpuscles exposed to the surface, short cross linkages, small and regular (diameter~0.3μm) cavities. But when the myosin was equilibrated in 0.2mol/l KCl by overnight dialysis (4□), another entirely different three dimension matrix formed and gel hardness and WHC increased significantly ($p<0.01$) compared to those at 0.6 mol/l KCl (Figure 1C). Gels at 0.2mol/l KCl formed a strand-type network (Figure 3-A, B, D, E). And PM gel was more homogeneous than SMp gel. Diameter of the strands is less than 0.1μm, and the length varied from 0.5 to 2.5μm. Most of the holes in PM gels were near circinal (most with diameter0.2~0.5μm). In some way, SMp myosin gave rise to denser strand than PM myosin. The strands tended to array in the same direction, so a kind of zonary or sandwich-like structure occured with small hole being in the strand region.

Ultrastructure of myosin gels at pH5.0 and pH5.5 showed serious protein-protein and protein-solvent interactions based on the charge distribution in myosin molecules(Figure4). When heated (pH5.0), molecules denatured and aggregated. Myosin conglomerations developed into column-like cross-linkages (diameter0.15~0.3μm, length 0.8~1.5μm). At pH5.0, the ultrastructure seemed to result from a "collapse" with long (0.6~1.2μm) and thin(~0.1μm) strand. Large cavities were left in these networks. Myosin formed consistently distributed three-dimension ultrastructure at pH6.0 and pH6.5 respectively. While molecules at pH6.5 aggregated into denser structure than pH6.0, a small sheet-like aggregate evenly distributed throughout the gel matrix. When pH increased to pH7.0, pH7.5 and pH8.0, gel structure became coarser with larger granular and holes in the network. In coincidence, the repulsion between molecules increased and coarser structure came into being as a result of more negative ionic in the protein.

Many studies have pointed out the difference between myosin gels of different muscle type, and generally concluded that white muscles (fast-twitch, like PM muscle) exhibited a higher gel-forming ability than those from red muscles (slow-twitch, like SMp muscle). (Egelandsdal *et al* 1995, Culioli *et al* 1993, Xiong, Y.L.1994). This, on the whole, resulted from the different cross-linking capacity of myosin heavy chain, and also the difference of surface hydrophobicity of denatured myosin and temperature discrepancy at which myosin denatured. The result of this experiment conducted was not the same with those represented in other literatures.

Salt and pH could affect the water balance and charge equilibrium in muscle and muscle product. Offer and Knight (1988) suggested that this balance was determined by (a) electrostatic repulsion, (b) restraining forces in structural protein, (c) chemical potential in the system. Water can be held in the gel by capillarity, electrostatic interaction at the protein surface and among the network. It has been known that myosin can only be soluble at high enough ionic strength (>0.3), but water holding capacity was not the same as the number of soluble protein in the solution. Heat-induced gelation could still have good WHC at ionic strength 0.2(Figure 1C). As demonstrated earlier (Boyer *et al* 1996a), myosin formed strand-type gel at ionic strength 0.2 and short cross-linkage gel with aspheric granular on the surface at ionic strength 0.6. Although there were large cavities in strand-type network, the thick strands were necessary for higher hardness and still could hold much water in the strand strips (Figure3A, B, C, D), While the granular structure lost much water when gel was under centrifugation at 10,000×g, 4ºC. Feng and Hultin(2001) also found that strong gels with

good WHC could be formed under low ionic strength conditions, and suggested that electrostatic repulsion of proteins is a major driving force behind gel formation and WHC.
Water loss decreased when pH increased from 5.0 to 6.0,and then increased above pH6.0, indicating that the iso-electricity point might be near pH6.0. This was the same as Kristinsson *et al* (2003). Morita, *et al* (1987) also found that PM muscle protein formed the hardest gel at pH6.0, while SMp gel was hardest at pH5.5. But at high ionic strength (0.6mol/l KCl) and high pH (>6.0), gel hardness and WHC were lower than at other conditions, which could result from electric screening behind this phenomenon, weakening the repulsion between neighboring matrix charges.

Conclusions

Myosin solution could form hard enough heat-induced gel with acceptable WHC only when concentration was above 5mg/ml. At ionic strength 0.2, gel had higher hardness and good WHC with strand-type ultrastructure, while myosin at ionic strength 0.6 aggregated into homogeneous network with aspheric granular on the surface and short cross-linkage throughout the gel matrix. Strong gel and good WHC could be formed at pH5.5 or pH6.0 at ionic strength 0.6. When pH raised above 6.5, myosin denatured and aggregated into coarse network. Gel hardness decreased with increase of ionic strength, but the maximal WHC was obtained at ionic strength 1.0. There was little difference between gelation properties of PM and SMp muscle myosin.

Introduction

Meat is frequently associated with a "negative" health image due to a "high" fat content or in cases of red meat as a cancer promoting nutrient. Therefore a low meat intake, especially red meat is recommended to avoid risk for cancer, overweight and at least metabolic syndrome. However, this discussion overlooks the fact, that meat is an important source for a couple of micronutrients such as iron, selenium, vitamins A, B12 and Folic acid. These micronutrients are either not present in plant derived food or have a poor bioavailability. In addition, meat as a protein rich and carbohydrate "low" product contributes to a low glycemic index which is assumed to be "beneficial" with respect to overweight, diabetes development and cancer (insulin resistance hypothesis). Taken together meat is an important nutrient for human health and development. As an essential part of a mixed diet meat ensures adaequate delivery of essential micronutrients and amino acids and is involved in regulatory processes of energy metabolism. The following article will review the role of meat as a micronutrient source, especially for groups at risk for low intake or higher need and the importance of the single micronutrients for maintaining health.

Is there any benefit, if meat is avoided in human nutrition? Does meat promote or prevent cancer?

It is frequently argued that a diet which contains only "traces" of meat or excludes meat completely might be preventive with respect to colon cancer. Based on a couple of studies and with respect to the cancer preventive effects of selected nutrients present in meat, this hypothesis seems more and more unlikely.

Proteins

It has been assumed, based on per capita protein intake and colon cancer risk, that total protein, is related to colon cancer risk (Youngman and Cambell, 1998). However the majority of epidemiological cohort and case control studies could not confirm these assumptions. Only for red meat derived protein there is some evidence that risk increases if red meat is part of the diet twice a day and more (MacIntosh and Le Reu, 2001) or processed (cooked or fried). Whether the non-fat matrix of meat, e.g. the amino acid composition or the amount of heme iron plays a role in carcinogenesis is not really understood. McIntosh and co workers observed a non significant increase from 33% to 59% in incidence of mature rats with DMH-induced intestinal tumours when barbecued beef was substituted for whey protein concentrate against a high fat (20%) diet background (MacIntosh et al., 1998). Whether the concentration of protein in a diet determines the risk for cancer is controversly discussed (MacIntosh and Le Reu, 2001). In contrast the type of protein seems more important with respect to carcinogenesis. A high methionine diet determined by type of protein as well as quantity ingested has been reported to lead to increased circulating insulin which has been

assumed to contribute to colon carcinogenesis (McKeoween-Eyssen 1994). From epidemiological studies there is accumulating evidence that support the insulin resistance (IR) hypothesis to explain the risk for colon cancer. It was hypothesised that IR leads to increased initiation and promotion of colon cancer by an elevated serum insulin as a growth factor or raised glucose and triglycerides as fuels (McKeoween-Eyssen 1994). Bruce and co workers (Bruce et al., 2000) summarise different reasons which strengthen the hypothesis: Colon cancer patients frequently have evidence of glucose intolerance and insulin resistence (IR); cohorts of type 2 diabetes have been found to have an excess mortality due to colon cancer; cohort and case control studies have revealed a clear association of early colon cancer, colon cancer and colonic polyps with increased levels of fasting insulin, triglycerides, VLDL and abdominal obesity; subjects who developed colonic polyps consumed more carbohydrates with a higher glycemic index than controls; recent case control studies have also shown an association between plasma insulin like growth factor I (IGF-I), which is often increased in insulin resistant individuals, and IGF-binding protein (IGF-BP) levels with risk for colon cancer. From a couple of animal experiments there is evidence that IR leads to an increased colon cancer risk.

Diets with a high glycemic index are thought to be associated with or to favour insulin resistance (Frost et al., 1998). Red meat however, have a low glycemic index and may not contribute to the metabolic syndrome as long as its fat/energy content does not contribute primarily to the daily energy intake. Koohestani and co-workers (1997) showed that IR rats on a high fat diet promotes aberrant crypt formation (ACF) as an important step in colon carcinogenesis. Based on their results they conclude that: diets high in energy, saturated fat, and glycemic carbohydrate and low in w3-fatty acids could be deleterious affecting cell signalling in colonic cells in ways that lead to IR and colon cancer. Dietary intervention that reduce IR may also reduce colon cancer risk. So far low fat meat seems not to contribute to colon cancer.

Fat

Several epidemiological early case control and cohort studies suggested a positive correlation between fat intake and incidences of breast-, colon- and prostate cancer (Schottenfeld and Fraumeni, 1996; Potter et al., 1993). However more recent cohort, large case control and pooled analysis of 13 case control studies failed to detect an association between fat intake and colon cancer (Howe et al., 1997; Giovannucci et al., 1994). The relation between dietary fat intake and breast cancer has been examined in a couple of prospective studies. In a pooled analysis no overall association was seen for total fat intake over the range of 15% to > 45% of energy from fat (Hunter et al., 1996). In contrast, among the small number of women consuming less than 15% of energy from fat, breast cancer risk was elevated twofold. With respect to prostate cancer the few existing studies show a relative consistency in supporting an association between consumption of fat containing animal products and cancer incidence. However the majority of the studies were not adjusted for total energy intake. Studies adjusting for energy intake did not find an increased risk (Kolonel, 2001). Meat intake however, correlates more or less with prostate cancer risk. 16 out of 22 case control or cohort studies showed an increased risk above a risk ratio of 1.3. A recent prospective study (Michaud et al., 2001) documented an elevated risk for prostate cancer (RR 1.47) and red meat consumption (>5/week). Up to 2-4 times a week the RR was below 1.0 (0.96) demonstrating that moderate red meat consumption as usually recommended does not contribute to prostate cancer risk.

Inspite the long history of studies on fat and cancer, there remains some controversy. It is more or less generally suggested that animal fat rich in saturated fat is more closely related to cancerogenesis and plant derived mostly unsaturated fat (PUFA) is more protective. In animal models, the tumour promoting effect of fat intake have been observed primarily for PUFA (Hopkins and Carroll, 1979; Hopkins et al., 1981) A couple of studies show that polyunsaturated w6 fatty acids (linoleic acid) enhance cancer development in rodents (Carroll 1991; Fay et al., 1997). The prostaglandin E2 (PGE2) seems to be involved in colon carcinogenesis and is formed from w6 fatty acids (arachidonic acid). EP1 (PGE2-receptor) k.o. mice showed resistance to AOM induction of neoplastic colon lesions (Watanabe et al., 1999). w3 fatty acids (linolenic acid) however, suppress colon carcinogenesis by inhibiting the arachidonic pathway (Takahashi et al., 1997).

The suggestion that consumption of red meat as a source of dietary fat increases risk of colon cancer is based on the rather simple fat-colon cancer hypothesis, which is based on the premise that dietary fat promotes excretion of bile acids which can be converted to carcinogens (Reddy 1981). The controverse results from

different studies and the fact that meta analyses show that fat might be a rather minor component, if even any, in cancerogenesis of the colon or in other cancer sites might be explained in different ways. The fat content of red meat varies in a wide range and shows different patterns. So palmitic acid but not stearic acid present in different amounts in red meat has been shown to be a strong mitogen of adenoma cells in culture (Friedman et al., 1989). Fat, derived from red meat, might be less absorbed, due to either its composition (stearic acid) or due to matrix (muscle) interactions. Polymorphisms of genes involved in the expression of cleavage and reesterification of triglycerides may also play important roles regarding the individual susceptibility. Finally, components not belonging to lipids might contribute to carcinogenesis such as HCAs or at least the iron content of meat. Dietary iron enhances lipid peroxidation in the mouse colon (Younes et al., 1990) and increases the incidence of DMH-induced colorectal tumours in mice and rats (Siegers et al., 1988; Nelson et al., 1989). Indeed, studies in humans point on an relationship between body iron stores and the incidence of colon tumours (Stevens et al., 1988; Knekt et al., 1994a). Finally carcinogens and promotors e.g. HCAs are formed when meat is fried or cooked and may contribute more or less to the individual cancer risk, especially in colorectal, breast and prostate cancer.

Processed meat and genetic polymorphisms

HCAs are converted to their hydroxyamino derivatives by cytochrome P450s especially CYP 1A2 and further activated by esterification enzymes acetyltransferase and sulfotransferase. The reactive ultimate forms produce DNA adducts with guanines at their C8 position, resulting in base substitution and at least mutation. Similarly oxidative modification of the DNA via reactive oxygen species (ROS) results in the formation of 8-oxo-deoxy-guanin with subsequent base substitution and mutation.
Epidemiological studies revealed some positive (Zheng et al., 1998) and some negative (Augustsson et al., 1999) links between cancer risk and intake of welldone meat or fish. Studies that have examined intensity of cooking have tended to show positive associations with breast cancer (Knekt et al., 1994b), others not (Ambrosone et al., 1998). The latter investigated the role of genetic polymorphisms of enzymes involved in DNA adduct formation of HCAs, which could play at least a critical role in individual cancer susceptibility. HCAs require enzymatic activation to bind to DNA and to initiate carcinogenesis. N-acetyltransferase (NAT2) may play a role, its rate determined by a polymorphic gene. The results of Ambrosone and coworkers (Ambrosone et al., 1998) were recently confirmed by studies of Delfino and coworkers (2001) who did not find neither a correlation between NAT2 and breast cancer nor any association between red meat intake for any doneness and breast cancer.

Genetic polymorphisms including environmental aspects (gene environment interactions) may also play a critical role in colorectal cancer with respect to red meat intake. Le Marchand (1999) investigated the colorectal cancer rates in Japanes immigrants in Hawaii. The colorectal cancer incidence of these group (214.000 immigrants between 1886 and 1924) was intially very low and is now the highest in the world. The fast acetylator genotype (NAT2), without the polymorphism is present in 90% of Japanese compared with 45% of Caucasians; the frequency of CYP1A2 phenotype is similar in both groups. Consumption of a welldone meat together with a specific genotype of NAT2 and CYP1A2 may increase colorectal cancer risk substantially. Among the Japanese migrants who ate well done red meat, those without the polymorphisms in both NAT2 and CYP1A2 had a 3.6 times greater risk of developing colon cancer than those with the polymorphisms. Another family of genes might determine individual susceptibility: glutathione transferase M1 (GSTM1) and T1 (GSTT1). Both code for cytosolic enzyme glutathione S-transferase which are involved in phase 2 metabolism especially in polycyclic aromatic hydrocarbon metabolism. The results of the few studies dealing with genetic polymorphisms of GST are inconsistent. Two studies suggest increased colon cancer risk in subjects with high meat intake and GST nonnull genotype, contrary to the underlying hypothesis. One study suggests a strong inverse relation between colorectal adenomas and broccoli consumption, particularly in subjects who are GSTM1 null (review see Cotton et al., 2000). As long as genotypically defined cohorts are not studied with respect to their susceptibility against meat intake (in different forms) the risk of red meat cannot be clearly identified. White meat and fish seem to be without risk, red meat only in a form were cytotoxic by-products such as HCA are formed.

Formation of HCAs can be significantly reduced by inexpensive and practical measures like avoidance of exposure of meat surfaces to flames, usage of aluminium foil to wrap meat before oven roasting and the

employment of microwave cooking. Another protecting approach is the combination with protective bioactive constituents derived from plant food. For example diallyl sulfide an organosulfur compound in garlic, blocks HCA carcinogenesis (Hasegawa et al., 1995; Morie et al., 1999). Nevertheless, even there may be some induction or promotion factors in meat it may depend on the composition of the diet whether anticarcinogenic factors from plants neutralise any harmful factors in meat. In addition meat contains bioactive constituents known to be protective against cancer formation.

Protecting factors in meat with respect to cancer

Folate

Meat is an important source for methyl donors such as folate and vitamin B12 and transfer factors methionine and choline. Folate and methionine as methyl donors influencing methyl group availability may also been associated with colon cancer incidence. It is frequently argued that the increased risk for different types of cancer resulting from low intake of fruits and vegetables is a result of a folate deficient diet, because fruits and vegetables are important sources for folate. Indeed, this is true, however it has to be considered that the bioavailability of folate from meat and liver is much better than from fruits and vegetables. A few studies measured folate directly and it was claimed that a low folate intake has been related to an increased occurrence of colon adenomas (Giovannucci et al., 1993a; Benito et al., 1991) and cancer (Freudenheim et al., 1991; Lashner et al., 1989). Zhang and coworkers (1999) studied the effect of alcohol and folate on breast cancer. The increased cancer risk associated with alcohol consumption (>15g/day) was reduced in women who consumed at least 300µg folate/day. The major source of folate were supplements. Even an intake of 300µg/day does not reach the RDA (400µg/day) this study shows that increasing the intake might be beneficial with respect to cancer. Indeed, increasing folate intake via supplementation, a form which has a very good bioavailability compared t vegetable derived folic acid, decreases risk for colon cancer significantly (Giovannucci et al., 1993b). The decreased risk however was evident not before 15 years, documenting that protective factors, if they indeed exist as single bioactive constituents need to be present in the diet for a long time period. Vice versa there absence or a low intake might also contribute to an increase cancer risk after a long time period. In rodents, diets deficient of methyl donors or transfer factors (folate, B12, methionine, choline) induce tumours at different sites (Shivapurkar and Poirer, 1983; Wainfan et al., 1989; Cravo et al., 1992). A methyl deficient diet lowers the concentration of the methyl donor S-adenosylmethionine which leads to a reduction in methylation of DNA cytosine. Tumour supressor genes are inactivated by methylation of normally unmethylated sites. DNA hypomethylation due to a diet low in methyl donors (e.g. low in meat) may contribute to a loss of protooncogene expression (Nyce et al., 1983). Indeed, throughout the different stages of colonic neoplastic transformation genomic hypomethylation (Goelz et al., 1985) methylation of usually unmethylated sites (Makos et al., 1992) and abnormal elevated DNA methyl transferase activity (Issa et al., 1993) is described.

An additional aspect, also involved in methylation reactions, which might contribute to the individual colon cancer risk is a genetic polymorphism of a key enzyme of folate metabolism: the Methylenetetrahydrofolate-reductase (MTHFR). This encyme converts 5,10- methylenetetrahydrofolate to 5- methyltetrahydrofolate, the major circulatory form of folate in the body and primary methyl donor for the methylation of homocysteine to methionine. This pathway is a critical key in the methylation process of the DNA. As described above alterations in the methylation process can result in abnormal expression of oncogenes and tumour suppressor genes (Baylin et al., 1991). The polymorphism of the human MTHFR gene (alanine to valine substitution, coding for a thermolabile enzyme with reduced activity) results in elevated plasma homocysteine levels. Homozygous individuals have 30% normal enzyme activity, heterozygous 65%. Up to now there are controverse results in correlating this polymorphism with individual colon cancer risk. However, supplementation of folate or a diet rich in folate with optimum bioavailability lower homocystein and might therefore influence the individual risk (Bronstrup et al., 1998)

Vitamin A

The German society for nutrition recommends the increase in vitamin A intake for pregnant women by 40% and for breastfeeding women by 90%. Pregnant women or those who want to become pregnant are asked to avoid the intake of liver out of very unsure scientifically proved reasons, therefore the provitamin A-carotenoid ß-carotene stays the essential vitamin A source. The most important bearers of vitamin A are

orange and deep green vegetable followed by enriched juices, which represent between 20 and max. 40% of the daily supply. In Germany the intake in the mean is by about 1.5 and 2 mg of ß-carotene a day. If one supposes a conversion rate for ß-carotene for juices of 4:1, for fruit and vegetable of 12:1 up to 26:1, therefore this supply leads to a vitamin A sufficiency of 10 to 15%. Because the liver consumption of the population per head and per year amounts less than 500 g, ß-carotene is an important vitamin A source for young women and especially pregnant women and breastfeeding women.

Studies from Great Britain showed that in the middle and working class the vitamin A supply can be seen as insufficient. The American association for paediatrics called vitamin A as one of the most critical vitamins during pregnancy and the breastfeeding period, especially in terms of the lung function and its maturation. If the vitamin A supply of the mother is too low, the supply of the fetus is too low too and also the values of the mother's milk which can't be compensated by postnatal supplementation. At the same time one has to keep in mind that there is a relationship between folic acid, vitamin A and iron status and low birth weight. This applies especially to earlyborn's which show a direct correlation between the vitamin A supply and the turn up of complications like the respiratory arrest syndrom, as one of the most frequent and serious complications.

The major source of vitamin A is liver, which contributes to approximately 75% to the human vitamin A intake. Concerning a sufficient vitamin A supply, the provitamin A, ß-carotene is of minor importance. Its cleavage efficacy seems to be nearer to 1:12 and not 1:6 as frequently mentioned. Beside its well known effects in the visual cycle vitamin A plays an important role especially in mucous membranes.

Is a sufficient supply of vitamin A involved in the individual lung cancer risk? On the basis of a few reports it is assumed that a „local" vitamin-A-deficiency exists in meta- and dysplastic-areas. Measurements of vitamin-A concentrations in metaplastic areas of the respiratory epithelium and the cervix epithelium actually proved that vitamin A, in contrast to the surrounding healthy tissues, was no longer to be found.

At the moment it is difficult to distinguish between cause and effect. Studies carried-out by Edes and co-workers (Edes, 1991) hint to an induction of metaplasia caused by a vitamin-A-deficit. These studies showed that a depletion of vitamin-A-ester stores in different tissues (Edes, 1991) is caused by toxins, that are present in cigarette-smoke (predominantly polyhalogenated compounds).

Epidemiological evidence supports the assumption that the development of obstructive respiratory diseases plays an important role in the scope of cancer mortality of smokers. It was shown that the relative risk for smokers to be affected by lung cancer, when they suffered from obstructive ventilation disorder (FEV 1% < 60 (Melvyn et al., 1987) respectively 70) (Skillud et al., 1987), was significantly higher than that of comparative groups with normal lung-function-parameters.

A survey about the dietary habits within the scope of the „National Health and Nutritional Examination Survey" showed that an inverse correlation (Morabia et al., 1989) exists between obstructive respiratory diseases (COPD) and vitamin-A-supply as the only one of 12 examined dietary components. COPD however, increases lung cancer risk significantly. If a diminished supply of vitamin A increases the appearance of obstructive respiratory diseases, a marginal or local vitamin-A-deficit could be responsible for the observed changes of the respiratory mucosa. Such a deficit results in a loss of cilia, an increase of secreting cells and finally the formation of squamous metaplasia (Stofft et al., 1992; Chytil, 1985; Biesalski et al., 1985).

Such changes (decrease of ciliated cells with simultaneous increase of the secretion) are noted for smokers (Gouveia et al., 1982; Mathe et al., 1983) and cause a reduction of the mucociliary-clearance. This reduction of the mucociliary-clearance, associated with an increased adsorption of the respiratory syncytial virus (RSV) (Donelly, 1996), could explain the extraordinarily high morbidity and mortality for respiratory infections of children with vitamin-A-deficiency in developing countries (Sommer, 1993).

There is sound evidence from experimental studies that the alteration of the respiratory mucosa, caused by the vitamin-A-deficiency, can be redifferentiated into its functional original epithelium, in vivo as well as in vitro, following vitamin-A-supply (Biesalski et al., 1985; McDowell et al., 1984a,b, 1987a,b; Rutten et al.,

1988 a,b). Squamous metaplasia of the bronchial mucosa, which occurs in smokers in spite of a sufficient supply with vitamin A as an effect of inhalative noxae could also be reversed through systemic application of high retinoid-concentrations in vitro (Lasnitzky and Bollag, 1982; 1987) and in humans in vivo (Gouveia et al., 1982; Mathe et al., 1983).

Selenium

Selenium is found largely in grains fish and meats and enters the food chain through plants at geographically variable rates dependent on selenium concentration of the soil. The best known biochemical role for selenium is as part of the active site of the enzyme glutathione peroxidase (GPx). The metabolic function of this enzyme are vital for cells, as it is part of a mechanism responsible for the metabolism and detoxification of oxygen. It is assumed that GPx can protect the DNA from oxidative damage and consequently from mutation leading to neoplastic transformation of cells (Combs and Clark, 1985). At relatively high levels selenium protects against the action of certain carcinogens in various animal models (Halliwell and Gutteridge, 1989). In in vitro and in vivo studies, organic and inorganic selenium has been demonstrated to inhibit proliferation of normal and malignant cells and inhibit tumor growth (Griffin, 1982; Redman et al., 1997). Apoptosis may result from competition of selenium for s-adenosyl-methionine with ornithine decarboxylase (ODC). ODC acitivity is indeed critically involved in cancerogenesis. From geographical studies it is documented that in areas with sufficient selenium concentrations in the diet (depending on selenium concentrations of the soil) there is an inverse relationship between selenium status and cancer (Schrauzer et al., 1977; Clark et al., 1991). Epidemiological studies showed inverse associations of selenium intake or plasma levels and cancers of different sites (prostate, colon, skin etc.). In a recent double blind placebo controlled cancer prevention trial 200µg selenium (approx. 3 time the RDA) were given daily to patients with histories of basal and squamous skin carcinoma (Clark et al., 1996). Selenium supplementation did not influence the primary endpoint prevention of recurrent skin cancers, but was surprisingly inversely associated with the incidence of and mortality from total prostate, lung and colorectal cancers. Recently Yoshizawa and co workers (1998) reported a strong inverse association of toenail concentration of selenium and prostate cancer risk (65% reduced risk in the highest quintile). Toenail concentration reflect long term intake of selenium with the diet and is consequently influenced by bioavailability. From the intervention trial and from epidemiological studies there is now evidence indicating "that substantial increases in the consumption of selenium by men taking 80-90µg/day or more may have striking impact on prostate cancer rates" (Giovannucci, 1998). Recent surveys indicate that average intake of selenium may be as low as 30-40µg/day (Rayman, 1997). Intake data however do not really reflect the bioavailability. Consequently the diet has a strong influence on total selenium supply of tissues. Especially in areas with low soil selenium dietary sources containing substantial amounts of selenium with good bioavailability should be recommended. In the US Selenium is mainly supplied by cereals, breads, meats and meat products. Beef alone is estimated to contribute approximately 17% of the total selenium in the American diet. Two recent studies in humans showed that meat was as good a source of selenium, as is wheat (van der Torre et al., 1991) and that SeMet was absorbed more rapidly than selenite in selenium deficient men (Xia et al., 1992). In a recent study the bioavailability of selenium was estimated from various portions of fully cooked commercial cuts of beef, including liver, striploin, round, shoulder and brisket in rats (Shi and Spallholz, 1994). The bioavailability from the beef diets was compared with that of selenium as selenite or L-selenomethionine (SeMet). Liver GPx recovery (after depletion), muscle tissue depostion and plasma levels were taken as markers of bioavailability. Liver GPx-recovery was highest from SeMet > beef muscle > selenite = beef liver. Muscle deposition was highest from SeMet > beef muscle > selenite = beef liver. From this results the authors concluded that the bioavailability of selenium from beef is higher than or at least equal to that of selenite and slightly lower than that of SeMet. Taken together meat is an important source for bioavailable selenium.

Zinc

Zinc is a component of a couple of metalloenzymes and is important for cell growth and replication, osteogenesis and immunity. It may further contribute to the overall antioxidative defence. The primary dietary sources of zinc are red meat, sea food, poultry, grains, dairy, legumes and vegetables (Groff and Grooper, 2000). Lower zinc levels were described in cancer patients (without answering the question of cause or consequence) (Mellow et al., 1983; Rogers et al., 1993); others did not find this association (Kok et al., 1988; Kabuto et al., 1994). There is good evidence that zinc may critically contribute to prostate cancer incidence. Total zinc levels in the prostate are 10 times higher than in other soft tissues (Mawson and Fischer

1952). Uptake of zinc via a membrane transporter into prostatic epithelial cells is under the control of hormones (testosterone, prolactin) (Costello et al., 1999). Physiologic concentrations of zinc inhibit growth of androgen sensitive and androgen-independent prostate cancer cell lines via cell cycle arrest, apoptosis and necrosis (Iguchi et al., 1998; Liang et al., 1999). Epidemiological findings are not consistent and a few studies estimating the effect of supplementation on prostate cancer risk are more or less controversial (for review see Platz an Helzlsouer, 2001). One important reason for this inconsistency might be the high variability of zinc content of different sources, especially meat and sea food. Furthermore zinc has a much better bioavailability from meat than from vegetables (Groff and Groopper, 2000) and other factors, present in the diet may increase (citric acid, histidine, cystein) or decrease (phytate, oxalate) absorption of zinc (Groff and Groopper, 2000). Consequently, the use of food questionnaires might not be a sufficient approach to measure zinc intake. Adequate biomarkers, at present not available, may help to estimate the individual zinc status and consequently the individual risk. At present there is no clear cut evidence for a preventive effect of zinc on prostate cancer from epidemiological studies. Some small case control studies indicate low plasma zinc or low prostatic zinc levels in patients with prostate cancer compared with healthy controls (for review see Platz an Helzlsouer, 2001). An optimum zinc intake can be recommended not only with respect to prevention and intakes below RDA should be avoided. One factor contributing to low intake might be a decline in red meat consumption which has been reported in New Zealand (Laugesen and Swimburn, 2000), as well as in UK (Whitehead, 1995), USA (Popkin, 1989) and Canada (Zafiriou, 1985), concomitant with an increase in intakes of unrefined cereals, nuts and legumes. Read meat is a rich source of readily available zinc, whereas cereals contain different levels of phytic acid, a potent inhibitor of zinc absorption. Indeed, the recommendation to decrease or even avoid meat intake may result in a low zinc status as recently documented in women from New Zealand (Gibson et al., 2001). In a cross sectional study of 330 women the authors assessed the interrelationship among dietary intakes, biochemical zinc status and anthropometric indices. Changes in food selection patterns (reduction of red meat) were suggested to be responsible for a lower biochemical zinc nutriture. This study shows exemplary that a mixed and balanced diet including meat and meat products is the best way to ensure sufficient intake of all essential and potentially cancer preventive components.

Conclusion:
Meat consumption, especially red meat, is not per se carcinogenic, even it contains components which, based on epidemiological and animal experiments, are assumed to contribute to cancer formation. On the other hand lot of studies exist which demonstrate a reduced cancer risk in persons with a high intake of fruit and vegetables. As a basis for the preventive effect protecting factors such as carotenoids, flavonoids and further phytochemicals are discussed. Within these fruit and vegetables derived protecting factors folic acid, selenium, zinc and other components are claimed to be preventive candidates. Why should theses compounds less effective if they reach the body via meat as an important source? The balance of promoting and protecting factors within the diet is important for the protection against cancer. Furthermore the IR-hypothesis shows that a nutritional behaviour leading to a metabolic syndrome (high energy, high glycemic carbohydrates) might favour colon cancer or even cancers from other sites. The “goals for nutrition in the year 2000” (Willett, 2000) give a very good and comprehensive advice: “ Current nutritional recommendations for the prevention of cancer include increased consumption of fruits and vegetables; reduced consumption of red meat and animal fat; and avoidance of excessive alcohol. For many individuals a daily multivitamin that contains folic acid may also be part of a reasonable cancer prevention strategy.”
To improve the “preventive capacity” of an individual a balanced diet, rich in fruits and vegetables including meat and meat products in moderate quantities, normal body weight and a reasonable amount of exercise is the best choice.

The importance of meat as a source for micronutrients

The reason for the importance of meat as an essential source for a couple of micronutrients is due the the fact that meat is either the only source or has a much higher bioavailability.

Two important micronutrients occur only in meat: The vitamin A and B12. Both cannot be compensated by plant derived provitamins. A B12 provitamin does not exist and the provitamin A, ß-carotene, has to be taken in high amounts due to a poor conversion rate (1:12).

With respect to iron, iron has a higher bioavailability when derived from meat as hem iron than plant derived iron. Similarly folic acid has a nearly ten-fold higher bioavailability from meat (especially liver) and eggs than from vegetables. Consequently a low or near to cero intake of meat (including liver) is associated with a risk for deficiencies in selected micronutrients.

Who needs meat – or: are there groups at risk for a low intake of meat derived micronutrients?

Elderly people are generally considered at risk to develop vitamin and trace element deficiencies, especially regarding the vitamins A, D, E, and folate as well as iron and calcium (Martins, Dantas, Guimar, Amorin, 2002; Bates et al., 2002; Anderson, 2001; Viteri & Gonzalez, 2002). The multifactorial cause of this health hazard comprise quantitative and qualitative decreased food intake, reduced energy expenditure due to sedentary life style and loss of metabolic active body cell mass, and the development of chronic age-associated disorders.

It was generally assumed that impaired bioavailability of micronutrients was a common problem among elderly. However, the digestive and absorptive capacity of the digestive tract is well retained through ageing and if malabsorption of macronutrients occurs it is the result of a disease rather than ageing itself (Black, 2001). An exception to this rule is the impaired bioavailability of dietary iron due to gastric mucosal atrophy which occurrence is age-related and in many cases could be regarded as a disorder rather than a disease. Nevertheless, the frequently occurring atrophic gastritis in elderly, which also affects vitamin B12 absorption, should be one reason to recommend meat intake in this risk groups.

Adequate nutrition during pregnancy plays an important role in the well-being of mother and child and influences health of the offspring during childhood and adulthood. Nutritional requirements are increased during pregnancy, but will generally be met by dietary intake and adaptive physiological changes (Draper, Lewis, Malhotra & Wheeler, 1993). However, the micronutrient status of vitamin D, folic acid, iron, and zinc may become compromised without supplementation (Draper, Lewis, Malhotra & Wheeler, 1993; Fogelholm, 1999; Saletti, Lindgren, Johansson & Cederholm, 2000) especially when meat is avoided, which can be frequently seen in women in the child bearing age. Folic acid supplementation is generally recommended to decrease the risk of serious births defects. Especially in multifarious women the essential fatty acid status may become impaired and negatively affects the neurological and cognitive development of the offspring (Lowik, van den Berg, Schrijver, Odink, Wedel & Houten, 1992; Reynolds, 2002).

The micronutrient intake of vegans is easily imbalanced with respect to the recommended dietary allowances. Especially the intake of vitamin B12, riboflavin, and selenium often is inadequate. Even the use of dietary supplements often does not meet the recommended intake of vitamin B12 and selenium (Boelsma, Hendriks & Roza, 2001; Andersson et al., 1986).

Although it seems obvious that subjects on a weight reduction diet are at risk to develop micronutrient deficiencies, the scientific evidence for this is weak. Most reports include less than fifty subjects and deal with the combination of energy restriction and increase of physical activity, and hence are difficult to interpret (Philipsen-Geerling & Brummer, 2000). The micronutrients at risk appear to be iron, magnesium, zinc, fat soluble vitamins and essential fatty acids. Although a nutritionally adequate low-fat diet seems feasible in a motivated, free-living population (Gassull & Cabre, 2001), data exist which show that a high protein intake even when associated with a higher fat intake might favor weight loss.

A recent meta-analysis of studies dealing with dietary weight loss show that protein rich diets low in carbohydrates and a moderate or high fat content resulted in a better weight loss than diets low in fat and protein and rich in carbohydrates (Bravata et al., 2003). Several factors are discussed to contribute to this increased weight loss: better satiety, higher energy expenditure (thermogenesis), greater loss of fat cell mass.

Energy restricted diets and traditional cholesterol lowering diets are typically focussed on the reduction of total fat intake while simultaneously increasing the proportion of polyunsaturated fatty acids (PUFA's). However these PUFA's usually contain high concentrations of n-6 fatty acids and low amounts of n-3 fatty acids. This may have an adverse effect not only on reducing the risk for obesity-related metabolic disorders such as vascular disease and heart rhythm disturbances, but also on the regulation of the intermediary metabolism of brain monoamines as serotonin, which may lead to impaired mood status and depression (Alonso-Aperte & Varela-Moreiras, 2000).

It is well known that malnutrition is far more common among institutionalized and chronic hospitalized elderly compared to free-living subjects in the community and that the prevalence of malnutrition is associated with the severity of morbidity, functional impairments and mental state (Bates, Mansoor, van der

Pols, Prentice, Cole & Finch, 1997; Selhub, Jacques, Bostom, Wilsin & Rosenberg, 2000; Rasmussen, Ovesun, Bulow, Kudesn, Laurberg & Perrild, 2000; Koehler, Baumgarter, Garry, Allen Stabler & Rimm, 2001). The deficiency effects a broad spectrum of micronutrients, such as the B vitamins, especially B1, B6, folate and B12, vitamin C, vitamin D and E, essential fatty acids and selenium (Brubacher, Moser & Jordan, 2000; Bates, Prentice et al., 1999). Thiamine and folate status need special attention in this respect as a deficiency of these nutrients is associated with depression and impaired cognition and dementia (Block, Norkus, Hudes, Mandel & Helzlsouer, 2001; Report on Health and Social Subjects No. 49, 1998). Intervention trials with micronutrient supplementation consisting of zinc and selenium, vitamin C, beta-carotene and alpha-tocopherol were associated with a reduction of infectious events, probably due to the micronutrients administration rather than the supplementation of vitamins (Gey, Brubacher & Staehelin, 1987; Gey, 1993).

Chronic use of drugs may lead to micronutrient deficiency by decreasing food intake mainly due to impaired appetite or upper GI motility, by decreasing the bioavailability of micronutrients, for example cholestyramine which impaires the absorption of fatty acids and fat-soluble vitamins, or by interfering with metabolism (Gregory, Foster, Tyler & Wiseman, 1990). A number of micronutrients, such as zinc and magnesium, play a role in phase I oxidation reactions involved in drug metabolism. Typical examples are the increased folate requirements with chronic use of sulphasalazine, methotrexate, or valproic acid. However, a relevant interaction between drugs and specific micronutrients only occur in case of prolonged use of specific drugs in high doses in susceptible subjects.

Selected meat derived micronutrients

Meat is an excellence source for different micronutrients: Low fat pork meat contains 1.8mg iron, 2.6mg zinc, pig liver contains 360mg magnesium, 20mg iron and 60µg selenium per 100g. Meat and liver (100g/day) can cover up to 50% of the RDA for iron, zinc, selenium, Vitamins B12, B1, B2, B6 and 100% of vitamin A.

Vitamin A
The German society for nutrition recommends the increase in vitamin A intake for pregnant women by 40% and for breastfeeding women by 90%. Pregnant women or those who want to become pregnant are asked to avoid the intake of liver out of very unsure scientifically proved reasons, therefore the provitamin A-carotenoid ß-carotene stays the essential vitamin A source. The most important bearers of vitamin A are orange and deep green vegetable followed by enriched juices, which represent between 20 and max. 40% of the daily supply. In Germany the intake in the mean is by about 1.5 and 2 mg of ß-carotene a day. If one supposes a conversion rate for ß-carotene for juices of 4:1, for fruit and vegetable of 12:1 up to 26:1, therefore this supply leads to a vitamin A sufficiency of 10 to 15%. Because the liver consumption of the population per head and per year amounts less than 500 g, ß-carotene is an important vitamin A source for young women and especially pregnant women and breastfeeding women.

Studies from Great Britain showed that in the middle and working class the vitamin A supply can be seen as insufficient. The American association for paediatrics called vitamin A as one of the most critical vitamins during pregnancy and the breastfeeding period, especially in terms of the lung function and its maturation. If the vitamin A supply of the mother is too low, the supply of the fetus is too low too and also the values of the mother's milk which can't be compensated by postnatal supplementation. At the same time one has to keep in mind that there is a relationship between folic acid, vitamin A and iron status and low birth weight. This applies especially to earlyborn's which show a direct correlation between the vitamin A supply and the turn up of complications like the respiratory arrest syndrom, as one of the most frequent and serious complications.

The major source of vitamin A is liver, which contributes to approximately 75% to the human vitamin A intake. Concerning a sufficient vitamin A supply, the provitamin A, ß-carotene is of minor importance. Its cleavage efficacy seems to be nearer to 1:12 and not 1:6 as frequently mentioned. Beside its well known effects in the visual cycle vitamin A plays an important role especially in mucous membranes.

Vitamin A is essential for growth and development of cells and tissues. In its active form, retinoic acid, it controls the regular differentiation as a ligand for retinoic acid receptors (RAR, RXR) and is involved in the integration (gap junction formation) of cell formations (Kurokowa et al., 1994; Morree, 1992). Vitamin A plays a substantial role, especially in the respiratory epithelium and the lung. During moderate vitamin-A-deficiency, the incidence for diseases of the respiratory tract is considerably increased and repeated respiratory infections can be influenced therapeutically by a moderate vitamin-A-supplementation (Pinnock et al., 1986; Sommer, 1993; West et al., 1991). In addition to the importance of the vitamin for the lung function, vitamin A is also responsible for the development of many tissues and cells as well as for the embryonic lung development. Recent studies proved that the control occurs by different expressions of retinoid receptors as well as by time-dependent changes of the vitamin A-metabolism respectively via cellular vitamin A-binding proteins (CRBP: cytoplasmatic retinol binding protein; CRABP: cytoplasmatic retinoic acid binding protein).

The influence of vitamin A for the maturation and differentiation of the lung
The alveolar cells of type II are especially prepared to synthesize and secrete the surfactant (Zachman, 1989). Retinoic acid (RA) is able to stop, concentration-dependently (Metzler and Snyder, 1993) the expression of the surfactant-protein A (SP-A) in human fetal lung explants. Insulin, TGF-ß and high concentrations of glucocorticoids can also down-regulate the SP-A-mRNA-expression (Weaver and Whitsett, 1991) , but lower concentrations of glucocorticoids are stimulating the expression of these genes (Odom et al., 1988). In contrast, the SP-B-mRNA-expression is increased in human fetal lung explants both by hyperoxia (rats) (Metzler and Snyder, 1993) and by dexamethason (human fetal lung explant) . Consequently, the formation of some surfactant-proteins is regulated differently and selectively by RA together with glucocorticoids.

Prostaglandins of type PGE2 are able to increase the surfactant-synthesis. Under the influence of EGF (epidermal growth factor) the formation of prostaglandin rises, especially of PGE2. On the other hand, the expression of the EGF-receptor is increased by RA. EGF increases the proliferation of the lung tissues and this leads to an amplified formation of surfactant phospholipids (Sundell et al., 1980). RA as well as EGF are both leading to an increase (40%, 80%) of the PGE2-secretion in fetal lung cells of the rat in vitro (Haigh et al., 1989). The combination of RA and EGF though leads to a more than a six-fold increase of the PGE2-secretion. Consequently, RA can interfere in the lung development by its modulating effect on the EGF-expression and the subsequent PGE2-induced surfactant formation. A sufficient and continuous availability (either on the blood pathway or by local storage sides) is pivotal, especially for a time-dependent regulation of the lung-development and the related formation of the active metabolite retinoic acid.

Vitamin-A kinetic during fetal lung development
In fibroblast-like cells close to the alveolar cells, in type-II-cells as well as in the respiratory epithelium retinyl-esters, as local extrahepatic stores are present. The importance of these retinyl-esters as „acute reserve“ during the development of the lung becomes apparent during the late phase of gestation and the beginning of lung maturation. During this period a rapid emptying of the retinyl-ester storage’s in the lung of rat embryos occurs (Geevarghese and Chytil, 1994). This depletion is the result of an increased demand in the process of the lung development, because the retinoic acid is „instantly“ needed for the process of cellular differentiation (e.g. proximalization) and metabolic work (surfactant).

The prenatal lung development is also influenced by glucocorticoids. The steroid hormones have a similar effect on lung development as vitamin A resp. the two factors complement each other. This is not surprising, because the receptors for steroids and retinoids belong the same multireceptor-complex. The mode of action of glucocorticoids does not only come into action on the level of gene-expression, but seems to have an impact in a much earlier phase of the vitamin release. The application of dexamethason leads to an increase of the maternal and fetal retinol-binding protein. Thus, the vitamin A-supply is improved via the regular hepatic export pathway. Such an increase of the vitamin-A-concentration in the systemic circulation diminishes obviously the morbidity and mortality of prematures due to bronchopulmonal dysplasia (Shenai et al., 1987; 1990). Dexamethason respectively glucocorticoids are not only leading to an improvement of the total vitamin-A-supply through a change of the release from the liver, but they also influence, as recently described (Geevarghese and Chytil, 1994), the metabolization of the vitamin-A-esters, which are stored in the lung. After administration of dexamethason, as well as after administration of steroids, a significant reduction of retinyl-esters in the maturing lung can be detected, together with a moderate increase of retinol,

the hydrolyzation product of retinyl-ester. This observation may explain the therapeutical success with steroids respectively also their failures during the therapy of lung-distress-syndrome of prematures. As far as an insufficient supply is concerned, inappropriate retinyl-ester stores, caused by a shortage of supply of the fetal lung during the late pregnancy, the regulatory effect of glucocorticoids for the vitamin-A-metabolism of the lung cells cannot take place.

Very low plasma-vitamin-A-levels (Shenai et al., 1981) are recurrently found in prematures, especially in cases with lung-distress-syndrome. This can, amongst other things, be attributed to the relative immaturity of the liver for the synthesis of retinol-binding proteins. The neonate is almost exclusively dependent on the mother in its supply, this includes the lung retinyl-esters which are either absorbed by the cells directly (from chylomicrons) or by esterification of retinol after uptake into the cells. These lung retinyl-ester stores can only be sufficiently filled if the mother guarantees an appropriate vitamin-A supply especially during the late pregnancy.

The influence of an insufficient vitamin-A-supply on the post-natal development of the lung
A disease seen recurrently in connection with vitamin-A-supply is the bronchopulmonary dysplasia (BDP). The pathogenesis of BDP certainly depends on a multitude of factors. Some of the observed morphological changes are very similar to the ones seen in vitamin-A-deficiency of humans and animals. In particular, there is focal loss of ciliated cells with keratinizing metaplasia and necrosis of the bronchial mucosa as well as an increase of mucous secreting cells (Stahlmann, 1984; Stofft et al., 1992).

Especially focal keratinizing metaplasia, as it may occur after a vitamin-A-deficiency, is strengthening the assumption of an impairment of the differentiation on the level of the gene-expression. Since vitamin A regulates the expression of different cytokeratins and therefore influences the terminal differentiation, it seems obvious to suppose common mechanisms. Consequently, the premature but especially the neonate are dependent on a sufficient supply with vitamin A, to ensure the regulation of the cellular differentiation of the respiratory epithelium and lung epithelium. The earlier a child is born before due date, the lower its serum-retinol-levels are (Mupanemunda et al., 1994). Since a further decrease of the serum-retinol-level and RBP-level occur postnatally, the plasma value at the time of birth, is considered to be a critical parameter regarding the lung development.

Repeatedly it was shown that serum-retinol-level and RBP-level in prematures are significantly lower than in neonates (Shah and Rajalekshmi, 1984). In the liver of prematures significantly lower retinol levels can be found in comparison to neonates (Shenai et al., 1985). Plasma values lower than 20 µg/dl are not rare in this case and they should be taken as an indicator of a relative vitamin-A-deficit.

Reduced plasma levels during the first months of life have got a considerable influence on the overall development as well as on the susceptibility of infants to infections. With reduced retinol-plasma-levels repeated infections are more often described (Barretto et al., 1994; Filteau et al., 1993; Pinnock et al., 1986) and they are counted among the main complications of a poor vitamin-A-supply in developing countries. In addition, the serum vitamin-A level during infectious diseases, particularly of the respiratory tract, continues to drop (Neuzil et al., 1994). On the one hand, this can be explained with an increased metabolic demand and on the other hand with an increased renal elimination of retinol and of RBP during acute infections (Stephensen et al., 1994).

Conclusion:
The discussion whether liver as a component of a healthy diet should be avoided is primarily based on questionable contaminants suspected in the liver (e.g. hormones, xenobiotics, metals etc.). If ß-carotene arriving from vegetables would be the only source of vitamin A we must eat more than 500g mixed and ß-carotene rich vegetables per day to reach the recommendations of 1mg retinol. Concerning contaminants it has not been evaluated whether this amount of vegetables contains more contaminants than a portion of liver. A small portion of liver (100g) twice a month is neither toxic nor teratogenic and contributes to a sufficient supply of the body with vitamin A.

Iron

Iron supports oxidative metabolism. It is essential for gas exchange at the tissue and cellular levels through hemoglobin oxygenation in red cells and myoglobin in skeletal muscle (Beard, Dawson & Pinero, 1996). Moreover, iron-containing enzymes are involved in cellular energy metabolism and in host-defense responses (Beard, Dawson & Pinero, 1996; Griffiths, 1996). These various roles are due to iron's biological catalytic activity. Like many other transition elements, it posses unfilled atomic orbitals that allow it to co-ordinate electron donors and participate in redox processes (Griffiths, 1996; Fraga & Oteiz, 2002).

Iron is one of the most abundant elements in the Earth's crust, paradoxically, iron deficiency is the most common and widespread nutritional disorder in the world (DeMaeyer & Adiels-Tegman, 1985). Due to biological losses such as cyclical monthly bleeding of fertile-aged women, excessive infestation with blood-feeding parasites, or poor bioavailability of iron from plant-based diets, it is estimated that as many as 4-5 billion people, 66-80% of the world's population, may be iron deficient (DeMaeyer & Adiels-Tegman, 1985; World Health Organization, 1992). At any given time, 2 billion people – over 30% of the world's population – are anemic, mainly due to iron deficiency, and in developing countries, frequently exacerbated by malaria and worm infections (World Health Organization, 1992).

Iron deficiency is a particular risk for women and girls of child-bearing age, because of menstrual losses. In a recent Irish food consumption survey, almost half of women aged 18-50 year had inadequate iron intakes when compared with national average requirements [62]. In the British National Diet and Nutrition Survey, iron intakes were found to be low in girls (aged 7-18 years), with iron intakes decreasing with age. Adolescent females (15-18 year) were found to have extremely low intakes of iron when compared with UK dietary reference values. Dietary supplements made no difference to mean intakes and iron status was also low in these groups. Depending on the composition of the individual diet the bioavailability of iron can differ 5 to 10-fold (lit 8 und 9 aus fleisch und gesundheit). The different bioavailability depends on the presence or absence of different ligands (phytates from cereal products, tannins from coffee and tea and oxalates from vegetables) which form complexes with iron and zinc and block their absorption. A diet which is primarily composed out of vegetables, rice, beans and corn is associated with a poor iron bioavailability which at least explains the high incidence of anemia in developing countries. 100g pork meat added to the above described vegetarian diet increases the iron absorption 3.6 fold.

Folic acid

In European countries the average folate intake in adults was found to be remarkably similar, around 300 µg/day in adult males and 250 µg/day in adult women (De Bree, van Dusseldorp, Brouwer, van het Hof & Stegers-Theunissen, 1997). This is about the recommended intake level, but lower than recommended for pregnant women and women with pregnancy wish. For these groups an intake of >400 µg/day is considered protective against neural tube defects. More than 90% of women in the childbearing age have dietary folate intakes below this optimal level. However, it must be realised that it is difficult to assess dietary folate intake because databases often do not have complete and updated information for folate content of many foods.

The link between poor folic acid status and neural tube defects is well documented but poorly characterized. Poor status is also linked to raised plasma homocysteine, a risk indicator for cardiovascular diseases and poor status may also increase the risk of neurological disorders and cancers. Supplementation with folate (100% bioavailability) reduces risk for neural tube defects up to 70%. Regarding the bioavalability, liver might be also a good source.

Vitamin B12

Vitamin B12 is found only in animal products. In a recent UK study of 250 vegetarian and 250 vegan men, approximately one quarter of vegetarians and more than half of vegans had sub-optimal intakes of vitamin B12. Plasma vitamin B12 levels were low in the vegetarians and extremely low in the vegan group, with more than a quarter below the threshold level where neurological signs may develop (130 ng/L) (Lloyd-Wright, Allen, Key & Sanders, 2001). The elderly are also at risk of vitamin B12 deficiency, due to physiological changes resulting in reduced absorption. In the UK, vitamin B12 status in some people aged 65 and over was inadequate. There was no difference in mean levels between men and women. However, vitamin B12 intakes were adequate when compared with UK dietary reference values (Finch et al., 1998).

Selenium
Selenium is often considered as belonging to the group of antioxidant nutrients, since it is incorporated into the enzyme glutathion peroxidase, which acts as a cellular protector against free radical oxidative damage. A secondary end-point analysis of a randomised placebo-controlled skin cancer prevention trial suggested that supplemental selenium might reduce the incidence of and mortality from cancers at several sites (Clark et al., 1996). However, the efficacy of selenium as a cancer preventive agent should await the results of large on-going controlled studies. Selenium is, like many other nutrients, necessary for a well-functioning immune system, and has been pointed out as particularly efficacious in HIV and AIDS. A systematic review found no evidence for a clinical relevant function of selenium in that respect (Ozsoy & Ernst, 1999).

Although selenium is widely distributed in the environment, the selenium content of foods is greatly affected by soil on which crops grow or animals graze. Recent evidence suggests that selenium intakes in most parts of Europe are falling and are low when compared with recommended intakes (Rayman, 1997; Rayman, 2000). Declining intakes in the last three decades have been attributed mainly to a change in the source of wheat for bread and cereal products, from predominantly North American to European origin (from a high to low selenium content). These are reflected in decreasing plasma or serum selenium levels. Due to its antioxidant effects, selenium may be protective against chronic degenerative diseases. In the UK, selenium intakes were low in the majority of the elderly (aged 65 and over) in the British National Diet and Nutrition Survey when compared with UK dietary reference values (Thane & Bates, 2001). Selenium intakes decreased with increasing age in this population subgroup. Sufficient zinc intake is important for the proper function of the immune system.

Zinc
Zinc deficient individuals demonstrate slower wound healing and are more prone to infections. However, studies of the effect of zinc supplementation aimed at the healing rate of venous leg ulcers have been inconclusive. A Cochrane review concluded that oral zinc did not appear to aid the healing of leg ulcers, and that there was only weak evidence that zinc was of benefit in patients with venous leg ulcers and low serum zinc (Wilkinson & Hawke, 2002). Zinc has been found to inhibit rhinovirus replication in vitro. Some studies have demonstrated that zinc may beneficially affect cold symptoms; however a meta-analysis of randomised controlled trials concluded that the evidence for the effectiveness of zinc in reducing the duration of common cold symptoms is lacking (Jackson, Lesho & Peterson, 2000). Finally, in settings with high rates of stunting and low plasma zinc concentrations, zinc supplementation may improve children's growth (Brown, Peerson & Allen, 1998). So far studies with supplementation did not reveal consistent results. However, a low intake of zinc is associated with a weakened immune system. T-cell-count, T-cell-proliferation- and function and NK-cell activity are reduced. Especially in elderly a reduced zinc status is evident (Lukito et al., 2004). In elderly a higher protein intake (together with slight exercise) stops sarkopenia, a progressive loss of lean body mass. During pregnancy and lactation a higher need of zinc is documented as well as during chronic inflammatory diseases (Rink and Gabriel, 2000).

Conclusion:
Meat as a component of a mixed and healthy diet contains important and essential micronutrients. The adaequate intake ensures a normal function of the immune system, the mucous membranes and the general metabolism of substrates. At least a sufficient intake ensures that during time periods of higher need e.g. diseases, pregnancy, this need is adequately covered. Especially in risk groups (elderly, pregnant women, growing children) meat should be consequently recommended.

Abstract

This article reviews the fat content and fatty acid composition of meats in the human diet and discusses nutritional facts related to meat, meat products and other meat-containing foods as sources of dietary fats. Meat is an increasingly important source of high-value animal protein worldwide. Meat fat comprises mostly monounsaturated and saturated fatty acids, with oleic (C18:1), palmitic (C16:0), and stearic acid (C18:0) being the most ubiquitous. Meat and meat products are considerable sources of cholesterol in the diet. In most industrialized countries, a high meat intake contributes to a higher than recommended total and saturated fat and cholesterol intake. Another concern is that meat may replace sources of other important nutrients in the diet. Therefore, the advice to consumers is to prefer lean meats and low-fat meat products and use meat in moderation only.

Keywords: meat, meat products, fatty acid consumption patterns, food sources of fatty acids, cholesterol, dietary intake

Rising global meat consumption

Meat is an important source of high-value animal protein in many regions of the world. Around the globe, the diets of relatively more urbanised populations are characterised by a higher content of meat, poultry and other animal products than the less diversified diets of rural communities (WHO, 2003). In South Asia and in Sub-Saharan Africa (excluding South Africa) meat consumption was still very low in the late 1990s, at under 10 kg annually per person. However, meat consumption has increased by, on average, more than 10% worldwide since the beginning of 1960s. Average annual consumption per person has increased by more than 20 kg during that period in Latin America and the Caribbean, East Asia and the industrialised countries. The consumption of meat is highest, on average close to 90 kg per year, in North America and most other industrialised countries (Bruinsma, 2003). Meat per se comprises roughly 10-20% of energy intake in most meat consuming countries (FAO, 2002; WHO, 2003). The combined share of energy of meats, meat products and of composite foods containing meats is larger, because of other energy-rich ingredients used in the preparation of these foods. The purpose of this article is to review the fat content and fatty acid composition of meats in the human diet and discuss nutritional facts related to meat, meat products and other meat-containing foods as sources of dietary fats.

Fat and fatty acid content of meats

Meat and meat products vary greatly in their fat content according to the animal species, age of the animal and part of the carcass used ([Swedish]Livsmedelverket, 2004; [English] Ministry of Agriculture, Fisheries and Food, 1998; Ovaskainen, Reinivuo & Korhonen, 2001). The fat content and fat composition is also affected by animal feeding, a fact that is exploited for modification of the meat fatty acid composition, with the relatively best results in single-stomached pigs and poultry (Wood & Enser 1997; Wood, Enser, Fisher, Nute, Richardson, & Sheard, 1999; Bolte, Hess, Means, Moss, & Rule, 2002). Data on the average fat content and fatty acid composition of meats and meat products are published as part of food composition tables throughout the world (e.g. Livsmedelverket, 2004; Ministry of Agriculture, Fisheries and Food, 1998; Ovaskainen *et al,* 2001).

The average fat content and fatty acid contents of selected meat fats and meats are shown in Figure 1 (modified from Livsmedelverket 2004, Ovaskainen *et al,* 2001). Total fat content of meats and meat products varies around 3-25 g/100 g. Chicken skin has an even higher fat content, about 48 g fat/100g (Fig 1). While cured beef and other cold-cuts may have a fat content of below 5%, the fat content in reduced fat sausages is usually around 10%, in common sausages around 15-25%, and twice as high in salami (~40%) and pepperoni (50%) type of sausages (Ministry of Agriculture, Fisheries and Food, 1998, Livsmedelverket, 2004, Ovaskainen *et al,* 2001).

Meat fat comprises mostly monounsaturated fatty acids (MUFAs) and saturated fatty acids (SFAs). The most ubiquitous fatty acids are oleic (C18:1), palmitic (C16:0), and stearic (C18:0) acids. Poultry and pork contain somewhat more unsaturated fatty acids (~10-15% of total fatty acids) than beef and lamb, and also a notable amount of polyunsaturated fatty acids (PUFAs). Linoleic acid (C18:2) is the predominant PUFA (~0.5-7%) , followed by alpha-linolenic acid (up to 0.5%) (Livsmedelsverket, 2004, Ministry of Agriculture, Fisheries and Food, 1998, Ovaskainen *et al,* 2001, National Public Health Institute, 2001). Trans-fatty acids comprise about 1-2 % of total fatty acids across all types of meat; in ruminant meats they represent ~2-4 %. Conjugated linoleic acid (CLA), a group of polyunsaturated fatty acids that appear in dairy products and are thought to have beneficial effects on health, are also found at low mg-levels in meats, especially in beef and lamb (Belury, 2002).

In addition to fatty acids, cholesterol is a nutritionally important component of meats. The cholesterol content of meats varies between about 30 and 120 mg/100 g of food, being even higher in offals (Ministry of Agriculture, Fisheries and Food, 1998; Ovaskainen *et al,* 2001; [Finnish] National Public Health Institute, 2001).

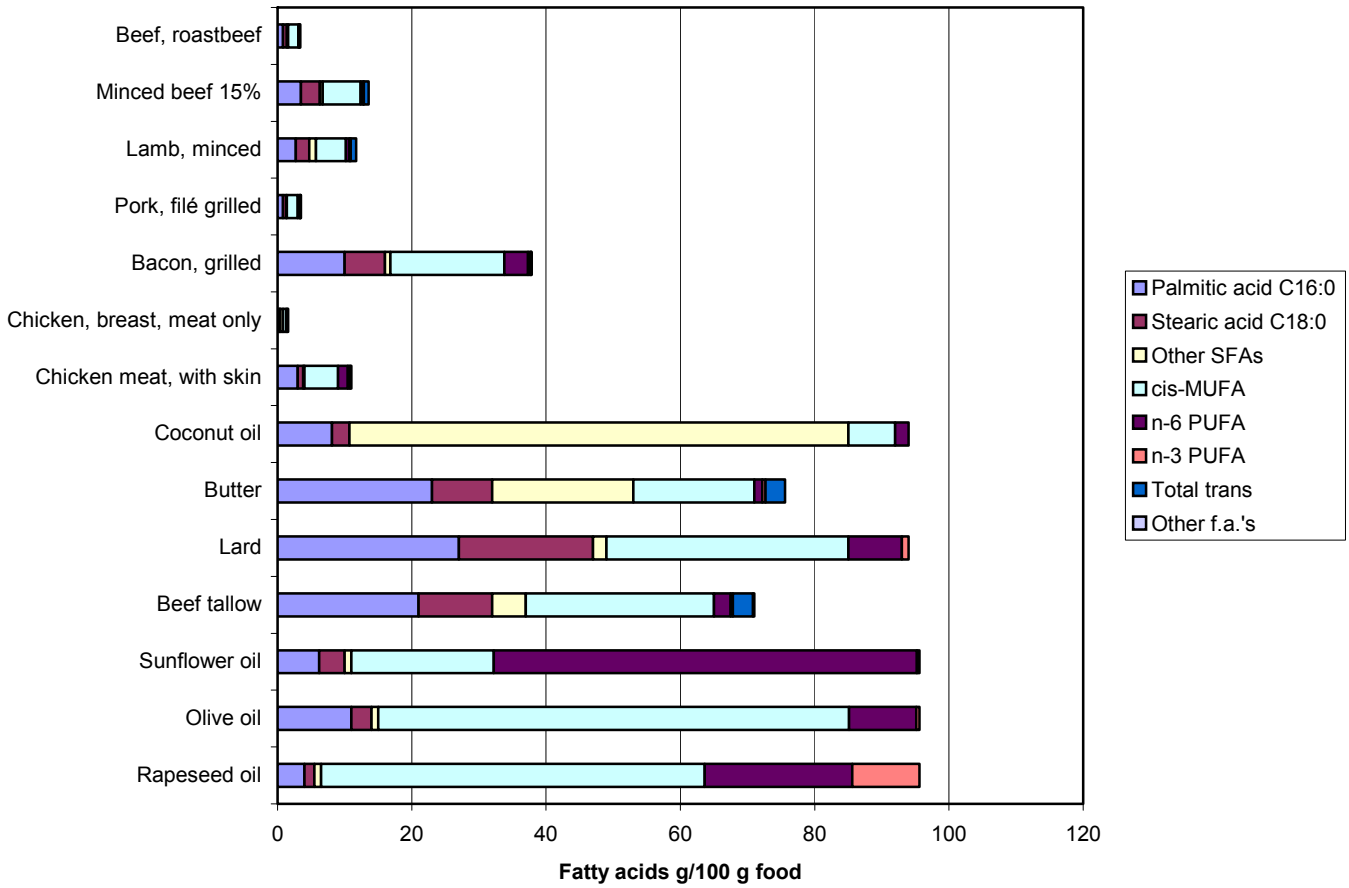

Figure 1. Common fat content and fatty acid composition of selected meats and fats (modified from Livsmedelsvärket, 2004, and Ovaskainen *et al,* 2001).

Fat contribution of meat in relation to recommended fat and cholesterol intake

The most recent nutrient intake goals published as a result of a joint WHO/FAO expert consultation (WHO, 2003) are based on the widespread consensus that a "balanced diet" has preventive effects on chronic non-deficiency diseases, e.g. obesity, type 2 diabetes, cancer and cardiovascular diseases. These guidelines include the following targets for fat intake: total dietary fat, 15-30% of energy (En%); saturated fatty acids (SFA), <10 En%; n-6 polyunsaturated fatty acids (n-6 PUFA), 5-8 En%; n-3 polyunsaturated fatty acids (n-3 PUFA), 1-2 En%; trans fatty acids, < 1 En%. The target for monounsaturated fatty acids (MUFA) is calculated as follows: MUFA = total fat – (SFA+PUFA+trans fatty acids). Saturated fatty acids are well known to raise total and low-density lipoprotein (LDL) cholesterol. The main causes of this effect are myristic and palmitic acids; stearic acid is converted to oleic acid in vivo and has not been shown to elevate blood cholesterol. Myristic and palmitic acids are common fatty acids in dairy products and meat.

When European patterns of food and nutrient intake were recently evaluated, it was shown that despite gastronomic diversity, in most EU countries where the available data allowed for analysis, a higher intake of total fat was associated with a higher intake of energy as well as, in most cases, of all main classes of fatty acids (De Henauw & De Becker, 1999; Haraldsdottir, 1999; Valsta, 1999; Hermann-Kunz & Thamm, 1999; Moschandrease & Kafatos, 1999; Löwik, Hulshof & Brussaard, 1999; Serra-Majem, Ribas & Ramon, 1999). Higher intake of saturated fat was mainly associated with higher intake of energy and MUFA (De Henauw & De Becker, 1999; Serra-Majem *et al,* 1999, Hermann-Kunz & Thamm 1999; Löwik *et al,*, 1999; Valsta 1999). The intake of cholesterol was shown to be higher in the high-fat as well as high-SFA intake groups in both Eastern and Western Germany (Hermann-Kunz & Thamm, 1999) and in the Netherlands (Löwik *et al,* 1999), but only in the high-SFA group in Greece (Moschandrease & Kafatos, 1999).

When in this European analysis the food intake in the high-fat quartile was evaluated, the higher intake of fat and/or saturated fatty acids was broadly associated with higher consumption of meat and/or meat products. In Belgium, the consumption of both fresh meat and processed meats was higher in the highest fat intake quartile of the adult population (De Henauw & De Becker, 1999). In a Danish analysis, it was shown that the high-fat diet consumers, defined as the top quartile of fat intake (% of energy), had a higher intake of fats (especially butter), meat and whole milk (Haraldsdottir, 1999). In an analysis of Finnish dietary intake data, the highest fat intake and highest SFA intake quartiles were both found to have a larger mean consumption of meats and to contain more consumers of pork meat and sausages. A similar pattern was seen in Spain for processed meat (Serra-Majem, Ribas & Ramon, 1999) and in Sweden for sausages (Becker, 1999). Interestingly enough, in the Finnish diet, the proportion of beef consumers was larger in the lowest fat intake quartile. Additionally, in the highest SFA intake quartile a larger mean consumption of poultry was found. By contrast, in Finland the lowest SFA intake quartile contained more poultry consumers than the high SFA intake quartile (Valsta, 1999). In Germany and the Netherlands the proportion of consumers of meat products in the overall population was close to 100 %, and the high-fat and high-SFA consumers ate more sausages and meat products compared to the low-fat or low-SFA consumers, respectively (Hermann-Kunz & Thamm, 1999; Löwik, Hulshof & Brussaard, 1999). In Greece, on the other hand, only the proportion of the population consuming pure meat was larger in the high-SFA quartile compared to the low-SFA quartile (Moschandrease & Kafatos, 1999). In the Irish population, those consumers with the fattier diets ate more red meat and sausages than those with a low-fat diet. The Irish pattern was based on a somewhat larger proportion of consumers of red meat and sausages in the high fat intake quartile and, in addition, a larger average portion size for red meat (Flynn & Kearney 1999). In Italy the association between high fat intake and meat consumption was less clear (Turrini, Leclercq & D'Amicis, 1999). These results indicate that like the consumption of dairy products, meat consumption is tied to higher saturated fat and total fat intake in most European countries.

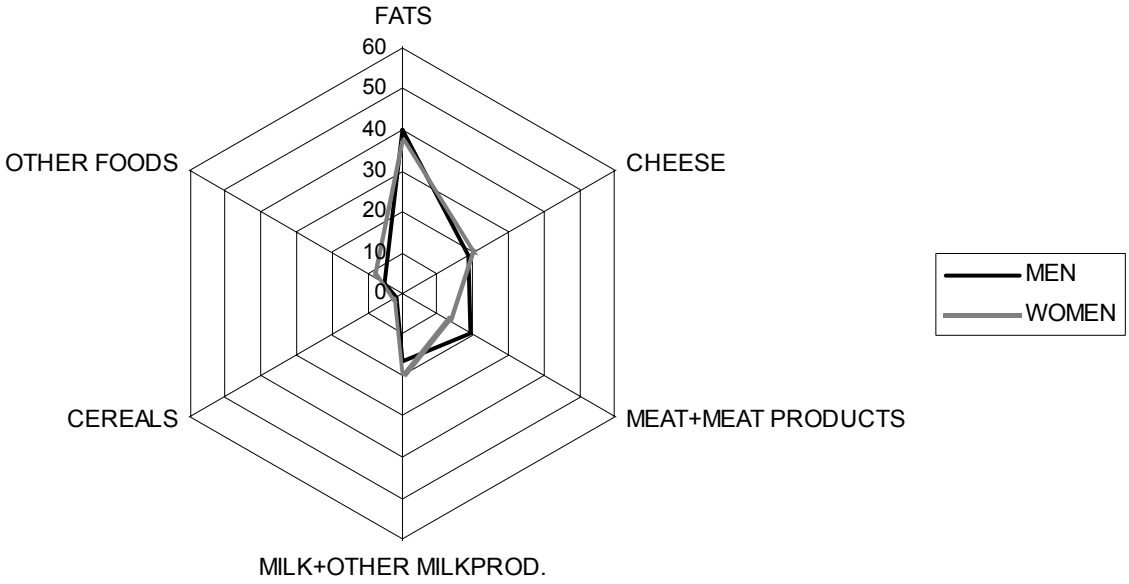

Figure 2a

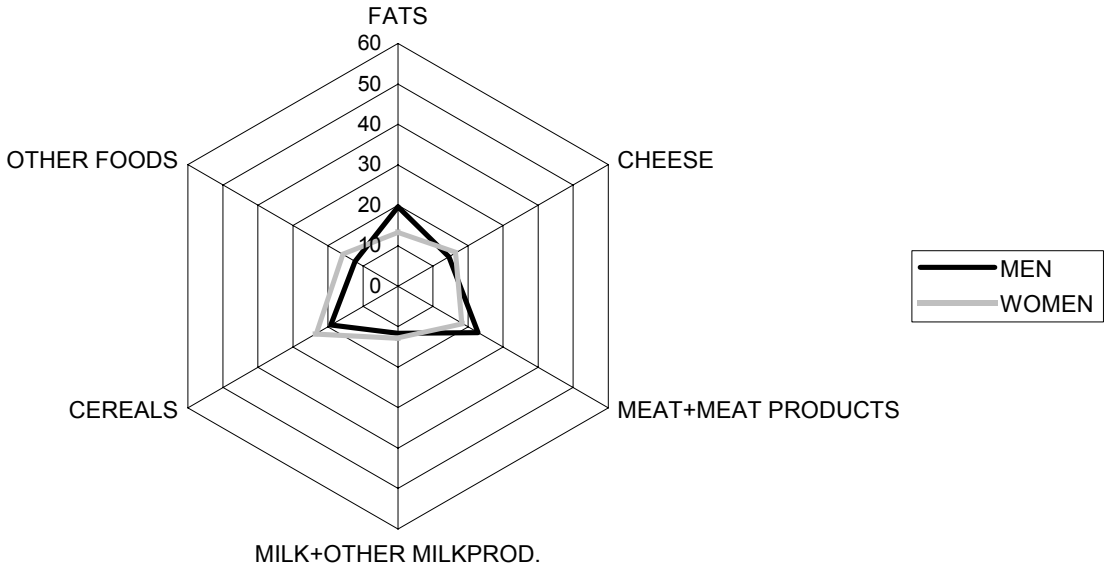

Figure 2 b

Figure 2 a and b. Sources of saturated fatty acids in the Finnish diet, a) at ingredient level, b) in prepared foods, (% of total intake) (Männistö, S., Ovaskainen, M-L. & Valsta, L., 2003).

In addition to the direct contribution of meat and meat products to dietary fatty acid composition, it is also nutritionally important to assess what components of diet are being replaced by growing meat consumption. In a large Swedish study, increasing total meat intake (expressed in quintiles and adjusted for energy, n=11648) was associated with decreasing intakes of poultry, fish, fruit, bread and cereals as well as cheese (Elmstahl, Holmqvist, Gullberg, Johansson and Berglund, 1999). Poultry and fish, bread and cereals are foods that decrease SFA intake when replacing red meat, while fruit decreases mainly the fat content and energy density of the diet when replacing meat.

Fresh meat, meat products and meat dishes as sources of fat and fatty acids

Approximately 60% of the SFAs in the U.S. diet are obtained from meat, poultry, fish and dairy products (Dupont, White & Feldman, 1991). In a more detailed analysis from the late 1980s of the fatty acid consumption pattern of Americans, it was shown that palmitic acid was the predominant SFA in the U.S. diet then, contributing 52-57% of SFA intake (Jonnalagadda, Egan, Himbach, Harris & Kris-Etherton, 1995). Of the SFAs, short chain fatty acids and lauric acid and myristic acid are obtained from dairy products, while the predominant sources of palmitic acid and stearic acid are meat, poultry, fish and blended foods. These same food categories were also the major source of monounsaturated fatty acids, especially oleic acid; among them, beef, pork and chicken meat were the main contributors (Jonnalagadda *et al,* 1995).

Another way of analysing the effect of meat and meat products on fat and fatty acid intake in diet is to compare their share of fatty acid intake at an ingredient level (fresh meat, plain meat products) with their share of fatty acid intake as prepared dishes. In Finland meat and meat products, as consumed, contributed to about one-fourth of the total fat recorded in the National FINDIET 2002 Survey (Männistö, Ovaskainen & Valsta, 2003). This study was carried out using the 48-h dietary recall method and the Finnish National Food Composition Database Fineli® (Ovaskainen, Reinivuo, and Korhonen, 2001) among 25-64-year-old men and women (n=2007). Accordingly, figures 2-4 show that in Finland the food group of fresh meat and meat products as consumed, contributes more saturated, monounsaturated and polyunsaturated fatty acids than do plain meat and meat products. This points to the fact that Finnish meat dishes are frequently prepared with fat-containing ingredients (cream, fat spreads, oils, etc.), which increase the often modest intrinsic fat content of meats.

Ways to modify the contribution of meats to fat intake and quality

Culinary traditions and recipes of meat dishes are an obvious focus if the share of fats from meat dishes and meat products is to be modified or reduced (Papadopoulos, Nowak, Miller, Cross, Savell, Brauchi & Scott, 1992). Fatty ingredients in meat dishes can be reduced in order to increase the nutritional quality of these foods. Methods of supplementation as well have been applied to this purpose in meat product development; for instance, it is possible to increase the proportion of unsaturated fats by processing vegetable oils into the meat product (Hammer, 1991). Manipulation of the fatty acid composition of animal feeds has successfully been used to improve the fatty acid profile of carcass fat in pigs (Morgan, Noble, Cocchi & McCartney, 1992, Vanoeckel & Boucque, 1992). Similarly, dietary fatty acid modification is considered a viable method of adding value to poultry products for the health conscious consumer (Hargis & Vanelswyk, 1993). In addition to both simple and more sophisticated techniques of this kind to modify the fat quality of meat products and meat-containing mixed dishes in order to follow nutritional recommendations, a commonly recommended approach is for consumers to moderate their intake of meat and meat dishes as well as other foods clearly contributing to dietary SFA content. (Dupont, White and Feldman, 1991; Smith-Schneider, Sigman-Grant & Kris-Etherton, 1992).

Conclusion

In conclusion, meat, meat products and meat dishes are sources of valuable, but replaceable, animal protein in the diet. From the point of view of fat content, the drawback of this protein source is that it is tied to a considerable level of saturated fatty acids and cholesterol. In several countries with a very low meat intake, a moderate increase in meat consumption could contribute to a nutritionally better diet. By contrast, in most industrialized countries, high meat intake contributes to a higher than recommended total and saturated fat and cholesterol intake and may replace sources of other important nutrients in the diet. Thus, as a part of a balanced diet in these countries, lean meats and low-fat meat products are preferred, and meat is recommended to be used "sparingly" (Willet, 2001) or at most in moderation today (National Nutrition Council, 1998, USDA 2000, Health Canada 2001).

Introduction

Sodium intake exceeds the nutritional recommendations in several industrialized countries. Excessive intake of sodium has been firmly linked to hypertension (Dahl, 1972; Fries, 1976; Law, Frost & Wald, 1991a,b,c). High blood pressure may in turn increase the risk of stroke and premature death from cardiovascular diseases. Tuomilehto *et al.* (2001) found that high sodium intake correlated with mortality and risk of coronary heart disease, independent of other cardiovascular risk factors, including blood pressure. These results provide direct evidence of the harmful effects of high sodium chloride (NaCl) intake in the adult population. Sofos & Raharjo (1994) have also presented a review on the health aspects of dietary sodium chloride and other salts.

The main source of sodium in diet is sodium chloride. On a population basis, it has been established that the consumption of more than 6 g NaCl/day/person is associated with an age-increase in blood pressure. Therefore, it has been recommended that the total amount of dietary salt will be maintained at about 5-6 g/day (Aho *et al*., 1980, WHO, 1990). Such recommendations are addressed to the general public. It is, however, recognized that genetically salt susceptible individuals and hypertensives will particularly benefit from low-sodium diets, the salt content of which should range between 1 and 3g/day.

Sodium chloride is one of the most frequently used ingredients in meat processing. Sodium chloride affects flavour, texture and shelf life of meat products. Besides the perceived saltiness, the NaCl brings out the characteristics taste of the meat product enhancing the flavour (Gillette, 1985). Sodium chloride also has an important role in the texture of meat products. It improves the water and fat binding properties of meat products resulting in the formation of a desirable gel texture upon cooking (Terrell, 1983). The preservative effect of NaCl is primarily due to its ability to lower water activity (Marsh, 1983; Sofos, 1984)

Most sodium chloride in the diet comes from processed foods. The NaCl contents of processed meat products should be reduced. To control the dietary intake of sodium from these products is difficult because of the different levels of sodium found in the same type of product. For example, in 30 liver sausages from different manufacturers the sodium content varied from 0.5 to 1.0 g/100 g (Greubel, Kluthe & Zuercher, 1997). Because of the large variation in NaCl content of the same type meat products, one easy way for reducing the average sodium intake is to reduce the NaCl content particularly of those products in which NaCl content is higher than the average.

Potential sodium chloride reduction depends on aspects connected with the type of the product, its composition, the type of processing required and the preparation conditions. These factors determine the type of product that can be modified and the technological limitations of salt reduction.

This paper reviews possibilities to reduce the sodium (NaCl) content in meat products. Mainly sensory and technological aspects will be covered.

Sodium intake and recommendations

Total dietary sodium intake in Europe has been estimated to range between 3.5 and 5 g/day (9 to 12 g NaCl) (Intersalt Cooperative Research Group, 1988). Finnish men consume on average 9.9 and women 6.8 g NaCl/d, respectively. The sodium intake from meat dishes is 22% for women and 24% for men (the National FINDIET 2002 Study, 2003).

The UK Department of Health has estimated the UK intake of sodium chloride at 8.2 g/person/day. Others (e.g. Godlee, 1996) refer to 9 g/person/day, calculated from data for urinary excretion of sodium. In populations with high sodium consumption there is usually no difference in sodium intake between normotensive and hypertensive individuals (Liu *et al.*, 1979; Morgan *et al.*, 1978; Schlierf *et al.*, 1980; Swaye, Gifford & Berrettoni, 1972; Tuomilehto, Karppanen, Tanskanen, Tikkanen & Vuori, 1980).

Sources of sodium from meat products

Meat itself contains sodium but the amount is less than 100 mg Na per 100 g. The main source of sodium in meat products is sodium chloride which is added during processing. Sodium chloride contains 39.3% sodium. Sodium is a part of also many other additives added when preparing meat products, e.g. in monosodium glutamate which is a flavour enhancer, sodium phosphates, sodium citrate and sometimes also sodium lactate. The amount of sodium from other additives is, however, much lower compared to the amount of sodium from sodium chloride. Practical experience has shown that when reducing NaCl content, meat industry may start to use sodium lactate to improve the shelf life and perceived saltiness. The amount usually added is 1.2% sodium lactate containing 0.24% Na. This amount of sodium equals to 0.6% NaCl.

The sodium chloride content of Finnish cooked sausages ranges from 1.6 to 2.2%, and that of cooked hams from 1.9 to 2.7%. This is equivalent to 0.6-0.9 g Na/100 g in cooked sausages and to 0.8 – 1.2 g Na/100 g in cooked hams. In other countries, meat products contain more NaCl. The sodium chloride content of meat products has been reduced, e.g. in Finland NaCl content of cooked sausages was in 1973 on average 2.4%, and in 1995 1.7% (Karanko & Puolanne, 1996). In the USA, the sodium content of 100 studied food products was shown to have reduced by 10-15% between 1985 and 1997. (Center for Science and Public Health).

Sodium reduction in meat products

Based on the scientific information, meat industry and consumers have become more aware of the relationship between sodium and hypertension and, therefore, in many countries, the demand for a variety of low salt meat products has increased. Food processors are developing numerous low-salt products to meet the demands of consumers. Developing low-salt meat products is, however, not straightforward. Sodium chloride plays such an important role in meat products. A particular problem with low-salt meat products is that not only the perceived saltiness, but also the intensity of the characteristic flavour decreases, when salt is reduced.

Meat product manufacturers have marketed low-salt alternatives, or have progressively reduced salt content over the years, where technological and microbiological considerations have made this possible. In most cases, when low-salt meat products are developed, the benchmark for the low-salt meat product is the normal-salt product. Consequently, the same quality characteristics must apply to low-salt meat products as to the correspondent normal-salt meat products. This causes problems because the properties of low-salt products are almost always different. The most important difference is the weaker characteristic flavour.

Before a satisfactory seasoning substitute to sodium chloride is found, the best way to reduce the intake of sodium would be for the food industry to gradually reduce the sodium chloride content in products. This demands that the formulations and the manufacture procedures of low-salt meat products must also be modified. Olson (1982) reported that a 25% reduction in NaCl is probably the most that can be achieved

without detrimentally affecting product characteristics (flavour, texture, shelf-life). Of course it is easier to reduce the higher salt contents than the lower salt contents without any detrimental effect. According to Ruusunen, Särkkä-Tirkkonen and Puolanne (1999), the NaCl content of cooked bologna sausages made with added phosphates may be reduced to 1.4% added NaCl without loss of flavour pleasantness. In cooked hams, based on saltiness evaluations it is possible to reduce the salt content of cooked ham to 1.7% NaCl (Ruusunen, Särkkä-Tirkkonen & Puolanne, 2001). The level of NaCl in the diet of a population determines the acceptable level to which NaCl content in meat products can be reduced. Consequently, same NaCl levels do not necessarily apply to every population.

There are several approaches for reducing the sodium content in processed meats: 1) lowering the level of sodium chloride (NaCl) added; 2) replacing all or part of the NaCl with other chloride salts (KCl, $CaCl_2$, and $MgCl_2$); 3) replacing part of the NaCl with non-chloride salts, such as phosphates, or with new processing techniques or process modifications; and 4) combinations of any of the above approaches (Terrell 1983; Sofos 1984, 1986, 1989).

Terrell and Olson (1981), Hand, Terrell and Smith (1982a,b) as well as Puolanne, Saarela and Ruusunen (1988) have studied meat products where NaCl has been substituted with other salts (KCl, $MgCl_2$). Replacement of sodium chloride by potassium chloride or magnesium chloride can lead to bitterness (Terrell and Olson, 1981), though some success has been achieved with a blend of sodium and potassium chloride.

The use of mineral salt mixtures is, however, a good way to reduce the sodium content in meat products. The same perceived saltiness can be achieved with salt mixtures at a lower sodium content (Puolanne *et al.*, 1988; Wettasinghe and Shahidi, 1997). In Finland, there are cooked sausages made with salt mixtures on the market where the salt content based on sodium chloride content is 1.2% or lower. These sausages are allowed to be labelled as low-sodium sausages.

There is, however, a disadvantage when using salt mixtures: the consumers will not get used to weaker perceived saltiness of low-salt meat products when salt mixtures are used, because of characteristic flavour still remains strong.

Perceived saltiness and flavour intensity

The perceived saltiness of NaCl in meat products is mainly due to the Na^+ cation with Cl^- anion modifying the perception (Miller & Barthoshuk 1991). Sodium chloride is also a flavour enhancer increasing the characteristic flavour of meat products (Gillette, 1985; Matulis, McKeith & Brewer, 1994; Ruusunen, Simolin & Puolanne, 2001; Ruusunen, Särkkä-Tirkkonen & Puolanne, 1999). Both the perceived saltiness and the flavour intensity depend on salt content in meat products (Matulis, McKeith, Sutherland & Brewer, 1995, Ruusunen *et al.*, 1999, Crehan, Troy & Buckley, 2000). The authors of this review stress that a certain amount of salt has to be added to food products before it can even be discerned. A small amount of sodium chloride might taste sweet (Beauchamp, Bertino & Moran, 1982) which is not appropriate in meat products. The sweet taste is probably due to stimulation of the receptors that mediate sweet perception rather than to stimulation of receptors mediating sodium chloride perception (Barthoshuk, Murphy & Cleveland, 1978).

Sensitivity may be defined as the ability to detect or recognize gustatory stimuli. Detection and recognition thresholds are extensively used measures of this taste attribute. All thresholds, however, are forms of discrimination relative to a background medium. Thus, the conditions under which a threshold is determined can greatly influence the resulting value. In addition, the sensitivity of individuals varies due to the influence of numerous endogenous and exogenous variables. With respect to the salty taste, one of the most important of these factors is the salivary sodium concentration. The taste receptors are bathed in saliva, and adapt to the sodium level of this fluid. To elicit a salty sensation, this level must be exceeded by a given amount in an individual. The perception of many flavour characteristics depends greatly on the nature of the food matrix. The food matrix plays an important role in controlling flavour release at each step of food product preparation and consumption. (Mattes, 1984, 1997).

Sensitivity to sodium chloride has been the most extensively studied parameter with respect to hypertension. Fallis, Lasagna and Tetreault (1962) were the first group to assess the NaCl detection and recognition thresholds of normotensives and hypertensives (diastolic blood pressure (DBP) >100 mmHg). While no differences in NaCl detection thresholds were observed, the hypertensives displayed elevated recognition thresholds.

Although many people add sodium chloride to enhance the taste of foods, their preference may change because of the pleasantness of NaCl is influenced by customary dietary levels. When someone follows a low-salt diet from a few weeks to a few months, they get used to the mild taste of low-salt products (Bertino, Beauchamp & Engelman, K., 1982; Blais *et al.*, 1986). There are various existing hypothesis about why diets with different salt contents changes one's preference to salt, for instance by changing the sodium content in saliva. An individual's partiality to salt can therefore be changed, but it is not necessarily easy, as a lower salt content in food does not initially meet one's expectations, customs and preferences. People get used to the taste of salty products faster than they do that of low-salt products (Bertino, Beauchamp & Engelman, 1986).

The manner in which sodium chloride is added effects how strong is the perceived saltiness. Sodium chloride has a more concentrated taste if it is sprinkled on a cooked meat instead of on raw meat before cooking. If sodium chloride is sprinkled on a cooked steak, only half as much NaCl to achieve the same level of perceived saltiness will be needed (Ruusunen, 1985).

The effect of fat and lean meat content on perceived saltiness

Fat and sodium chloride together contribute to many of the sensory properties that are characteristic of cooked sausage. When NaCl level rises it is more noticeable in fatty products than in lean ones (Hammer, 1981; Matulis *et al.*, 1994) However, Ruusunen *et al.* (2001) have shown that fat content of cooked sausages affects the perceived saltiness in different ways depending on the composition of the formulation. By replacing lean pork with pork fat, thus increasing the fat content and simultaneously reducing the meat protein content, perceived saltiness of sausages increases, but by replacing water with fat on an equal weight basis, the perceived saltiness of the sausage does not change. Therefore, the increase of meat protein content was supposed to reduce perceived saltiness. This result was confirmed with meat patties. More salt was needed in meat patties with high lean meat content to achieve the same perceived saltiness than in products with lower meat content (Ruusunen *et al.*, 2003, 2004). In meat patties, fat content had a smaller effect on perceived saltiness than lean meat content and their effects on perceived saltiness were opposite. It is also well-known that perceived saltiness is high in products with high amounts of loose water.

The theory of water-binding

Hamm (1972) and Offer and Knight (1988) have published comprehensive reviews about the technological effects of salts in meat. The above mentioned reviews concentrate on sodium chloride and phosphates, but other chloride salts and salts of weak acids are discussed, mainly to further elucidate the theories behind the effects of sodium chloride and phosphates. The reviews deal mostly with uncooked meat, and not so much with cooked meat or cooked meat products. Tornberg (2004) has recently presented a review on heat-treated meat products. The present chapter deals with effects of the lowering of the sodium content on the technological properties of meat products. Whiting (1988) also presented a review on solute-protein interactions in meat batter.

The effect of sodium chloride on meat proteins is most probable caused by the fact that chloride ion is more strongly bound to the proteins than sodium ion. This causes an increase in negative charges of proteins. Hamm (1972) concludes that this causes repulsion between the myofibrillar proteins (myofilaments), which results in a swelling of myofibrils or even a partial solubilisation of filaments, the latter is due to the repulsions of individual molecules. The cross-bridges between the filaments prohibit the unlimited swelling of the myofbrils. Polar groups of the side chains of the amino acids (ca. 76-80%) of the proteins bind water molecules on their surfaces by van der Waals' forces. The water molecules, being polar, then orient

themselves so that in a case of a negative ionic group there will be the positive part towards ionic group and the negative part pointing at the solution, and vice versa with positive groups. Additional water molecule layers will be formed on this so-called monomolecular layer with similar orientations. Thus, all the water molecules are more or less influenced by the pulling forces caused by the polar groups of the proteins. On the contrary, non-polar side chains of the amino acids push the polar water molecules causing arched-like structure around the non-polar group. The combined effect is that water molecules are pulled (polar groups) and pushed (non-polar groups) between the filaments creating a tension that forces the water molecules in an ice-like form in the protein network of filaments and transverse elements, like cross-bridges and Z-line. The factors inhibiting the unlimited swelling are the actomyosin cross-bridges between the filaments and Z-lines. The amount of the water bound is determined by the net charge of the proteins causing repulsion that increase the binding, and by the number and strength of cross-bridges that limit the binding.

This sounds reasonable, because the distances between the filaments surfaces are about 20 nm (actin to myosin and actin to actin) or 30 nm (myosin to myosin). This means a thickness of a layer of about 60 to 90 water molecules. The hypothesis explains the effects of salt content and pH, as well as the role of cross-bridges and consequently how water is retained in meat. However, the hypothesis does not take the effect of counter-ions, eg. the sodium ions, into account. Offer and Knight (1988) also claim that the distances between the filaments are too long to establish a repulsive force that would be strong enough to generate the water-binding.

Offer and Knight (1988) suggest an alternative hypothesis also based on the selective binding of chloride ions to the myofibrillar proteins. According to them this does not cause a marked repulsion between the filaments but between the molecules of myosin filaments breaking down the shaft of the filament. This will cause a loosening of myofibrillar lattice. If phosphate is not used, the S1 units of heavy meromyosin are still attached to actin filaments. Offer and Knight postulate that the swelling occurs by an entropic mechanism driven by the free, light meromyosin parts bound to actin filaments.

Offer and Knight (1988) also present another aspect that is close to the hypothesis of Hamm (1972). They start with the same selective binding of chloride ions as Hamm, but because the structural proteins are solid in meat and cannot move, electrical forces pull the counter-ions (sodium ions) very close to the filament surfaces thus creating an uneven distribution of ions in the water phase. This establishes an osmosis-like force within the filament lattice which in turn pulls water molecules into the system. This would cause an unlimited swelling, but the cross-bridges cause an opposite force that Offer and Knight call ‘elastic pressure’. In any case, osmotic pressure created by the uneven distribution of ions and the elastic pressure are equal at any moment. This explains the effects of salt content, cross-bridges, pH and the denaturation effects and resulting shortening of myosin S1–S2 complex as well.

The effects of NaCl on different proteins in meat are very complex, and the complexity increases if different concentration combinations of added NaCl, KCl and phosphates are acting simultaneously (see reviews of Hamm 1972 and Offer and Knight 1988). Conciselly, the solubility of myosin is increased as the NaCl concentration raises from 0.04 to 0.5 M. After the initial aggregation and formation of filaments the structures start to dissociate at salt contents higher than 0.25 M. The swelling of myofibrils starts at 0.5 M without added phosphates and at 0.4 M with added phosphates, where an extensive extraction of myosin also starts to take place.

The swelling depends on pH (Hamm, review 1972; Offer & Knight, review 1988). Without salt there is a maximum at pH 3.0, a minimum (the average isoelectric point of meat proteins) at pH 5.0 and from there a constant increase within the physiological pH range. Due to the selective binding of ions, salts move the isoelectric point. By 2% NaCl the isoelectric point and swelling minimum are at pH 4.0. (Hamm, review 1972). Wilding, Hedges & Lillford (1986) found that hypertonic salt solutions (KCl and KI) induce fibre shrinkage at pHs below the isoelectric point of myofibrillar proteins (pH 5.0), which actually means that the isoelectric point has moved to lower values. With NaCl there is a maximum in swelling as well as in heated gel strength at 6.0 (Hamm, review 1972; Ishioroshi, Samejima & Yasui, 1979) or at pH 6.2 (Puolanne, Ruusunen and Vainionpää, 2001). This seems to be due to the increased sodium ion binding to the negatively charged myofilaments, and the simultaneous weakening of the binding of chloride ions.

Minced meat and restructured products

Minced meat products and restructured meat products are made without or with added phosphates. There is a wide variety of meat products from all meat products made of lower quality of meat, fat, carbohydrates and other polymers, added proteins and added water. There is no particular technological minimum for sodium chloride content; meat patties can be made even without added sodium chloride (Booren, Jones, Mandigo & Olsen, 1981) by pressuring frozen meat to form the patty, or freezing the product after the formulation (Demos, Forrest, Grant, Judge & Chen, 1994). In these products, sodium chloride content, if used, is mainly determined by sensory aspects. Transglutaminase has also been used to increase the gel formation in patties thus increasing the yield (Nielsen, Petersen & Møller, 1995; Tseng, Liu & Chen, 2000).

Schults, Russel and Wierbicki (1972), Schults and Wierbicki (1973) and Kenney and Hunt (1990) found, using centrifuge methods with added phosphate, a steep initial reduction of cooking loss when the salt content increased from 0 to 1%, and the best bind was at 4% NaCl. On the contrary, in sausages a marked difference between phosphate and non-phosphate systems has been found between 1.0–1.5% NaCl (e.g. Puolanne & Ruusunen, 1980; Barbut, Maurer & Lindsay, 1988). Barbut & Mittal (1989) also found that there are differences between the proteins of beef, pork and poultry meat in gelation patterns and responses to salt.

Sodium chloride is, however, important decreasing the cooking loss and improving the texture. Sodium chloride increases the cohesiveness of the batter thus improving the moisture and fat retention. Schwartz & Mandigo (1976) studied several combinations of 0–2.5% NaCl and 0–0.5% sodium tripolyphosphate in restructured pork and found that salt increased TBA values, packaging loss, improved cooked colour, aroma, flavour and eating texture. Among the variables 0.75% NaCl and 0.125% sodium tripolyphosphate were needed when producing restructured pork. Matlock, Terrell, Savell, Rhee Dutson (1984a, b) found that phosphate improved scores of saltiness, juiciness, binding, and cooking yields, but they reported decreased rancidicy due to sodium tripolyphosphate. NaCl alone increased rancidity (Matlock *et al.* (1984b). With phosphate a 15% reduction in sodium content can be achieved (Matlock *et al.* (1984a). According to Ruusunen *et al.* (2004), the increase in NaCl content causes a marked decrease in cooking loss, but the effect on increasing the firmness is less pronounced. Phosphates improve the firmness; the same firmness can be reached in meat balls by ca. 40%, using basic potassium phosphate, less sodium than without phosphates (Ruusunen *et al.*, 2004). Also other ingredients such as soy protein, caseinate, gums etc. can be used to improve the technological properties of the patties, they do not necessarily affect the meat but the entire mixture.

In conclusion, decreasing the sodium content in minced meat products is not a major technological problem. NaCl increases, however, the bind, firmness, cooked yield and taste. The sensory effects such as perceived saltiness can be affected also by other components of the meal, and spices. The NaCl content in the products varies usually from 0% to about 2%. The level for most minced meat products could, however, be below 1.0%. It is also recommendable at homes and in catering to add the salt on plate just before eating in order to obtain the same perceived saltiness by much lower amounts of salt.

Cooked sausages

Sodium chloride increases the water-binding in meat linearly between ionic strengths of 0 to 0.8–1.0 in the water phase (Hamm 1972; Offer and Knight 1988). This corresponds to less than 5% NaCl in lean meat, provided that the water content is about 75%. Part of the water is tightly bound to the monomolecular layer (4 percentage points) and multimolecular layer (4–6 percentage points), which means that this water does not have the physical characteristics of free water and consequently solves less solutes. Therefore, it can be estimated that the ionic strength of salt must be calculated for 65g water in 100g lean meat. This must be taken into account when comparing the water-binding curves; e.g Offer and Trinick (1983).

Added polyphosphates cleave the actomyosin bond thus weakening the myofibrillar structure. The amount of cross-bridges per unit volume will decrease, which according to Hamm (1972) and Offer and Knight (1988) leads to an increased water-binding capacity. With added phosphates the water-binding curve is not

linear in relation to NaCl content. At low contents, up to 1.0% NaCl there is a linear relationship, but then water-binding increases considerably until levelling slowly off at 1.5% (Puolanne and Ruusunen, 1980). This means that a sausage of normal gel-forming capacity can be made with about 0.3–0.5% lower sodium chloride content when phosphates are used, compared with a sausage made without added phosphates. Offer and Trinick (1983) showed in a model study with isolated myofibrils that marked changes in myofibrillar structure take place at the ionic strengths of 0.3–0.4. This means 17.6–23.4 g NaCl/l, and in a sausage with 60% moisture (tightly bound water ca. 5 percentage points) and 20% fat a content the upper limit is 12.9 g NaCl/kg. It should be stressed, however, that although good water-binding can be obtained with this sodium chloride content in raw sausage batter, it does not necessarily form a heat stable gel. Practical experience suggests that about 15 g NaCl/kg is needed.

Another aspect to be considered in cooked sausages is the fat content. If both salt content and fat content are reduced simultaneously (low fat – low sodium product), some problems may arise. If the fat content of the above mentioned sausage is reduced by 30% (from 200 to 140 g fat/kg) and replaced with water, 14.3 g NaCl/ kg is now needed for an ionic strength of 0.4; i.e. the simultaneous reductions of both constituents are not easily achieved. However, compared to the present situation worldwide, an average NaCl content of 1.6–1.8% in cooked sausages would mean a reduction.

Sofos (1983) manufactured frankfurters with 2.5%, 2%, 1.5% and 1% NaCl. A reduction in salt content more than 20% (<2.0% NaCl) resulted in frankfurters of softer and less firm texture. Sofos (1985) was able to compensate the reducing of NaCl by adding sorbate, which is usually added for antimicrobial reasons. Hand, Hollingsworth, Calkins & Mandigo (1987) reduced simultaneously fat content and salt content in frankfurters (without phosphate). Low fat frankfurters with 1.5% NaCl had softer consistency that those containing 2.0 or 2.5% NaCl. They concluded, however, that modifications of the formulation, low fat – low salt frankfurters can be manufactured. Crehan *et al.*, (2000) stated that the high hydrostatic pressure processing can be used to improve the stability of frankfurters with reduced NaCl content (from 2.5 to 1.5%), but cook yield was not affected.

Whiting (1984a) concluded that when salt content is reduced (from 2.5% to 1.5%, without phosphate), water exudates will be affected first, then gel strength, but fat release will not occur until more extreme conditions will be encountered. Whiting (1984b) compensated the reduction of water-binding and gel strength with phosphates, the effect of which was virtually independent of the pH differences the individual phosphates. Puolanne *et al.* (2001) studied the combined effects of sodium chloride, pH and use of phosphates on the water-binding (related to gel strength) of meat using model sausages. Differences in pH were reached by selecting raw meats with different pH, and no adjustments of pH were made. It was clearly seen that the same water binding can be obtained by different combinations, pH being an important variable. In some countries acid phosphates are used for better keeping quality, but this may cause problems in gel strength especially if low-salt sausages are aimed at.

Another strategy is to utilise low-sodium salt mixtures. There are many commercial mixtures, and they usually contain potassium chloride. Hand, Terrell & smith concluded that NaCl (2.8%) can be replaced with 35% KCl (by ionic basis) but not with $MgCl_2$ without detrimental effects on shrinkage. This can be expected due to the high salt levels, but technological difficulties might have been expected if the reference salt content would have been markedly lower. We have studied (Puolanne, Saarela & Ruusunen, 1988) a commercial mixture (Pan-Salt®) that contains 58% NaCl, 27% KCl, 12% $MgCl_2$ or $MgSO_4$. In our study it was shown that the sodium intake can be reduced in sausages without added phosphates by 31–37% thus obtaining the same water-binding. Mg^{2+} ions form an insoluble salt with added phosphates, and therefore this salt mixture is more suitable for sausages without added phosphates. The study showed the effects of different anions and cations as could be expected from the lyotrophic series of ionic binding as given by Hamm (1972) and Offer and Knight (1988). The use of KCl in salt mixtures also gives an additional benefit due to the fact that potassium is a counter-ion to sodium and reduces the harmful effect of sodium on blood pressure.

Finally, the water-binding and heat stability of cooked sausage can be improved by potato starch, soy protein products, gums, caseinate, added meat protein (mainly collagen), pig skin etc. gel-forming ingredients (e.g.

Whiting, 1984b). Depending on the national quality policy this also offers a way of reducing the salt content.
The use of pre-rigor curing can replace the use of phosphates. Chloride ions increase the net charge of the myofibrillar proteins preventing the formation of actomyosin bonds. Jolley, Honikel & Hamm (1981) studied the pre-rigor curing effect and found a curvilinear relationship between NaCl and water-binding in uncooked homogenates with a good binding already at 1.3% NaCl. With cooked homogenates the relationship was linear, and they found that 1.7% NaCl would give the binding similar to the normal 2% in rigor meat homogenates. Puolanne & Terrell (1983 a, b), achieved the pre-rigor effect in experimental cooked sausages with a 1.5% NaCl, but they found that the effect is curvilinear, similar to the water-binding curve in sausages with added phosphate. It should also be mentioned that the formation of an excellent raw sausage batter with 1.0% NaCl can be obtained by using pre-rigor meat, but at least 1.5% NaCl is needed for the heat stability of the gel, similar to rigor meat and added phosphate (Puolanne & Ruusunen, 1980; Puolanne & Terrell, 1983a,b). Similarly Bernthal, Booren & Gray (1981) found that 2% NaCl resulted in a good water-binding in pre-rigor meat, but 1% was not markedly better than 0 or 0.5%. The use of phosphate with pre-rigor meat does not give a marked additional benefit (Puolanne & Turkki, 1983).

It can be concluded that without phosphate the NaCl content can be lowered to 1.5–1.7% and with phosphate to 1.4% without jeopardising the technological quality and yield.

Hams

The connective tissue membranes and cell membrane prevent the free movements of ions in muscular tissue. The diffusion of salts is very slow in meat; it is more the question of days for salt to diffuse than hours (Vestergaard, Risum & Adler-Nissen, 2004; Ockerman *et al.*, 2004). Offer and Knight (1988) mention the "tiger stripe" -type appearance caused by uneven distribution of brine just after the injections. The diffusion is normally accelerated by brine curing and subsequent tumbling for several hours.

Hamm (1981) and Offer and Knight (1988) pointed out that whole meat and a piece of meat behave in a different manner than chopped meat. In chopped meat the connective tissue is to a large extent disrupted and fibres and myofibrils are broken. Puolanne (1999) has calculated that during the normal chopping of cooked sausage batter the cutter knife smashes on average every point of the sausage batter at least once. Hence salt, water and phosphates are able to directly attach the filaments in every part of the batter. In addition, Offer and Knight (1988) concluded that the endomysial connective tissue acts as a mechanical restraint to swelling. They also stated that if myofibrils are exposed to large excess of salt solution, especially in the presence of polyphosphates, myosin molecules formed by depolymerisation of the thick filament will tend to be extracted, and this will not result in swelling. Wilding *et al.* (1986) also claim that endomysial sheath acts as a restraint to myofibrillar swelling.

Grabowska and Hamm (1979) stated that when using 2% NaCl and a meat:water ratio 1:1.5 about 20 % of the myofibrillar proteins are dissolved, and with the addition of 0.3% diphosphate the solubility is 35%. In larger meat pieces such as hams, this brine addition is impossible in practical terms. It can be concluded that in large meat pieces there will be a swelling of the myofibrils in situ. Thus, not only the swelling itself but also the heat stability of the system is a critical factor in determining the yield and juiciness.

In addition, meat contains triphosphatase and diphosphatase, which break down polyphosphates to ortophosphates at rates depending on pH and temperature. Therefore, the effects of phosphates in larger meat pieces are subjected to variation due to the rate of phosphate diffusion and consequently the state of phosphate hydrolysis; in chopped sausages there is not such an variation, and the contact with salt, water and phosphates as added, and myofibrillar proteins is almost instant. With laboratory tests we have, however, found that also in chopped sausage batters about one hour is needed for the salt, phosphate and water to have the maximal effects on the heat stability, which can be speculated to be due to the diffusion in the myofibrillar level (Unpublished observations).

Salt mixtures can be used in hams too, although their sensory characterisitics are more sensitive than those of sausages. Frye, Hand, Calkins & Mandigo (1986) replaced 50% NaCl (2%) with KCl (by ionic basis) in

hams, and concluded that hams with 2% NaCl had the best sensory scores, but a 50% replacement with KCl gave the best bind and acceptable sensory scores. Lin, Mittal & Barbut (1991) were able to obtain the best water-binding and cooked yield by replacing 15–18% NaCl (2%) with KCl in coarsely ground ham product.

As a conclusion, the recommendations given for hams should be about 0.3% higher than for cooked sausages, due to the lower fat content.

Fermented meat products

Salt, nitrite, pH and temperature control the fermentation as well as the safety and the quality of dry fermented meat products (Leistner, Herzog & Wirth, 1971). They are all inter-related, and if one of these factors is reduced it should be compensated with an increase of one or more of the other factors to keep the same safety and technological quality. Salt is such an essential constituent of dry fermented products that there are not so many studies on its reduction.

Petäjä, Kukkonen & Puolanne (1985) concluded that 2.5% NaCl is the lower limit for a good quality salami-type fermented sausage, but with 2.25% the sausages are less firm and the typical aroma is weaker and the yield lower than with higher salt contents. Also Stahnke (1995) found that a low NaCl content favours pH decrease. Cimeno, Astiasarán & Bello (1998, 1999, 2001) replaced NaCl with potassium, magnesium and calcium ascorbates and were able to reduce the NaCl content by about 50%. The only relevant difference was the lower consistency which is to be expected when the chloride ions are replaced with ascorbate ions that do not effectively react with myofilaments.

Peltonen (2003) studied the combined effects of sodium chloride and pH on the water-binding capacity of meat. The minimum water-binding was at pH 4.6–4.7, and the maximum ionic strength was at about 1.0 (Figure 1.). At high ionic strengths, however, there is no water-binding minimum at the range of pH 5.7–4.4. When the drying period starts, the water binding is high (pH 5.6 and ionic strength ca. 0.8-1.0 in the water phase), but starts to decrease with the decrease of pH and increase of ionic strength. This initial phase favours particle cohesion, and later on the decrease of water-binding favours the evaporation of water and thus the drying.

Recently, Olesen, Meyer & Stahnke (2004) found that NaCl (1.5 and 3.0%) had a strong effect on contents of volatile compounds in fermented sausage, and the effect was influenced by the ripening time. The relevance of the findings was not tested by sensory tests.

In dry fermented products a simple reduction cannot be made, because the low water activity has to be reached in order to control the microbial flora. Consequently the technological and microbiological as well as sensory characterics of the supplements compared to NaCl will decide to what extent NaCl can be replaced. Bitterness seems to be the most relevant sensory trait (Gou, Guerrero, Gelabert & Arnau (1995), but effects on microbial flora should not be forgotten.

It can be concluded that the regulation of the fermentation is the decisive factor in fermented sausages. This will limit the lowering to the level >2.0% NaCl.

Concluding remarks

In most countries and in most cases, sodium contents of meat products can be lowered markedly. High fat content, non-meat ingredients, pressure treatment etc. may allow even lower NaCl values for different products than mentioned in the text above. Perceived saltiness and overall acceptability of the low-salt products may, however, weaken. Particularly important is that increased meat protein content reduces perceived saltiness. The sodium content in consumers normal diet must also be taken into account; have they used to high or low salt content in their diet. This means that the values given above must always be tested product by product, by consumer segment and by nationality. Shelf life will also be affected when

lowering the salt content of meat products. By using salt mixtures the intake of sodium (NaCl) can be markedly reduced.

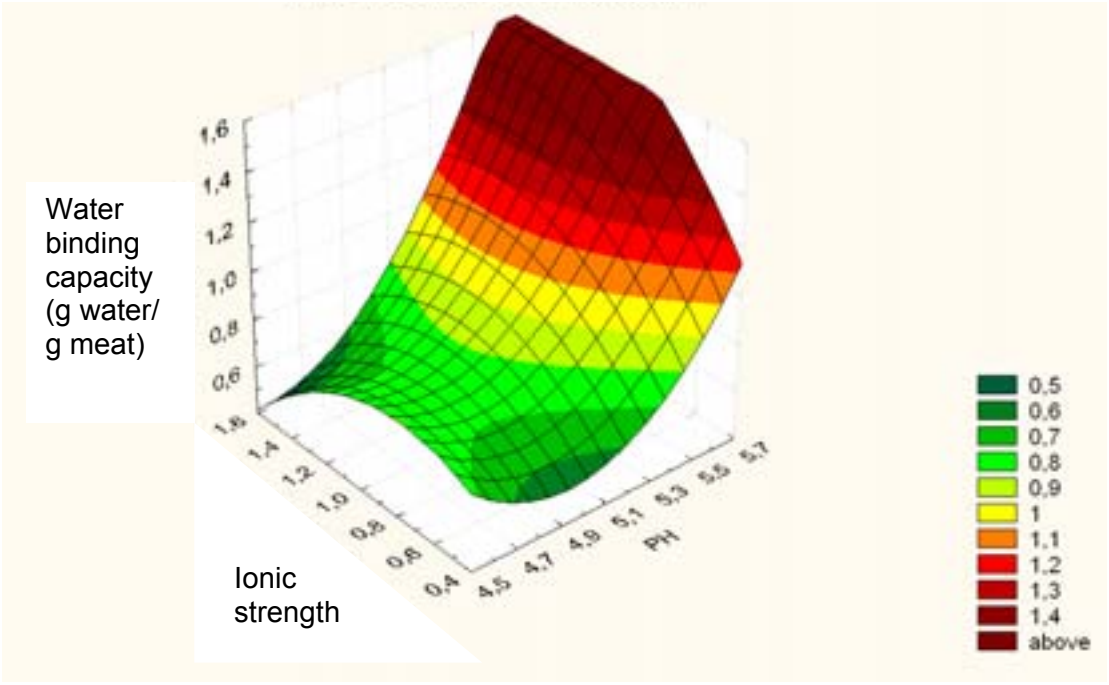

Figure 1. The effects of pH and ionic strength on the water-binding capacity of meat. (Peltonen, 2003)

Background

Pasture diets have sustained lower live weight gains relative to those achieved with high-concentrate diets, and the cattle finished at pasture have produced carcasses with a low fat content (Steen & Kilpatrick, 1998). But pasture-finished cattle may produce beef with a more desirable fatty acid (FA) composition in terms of its beneficial effect on human health (Kinsella, 1988), especially in relation to the content of *n-3* polyunsaturated fatty acids (PUFA) (French et al., 2000; Steen *et al*., 2003; Varela *et al*., 2004). On the other hand, breed can also affect muscle fat quality, where FA variations are mostly related to intramuscular fat levels and consequently to neutral and polar lipids ratios (Scollan *et al*., 2001).

Objectives

The purpose of the present work was to study the effect of breed and feeding system on intramuscular fat and total fatty acid contents of *Longissimus thoracis* muscle in beef cattle.

Materials and methods

Animal management

Eight yearling bulls from "Asturiana de los Valles" (AV) (beef breed adapted to extensive production systems) and eight yearling bulls from "Asturiana de la Montaña" (AM) (small to medium-sized hardy animals, adapted to mountain systems) were studied. Four AV and 4 AM animals were reared under extensive conditions on ryegrass and clover pastures and received a finishing diet during the last 60 days composed of concentrate meal (84% barley meal, 10% soya meal, 3% fat, 3% minerals, vitamins and oligoelements) and barley straw *ad libitum*. The other eight animals (4 AV and 4 AM) were managed under intensive system (concentrate meal, same composition) and barley straw *ad libitum* in the housing facilities of the Institute (S.E.R.I.D.A.). Animals were slaughtered with an average weight of 554 kg for intensively reared AV and 504 kg for extensively reared AV animals, and 463 kg for intensively reared AM and 461 kg for extensively reared AM animals. Slaughtering was performed in a commercial abattoir according to a routine procedure, and after dressing the carcasses were chilled at 3ºC for 24h.

Measurements

Twenty four hours *post-slaughter* the left half carcass was quartered and the part of the rib joint comprised between the 6th and 9th ribs extracted and transported to the laboratory. The 6th rib was excised and *Longissimus thoracis* (LT) muscle was separated, aged at 4ºC for 7 days and then minced with an electrical chopper, vacuum packed and kept at –20ºC until determination of intramuscular fat content by near infrared spectroscopy (Oliván *et al*., 2002). The LT of the 8th rib was extracted, vacuum packed and frozen at –80ºC for subsequent FA composition analysis by gas chromatography (GC).

Total fatty acid analysis

The FAs were extracted in 5M KOH in methanol/water (50:50) at 60ºC for 1 hour and esterified at 40ºC during 10 min with 2M trimethylsilyl-diazomethane in *n*-hexane according to Elmore *et al*. (1999) with some modifications. Separation of fatty acid methyl esters (FAMEs) was performed on a Varian CX3400 GC with a flame ionisation detector (FID) and a split/splitless injection port (50:1). GC analysis was performed using a B-PX 70 for FAME column (120m x 0.25mm i.d., 0.2µm film thickness) with programmed oven

temperature. Injector and detector ports were set at 270°C and 300°C, respectively. The carrier gas was hydrogen and the flow rate 1.6 ml/min measured at the initial temperature. Esterified FAs were identified according to similar peak retention times using standards and quantified according to internal standard method ($C_{23:0}$ methyl ester) added prior to saponification.

Statistical analysis

The statistical analysis was conducted using the SPSS11.5 program (2002). Principal component analysis was applied to explain, with a limited number of factors, the variation produced by breed type and feeding system on intramuscular fat level and on total fatty acid composition.

Results and discussion

The biplot (Figure 1) represents the first two principal components, which explained 72.8% of the variation observed on intramuscular fat level and fatty acid composition (individuals, groups and ratios). The first principal component (PC1) explained 55.6% of the variation observed, whilst the second principal component (PC2) explained an additional 17.2%.

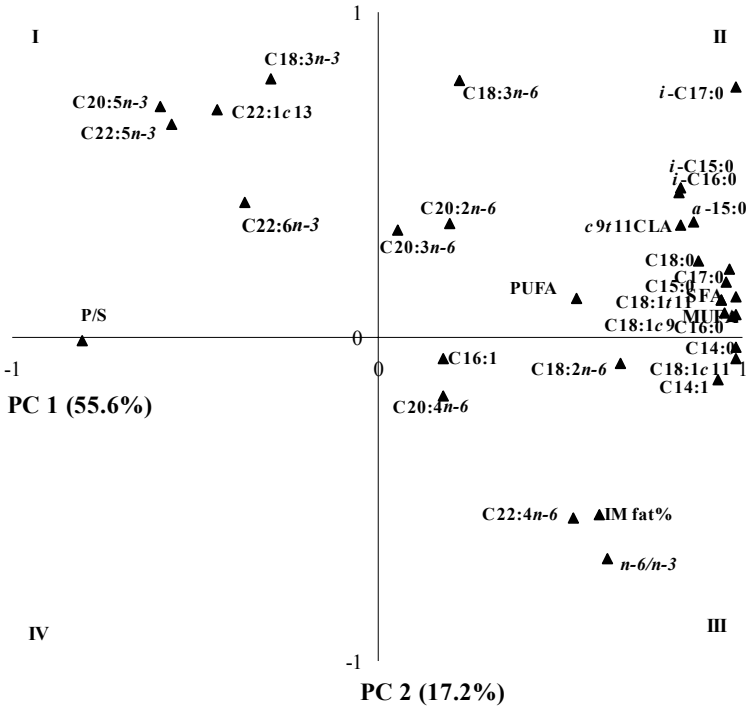

Figure 1. Biplot representation of principal components (PC1 & PC2) of different variables studied on the *Longissimus thoracis* muscle**.**

IM fat %: intramuscular fat percentage; *c*9,*t*11 CLA: *c*9,*t*11 C18:2; ∑SFA = C14:0 + C15:0 + C16:0 + C17:0 + C18:0; ∑MUFA = C14:1*c*9 + C16:1*c*9 + C17:1*c*10 + C18:1*t*11 + C18:1*c*9 + C18:1*c*11 + C22:1*c*13; ∑PUFA = C18:2*n-6* + C18:3*n-6* + C20:2*n-6* + C20:3*n-6* + C20:4*n-6* + C22:4*n-6* + C18:3*n-3* + C20:5*n-3* + C22:5*n-3* + C22:6*n-3* + *c*9*t*11 CLA*; n-6/n-3* = (C18:2*n-6* + C18:3*n-6* + C20:2*n-6* + C20:3*n-6* + C20:4*n-6* + C22:4*n-6*) / (C18:3*n-3* + C20:5*n-3* + C22:5*n-3* + C22:6*n-3*); P/S = ∑PUFA / ∑SFA.

The first principal component (PC1) was positively related to saturated, branched and monounsaturated FAs, and *c*9,*t*11 CLA contents. In consequence, it was also positively related to groups of aforementioned FAs (SFA & MUFA). In a lower degree, intramuscular fat level (IM fat %), PUFAs group and *n-6/n-3* ratio were also positively related to PC1. On the other hand, P/S ratio was negatively related to this principal component.

The second principal component (PC2), in general, was positively related to *n-3* FAs (in a low degree to $C_{22:6}$*n-3*) and *i*-$C_{17:0}$. However, it was negatively related to intramuscular fat level (IM fat %), *n-6/n-3* ratio and $C_{22:4}$*n-6*.

Figure 2 represents the projection of principal components (PC1 & PC2) for meat samples studied where meat samples were identified with feeding system and breed type labels. From these preliminary results it can be observed that feeding system was the most remarkable effect. In general, as there were some exceptions, extensively reared AV and AM breeds were separated from intensively reared AV and AM breeds. Both breeds (AV & AM) showed a similar behaviour from fat quantity and quality point of view when animals fed pasture. However, it is important to note that variability was higher in intensively fed animals in comparison to extensively fed ones. So taking into account the difficulty of the data interpretation, PC1 seemed to be negatively related to extensively reared animals and positively to intensively reared animals. And consequently, pasture fed animals could be related to *n-3* FAs and P/S ratio. This association between extensive system and *n-3* FAs was also seen by Steen et al. (2003) in pastured animals from crosses of the continental beef breeds and Varela et al. (2004) in extensively reared Rubia Gallega breed. On the other hand, animals fed with concentrate were related to PC1, and therefore, to SFAs, branched FAs, MUFAs, PUFAs (particularly *n-6* FAs), *c*9,*t*11 CLA, *n-6/n-3* and IM fat. Intensively fed animals of the rustic breed (AM), which basically laid in quadrant III, could be related to IM fat (%) and *n-6/n-3* ratio. In general feeding system effect seemed to be more clear in AM breed than in AV breed, as in the last one, when animals were fed with concentrate, high dispersion of the data was observed. On the other hand, the differentiation between both breeds was difficult on each feeding regime, and animals from both breeds appeared mixed in both feeding systems, concentrate and pasture.

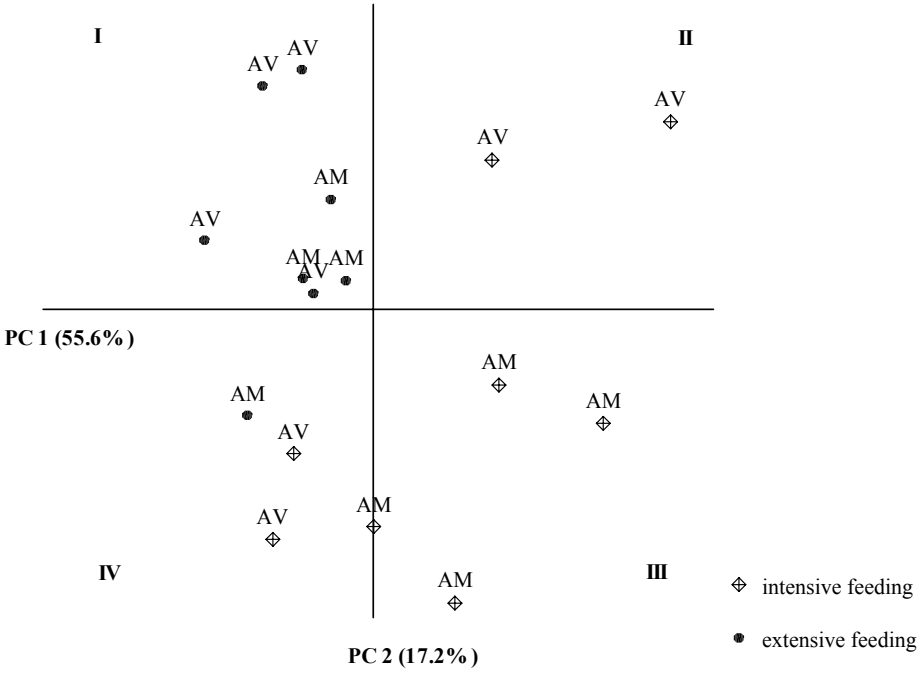

Figure 2. Projection of principal components (PC1 & PC2) of meat samples studied. AV: Asturiana de los Valles; AM: Asturiana de la Montaña.

Conclusions

These preliminary results from few animals are indicating that feeding system effect was more pronounced than breed type effect on intramuscular fat quality. Extensively produced meat showed a low fat content, high *n-3* PUFAs content and high P/S ratio, where pasture fed AV animals produced meat was the best adapted to human nutritional requirements. Breed effect was not significant in intensively, nor in extensively, reared animals.

Background

The conjugated linoleic acids (CLA), a group of positional and geometric octadecadienoic isomers with conjugated double bonds, are produced either in the rumen by the activity of microbial enzymes on polyunsaturated fatty acids (linoleic acid, 18:2 and linolenic acid, 18:3) or by endogenous desaturation (via delta-9 desaturase) of rumen derived octadecenoate isomers. Recent research has focused on the nutritional role of the CLA isomers because of their health benefits. These effects include potential anticarcinogenic, antiatherosclerotic and immune-modulating properties (Prates and Mateus, 2002; Demirel *et al*., 2004). Rumenic acid (*cis*-9,*trans*-11 CLA) has been associated with anticarcinogenic effects, while *trans*-10,*cis*-12 CLA isomer possesses an important role in the lipid metabolism (Fritsche and Fritsche, 1998). Meats from national demarcated regions with Protected Designation of Origin (PDO) are traditional meats (extensive production systems) produced in a delimited region whose quality is essentially due to the geographic environment. Furthermore, these PDO meats have supposedly unique characteristics, mainly in lipid fraction, linked to the local production systems and animal breeds.

Objectives

The aim of this study was to characterise the total CLA contents and CLA isomeric profiles of Portuguese traditional Arouquesa-PDO and Barrosã-PDO veal, both obtained from autochthonous calves fed extensively during summer (with the least abundant green pastures) and slaughtered in early autumn (October).

Materials and methods

Arouquesa-PDO and Barrosã-PDO veal were obtained from Arouquesa (7-8 months of age, 230 ± 28 kg live weight) and Barrosã (8-9 months of age, 192 ± 35 kg live weight) breed calves, produced in the north of Portugal (Fig. 1). The calves were reared on a traditional production pasture-based system according to the rules established in the product specifications. Muscles samples were collected from the ribeye (T1-T3 *longissimus thoracis* muscle, LT) and loin (L4-L6 *longissimus lumborum* muscle, LL) portions of *longissimus dorsi* muscle and from the distal region of *semitendinosus* muscle (ST) 2-3 days after slaughter (+1 °C). All muscle samples were ground using a food processor (3 × 5 s), vacuum packed and stored at -80 °C until analysed.

Total lipids were extracted from meat (dry matter) by ultrasonication, using methylene-chloride (4:1 v/v) (3×) and *n*-hexane (1×), as was previously described in Fritsche *et al.* (2000). Lipid contents of the test samples were calculated, in duplicate, by weighing the residues obtained after solvent evaporation under a stream of nitrogen. Methyl ester solutions of fatty acids were obtained by alkaline transesterification with sodium methoxide.

The methyl esters of CLA isomers were individually separated and quantified by triple column silver-ion (ChromSpher 5 Lipids, 4.6 mm ID × 250 mm, 5 µm particle size, Chrompack, Bridgewater, NJ, USA), using an HPLC system (HP 1100 Series, Hewlett-Packard, Palo Alto, CA, USA) equipped with autosampler and diode array detector adjusted at 233 nm, with a solvent (0.1 % acetonitrile in hexane) flow rate of 1 ml/min and injection volumes of 20-30 µl. The CLA isomers identification and quantification (external standard technique) were performed as described by Alfaia *et al.* (2003).

The data were analysed using the GLM procedure of SAS (1989). Total lipids and total CLA contents and the proportion of each CLA isomer were studied by analysis of variance, including the effects of breed and muscle type and their interaction. When the *F*-test was significant, the least-squares means were compared at a significance level of 5% ($P<0.05$).

Results and discussion

The intramuscular fat contents of the ribeye (T1-T3, LT) and loin (L4-L6, LL) portions of *longissimus dorsi* muscle and the distal region of *semitendinosus* (ST) muscle of Arouquesa-PDO and Barrosã-PDO veal are presented in Table 1. These data do not allow us to identify breed differences "*per se*" but the overall effect of breed and local production system (traditional production system). The content of total lipids (mg/g muscle) was similar ($P>0.05$) in the three muscles of both breeds. Our values were lower or similar to those reported by Roseiro *et al.* (2002) for Barrosã veal (2.97%, in *longissimus dorsi* muscle) but much lower than those reviewed by Chizzolini *et al*. (1999) for beef (6.3%, in *longissimus dorsi*, and 3.9%, in *semitendinosus* muscle). According to the criteria set by Food Advisory Committee (1990) (less than 5% of fat) these meats-PDO may be considered lean.

The isomeric distribution of individual CLA isomers (Fig. 2), the total content of CLA (mg/g muscle), as well as the content of some specific CLA (mg/g fat), are depicted on Table 1.

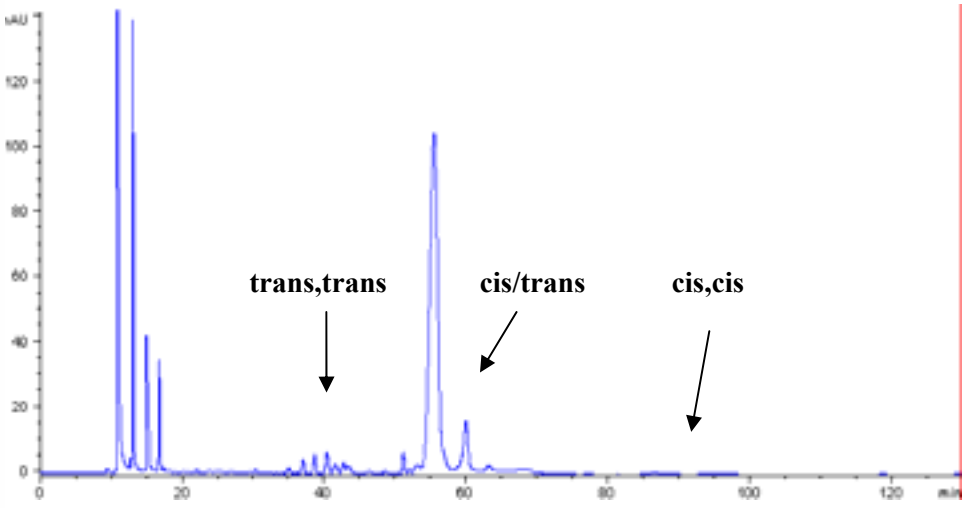

Figure 2. Typical Ag^{+}-HPLC chromatogram of CLA isomeric profile in veal from Arouquesa and Barrosã breed calves slaughtered in early autumn.

Figure 1. Geographical distribution of Arouquesa (A) and Barrosã (B) breed calves. Adapted from Direcção-Geral de Veterinária website.

The total CLA content was higher ($P<0.05$) in Arouquesa-PDO veal than in Barrosã-PDO veal, yet no significant differences were observed among the muscles within a breed. Furthermore, no significant differences were observed on specific CLA content in meat from LT, LL and ST muscles compared traditional veal obtained from calves of a different breed. The sum of *cis,trans* CLA isomers contributed around 93% (Barrosã breed) and 90.5% (Arouquesa breed) to total CLA. Total *trans,trans* CLA isomers contributed only with 9.0% and 6.4% in Arouquesa-PDO and Barrosã-PDO veal, respectively. The percentage of total *cis,trans* isomers is mainly due to the amounts of *cis*-9,*trans*-11 CLA isomer (84.7% to 85.5% for Barrosã-PDO and 79.3% to 80.6% for Arouquesa-PDO veal). The predominant CLA isomer, *cis*-

9,*trans*-11, showed significant differences between Arouquesa-PDO and Barrosã-PDO veal, and the variations in the amount of *cis*-9,*trans*-11 probably reflects either differences in the pasture composition or breed differences in delta-9 desaturase expression (Taniguchi *et al*., 2004). The interaction between breed and muscle type was significant for the proportions of *cis/trans*-12,14 and *trans*-11,*cis*-13 isomers. Finally, no significant differences in total *cis,cis* CLA isomers within each muscle and between the breeds were observed, and the mean amounts detected, mainly composed of the *cis*-9,*cis*-11 isomer, were lower than 0.6%.

Table 1. Analysis of variance and least-square means of total lipids and total CLA contents (mg/g muscle), specific CLA contents (mg/g muscle) and its individual isomers (% CLA) of intramuscular fat of the ribeye (T1-T3, LT) and loin (L4-L6, LL) portions of *longissimus dorsi* and the distal region of *semitendinosus* (ST) muscles of two traditional Portuguese breed calves slaughtered in early autumn.

Conclusions

These preliminary results indicate that when evaluating the CLA isomeric profile, and more specifically the content of the CLA in configuration *cis*-9,*trans*-11 in meat, one must take into account the overall effect of breed and local production system. From the nutritional point of view, the fat from the Barrosã veal may be more healthful because of its higher proportion of *cis*-9,*trans*-11 CLA isomer. Although no significant differences were found for specific CLA contents, the total CLA contents and the sum of *trans,trans* and *cis,trans* isomers were significantly influenced by the traditional production system. The results also showed that in general no significant differences occur within CLA isomeric profile in LT, LL and ST muscles for Arouquesa and Barrosã veal.

Background

Portuguese bovine meat production is based either on intensive rearing of crossbred and meat specialized exogenous breeds or on traditional extensive rearing of autochthonous breeds. The traditional meat production system of the Portuguese bovine autochthonous breeds represents an important socio-economical factor of wealth to the rural populations as it provides meat, milk and labor. In a recent past, the introduction of exotic bovine breeds specialized in meat or milk production, such as Charolais, Limousine and Friesian, have created a threat to the preservation of Portuguese autochthonous bovine livestock and to the traditional meat production system, characterized by the utilization of local agricultural resources with little or no costs in pellet feeding. In the present days, autochthonous bovine population is increasing thanks to active producer associations, and the meat of these breeds is being commercialized under the Protected Designation of Origin (PDO) certification, which obliges producers to follow the traditional rearing methods. Arouquesa and Barrosã, from the North Atlantic territory of Portugal, and Alentejana and Mertolenga, from the South Mediterranean territory of Portugal, are four commercially important autochthonous Portuguese breeds (Figure 1). It is supposed that each meat-PDO has unique characteristics, particularly in its lipid fraction, thanks to traditional, unique production system and to the breed own characteristics. However, for the consumers, the meat-PDO represents an expensive choice, which can only be justified by enhanced sensorial and nutritional characteristics.

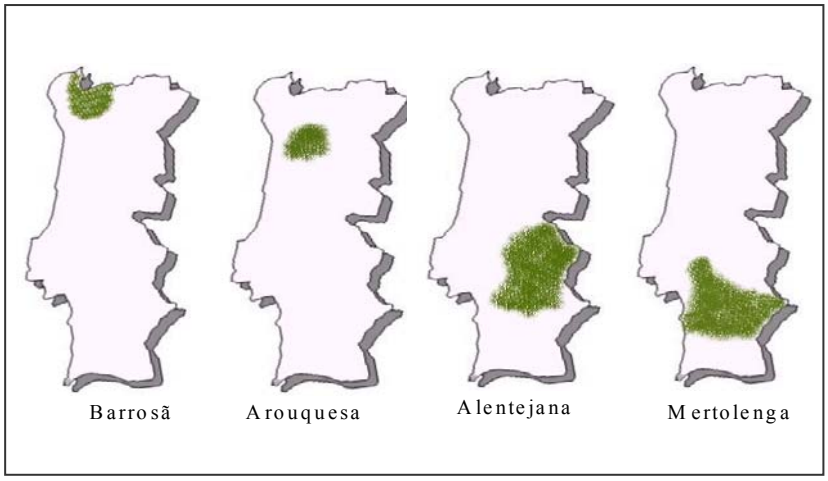

Figure 1. Geographical distribution of the Portuguese autochthonous bovine breeds analyzed in this study.

Objectives

The aim of this work was to compare the total content of lipids and cholesterol in Arouquesa-PDO veal, Barrosã-PDO veal, Alentejana-PDO beef and Mertolenga-PDO beef, all obtained from autochthonous bovines fed extensively during winter and early-mid spring (with the most abundant green pastures) and slaughtered in late spring (June).

Materials and methods

Meat samples from Arouquesa (113 ± 18 kg of carcass weight, 8.5 ± 0.9 months) and Barrosã (106 ± 21 kg, 7.9 ± 1.8 months) breed calves, and from Alentejana (357 ± 32 kg, 20 ± 2 months) and Mertolenga (236 ± 31 kg, 23.6 ± 2.8 months) breed bulls, were taken from the ribeye (*longissimus thoracis*; T1-T3), from the loin (*longissimus lumborum*; L1-L3) and from the distal portion of the *semitendinosus* muscle. The samples were collected in late spring, 2-3 days after slaughter, and stored at -80ºC until analysed.

Total lipids were extracted from meat (dry matter) by ultrasonication, using methylene-chloride (4:1 v/v) (3×) and *n*-hexane (1×), as was described by Fritsche *et al.* (2000). Total lipid content of the samples was calculated, in duplicate, by weighing the residues of solvent evaporation under a stream of nitrogen.

Total cholesterol was also extracted from meat (dry matter) with *n*-hexane after direct saponification with 0.5 M KOH solution for 15 min at +80ºC (Fletouris *et al.*, 1998). Cholesterol quantification was performed by normal-phase HPLC (column Zorbax Rx Sil, 4.6 mm ID × 250 mm, 5 µm particle size, Chrompack, USA), using an auto-sampler and diode array detection (DAD) at 206 nm, a solvent flow rate of 1 ml/min and injections volumes of 30 µl (Figure 2). The total cholesterol content in meat was expressed as a mean of two replicates with a variation coefficient lower than 3.5%.

The statistical analysis of the total lipids and total cholesterol contents were performed using the GLM procedure of SAS (1989) at a significance level of 5% ($p<0.05$). When the *F*-test of analysis of variance was significant, the least-squares means were compared at the same significance level.

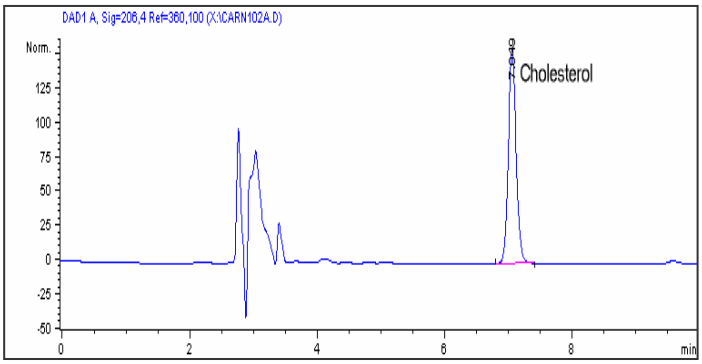

Figure 2. Typical normal-phase HPLC chromatogram of total cholesterol in a meat sample, detected at 206 nm.

Results and discussion

These data do not allow us to identify breed differences "*per se*" but the overall effect of breed and local production system (traditional production system). Total cholesterol content was higher in *semitendinosus* muscle than in the other muscles analyzed in all four breeds (Table 1). The total cholesterol content of Alentejano and Mertolengo bulls are similar to those reported for Podolian young bulls (Cifuni *et al.*, 2004) and feedlot beef cattle (Rule *et al.*, 2002). Arouquesa and Barrosã veal had slightly lower total cholesterol content than the average reported by Chizzollini *et al.* (1999). Total lipid content of meat did not show a common pattern in the different muscles of the four breeds (see Table 1). However, according to the criteria set by the Food Advisory Committee (1990) (less than 5% of fat), all meats analyzed were lean. This trait alone can be considered a quality characteristic of these meats-PDO, because it is independent of the season and availability of nutrition. The analysis of specific cholesterol content showed that *longissimus thoracis* had the highest content, while *longissimus lumborum* and *semitendinosus* had similar specific cholesterol contents in all breeds, except for Alentejana bulls. The specific cholesterol contents distribution among the different muscles analyzed did not show a regular pattern. The total lipid content and total cholesterol content showed a highly significant positive correlation ($R^2=0.135$, $P<0.0001$, $n=180$), although, according to earlier work, marbling depots seemed to have minimal effect on the total cholesterol content of meat (Kinney Sweeten *et al.*, 1990). This controversy may be explained by the fact that cholesterol deposits are mainly in the membranes not in the cytoplasm of the adipose tissue. The statistical analysis performed to evaluate the possible interaction between muscle and breed, revealed a significant interaction between the two factors for all analyzed parameters, which means an absence of a common pattern for the different muscles of the breed calves and bulls analyzed.

Table 1. Means of total lipids (TL, mg/g meat), total cholesterol (TC, mg/g meat) and specific contents of total cholesterol (SC, mg/g lipids) measured in *semitendinosus* (ST), *longissimus lumborum (LL)* and *longissimus thoracis (LT)* muscles of four Portuguese bovine meats-PDO.

	Arouquesa			Alentejana			Mertolenga			Barrosã		
	ST	LL	LT	ST	LL	LT	ST	LL	LT	ST	LL	LT

[1] – Significant interaction ($p< 0.01$) between muscle type (M) and breed (B); standard error of means (s.e.m.) = 0.0107
[2] – Significant M*B interaction ($p< 0.0001$), s.e.m. = 1.75
[3] - Significant M*B interaction ($p< 0.04$), s.e.m. = 2.647

Conclusions

We conclude that the Portuguese autochthonous breeds studied, although not specialized for meat production, represent an important source of lean meat with similar cholesterol content. These breeds are produced with the local resources in a production system where the specialized breeds cannot compete.

ANTIHYPERTENSIVE ACTIVITIES GENERATED FROM PORCINE SKELETAL MUSCLE PROTEINS BY LACTIC ACID BACTERIA

Arihara, K., Nakashima, Y., Ishikawa, S., Itoh, M.
Faculty of Animal Science, Kitasato University, Towada-shi, 034-8628, Japan

Background

Many kinds of bioactive peptides are known to be generated from food proteins (Korhonen & Pihlanto, 2003). Especially from milk proteins, such peptides (*e.g.*, antihypertensive, antimicrobial and mineral binding peptides) have been discovered considerably. In some countries (*e.g.*, Japan), food industry has shown a great interest in bioactive peptides from food proteins for developing novel functional foods.

Angiotensin I-converting enzyme (ACE) inhibitory peptides are representative bioactive peptides generated from food proteins. ACE plays an important physiological role in regulating blood pressure (Figure 1). Several inhibitors of ACE have been found to be effective as antihypertensive pharmaceuticals. ACE inhibitory peptides derived from food proteins have been reported to create antihypertensive effects in spontaneously hypertensive rats by oral administration (Yamamoto *et al*., 1999). The antihypertensive effect of ACE inhibitory peptides derived from the casein of sour milk, was demonstrated in hypertensive human patients (Hata *et al*., 1996). This product has been developed into a new physiologically functional food in Japan. Research has also been conducted to characterize the ACE inhibitory activity derived from other foodstuffs, such as maize, eggs, gelatin, fish and fish products. However, little is still known about the derivation of such peptides from muscle proteins of domestic animals.

Recently, we have found that enzymatic hydrolysates of porcine skeletal muscle proteins exhibited potent ACE inhibitory activity (Arihara *et al*., 2001). Among muscle protein hydrolysates produced with eight different proteases, the digest of thermolysin showed the most potent inhibitory activity. ACE inhibitory peptides, named myopentapeptide A (Met-Asn-Pro-Pro-Lys) and B (Ile-Thr-Thr-Asn-Pro), were isolated from the thermolysin hydrolysate. Moreover, hydrolysates of porcine myosin as well as some peptides identical to a sequence of myosin showed antihypertensive activity in spontaneously hypertensive rats (Nakashima *et al*., 2002).

The results of these studies suggest that ACE inhibitory and antihypertensive peptides are easily generated from muscle proteins by enzymatic digestion. Thus, in meat products, such as fermented meat products with long-term ripening, these kinds of peptides may be generated. In fact, we have already detected ACE inhibitory activity in several commercial fermented meat products (unpublished data). Naturally occurring ACE inhibitory activity has also been detected in well-ripened cheese.

Objectives

In the present study, we investigated the generation of ACE inhibitory and antihypertensive activities in porcine skeletal muscle homogenates fermented with lactic acid bacteria. Efforts were also made to purify and identify the corresponding peptides from the homogenates. Such activities and substances could be utilized for producing new healthy meat products, which might open up a new market in the meat industry.

Materials and methods

Materials and Reagents

Fresh pork trim (ham) was obtained from a local packer. Hippuryl-L-histidyl-L-leucine (Hip-His-Leu) and ACE (from rabbit lung) were obtained from Sigma Chemical Co. (St. Louis, MO). Other chemicals were obtained from Wako Chemicals Co. (Tokyo, Japan).

Preparation of Fermented Homogenates

Fermented muscle homogenate was prepared as shown in Figure 2. Porcine skeletal muscle was homogenated in a Waring-type blender with four volumes of distilled water. Glucose (2%) and one of 5 strains (*Lactobacillus gasseri* JCM1131, *L. rhamnosus* FERM P-15120, *L. acidophilus* IAM12475, *L.*

helveticus JCM1554, *L. delbrueckii* subsp. *bulgaricus* NCFB2483) of lactic acid bacteria were added to the homogenate. These 5 strains of lactic acid bacteria were selected according to their proteolytic activities in our previous study (unpublished data). After 72 h of fermentation at 37°C, homogenates were heated at 98°C for 10 min to inactivate the bacterial and muscle protease activities. After removal of insoluble materials by centrifugation, the supernatants were utilized for further experiments.

Assay of ACE Inhibitory Activity

The ACE inhibitory activity was measured by a spectrophotometric assay according to Cushman and Cheung (1971) with modification by Nakamura *et al*. (1995). This assay is based on the liberation of hippuric acid from Hip-His-Leu catalyzed by ACE. The method was slightly modified in the present study. A sample solution of peptides (15 µl) was mixed with 125 µl of 100 mM sodium borate buffer (pH8.3) containing 7.6 mM Hip-His-Leu and 608 mM NaCl and then preincubated for 5 min at 37°C. The reaction was initiated with the addition of 50 µl of ACE dissolved in distilled water (50 m units/ml), and the mixture was incubated for 30 min at 37°C. The reaction was stopped by adding 125 µl of 1N HCl. The hippuric acid liberated by ACE was photometrically determined at 228 nm after ethyl acetate extraction. The concentration of ACE inhibitors needed to inhibit 50% of ACE was defined as the IC_{50} value.

Antihypertensive Effect in Spontaneously Hypertensive Rats

Male spontaneously hypertensive rats (SHR), 10 week old, were purchased from Charles River Japan Inc. (Yokohama, Japan). The SHR were housed in cages on a cycle of 12 h of light and 12 h darkness. The temperature and humidity in the cages were maintained at 24°C and 50 to 60%, respectively. The SHR were fed a standard laboratory diet (CE-2; Clea Japan, Inc., Tokyo, Japan), and tap water was freely available. A solution containing peptides was adjusted to 50 mg of solid material per ml, and was administered on the rats at a dose of 1 ml ie., 150 mg/kg of body weight. The *in vivo* antihypertensive activity was measured by monitoring the systolic blood pressure (SBP) of the SHR, from 15 to 28 week old (280 to 390 g in body weight). Rats given the sample solution via a gastric metal zonde were put in a thermostatted box at 40°C for 15 min, and the SBP was measured with a tail cuff equipped with a programmed electrosphygmomanometer (BP-98; Sftron Co., Tokyo, Japan, Figure 4). Phosphate-buffered saline (PBS) was used as a control in SHR.

Purification of ACE inhibitory Peptide

The supernatant solution of fermented muscle homogenate was fractionated by high-performance liquid chromatography (HPLC) with reversed-phase mode (column: CAPCELL PAK C_{18} UG120 4.6 x 150 mm; Shiseido, Tokyo, Japan) as described previously (Arihara *et al.*, 2001). Elution was performed with a linear gradient system from solvent A (0.1% trifluoroacetic acid in CH_3CN) at a flow rate of 1m/min, and absorbance was detected at 215 nm (first HPLC run). The active fraction was lyophilized, dissolved with distilled water, and rechromatographed under the same conditions as described above (second HPLC run). The peptide samples were further purified by HPLC with the same system except for the elution solution (third HPLC run). Elution was performed with a linear gradient (solvent A: 0.015% ammonia in distilled water, solvent B: 0.015% ammonia in CH_3CN).

Analysis of Peptide

The molecular formula of the peptide was confirmed from its fast atom bombardment mass spectrum (FAB-MS) obtained using an HX-110 spectrometer (JEOL Ltd, Tokyo, Japan). The sequence of the peptide was analyzed by automated Edman degradation using a 470A Protein Sequencer (Applied Biosystems, Inc., Forster City, CA).

Synthesis of Peptide

The synthesized peptide used in this study was prepared by the solid phase method with a 430A Peptide Synthesizer (Applied Biosystems, Inc.). Hydrogen fluoride was used for removing the side chain-protecting groups and for cleaving the peptide from their solid support. The synthesized peptides were purified by HPLC on a reversed-phase column (CAPCELL PAK C_{18} UG120 4.6 x 150 mm; Shiseido, Tokyo) with a linear gradient of CH_3CN (0 to 20%) in 0.1% trifluoroacetic acid.

Results and discussion

All muscle homogenates fermented with any of the *Lactobacillus* strains (*L. gasseri* JCM1131, *L. rhamnosus* FERM P-15120, *L. acidophilus* IAM12475, *L. helveticus* JCM1554, *L. delbrueckii* subsp. *bulgaricus* NCFB2483) showed ACE inhibitory activities higher than non-fermented muscle homogenate (Figure 4).

Among these 5 strains, the homogenate fermented with *L. rhamnosus* showed the highest inhibitory activity. Further experiments were then carried out on the muscle homogenate fermented with *L. rhamnosus*. The single oral administration of this homogenate to SHR significantly decreased their systolic blood pressure (Figure 5). The peptide responsible for the ACE inhibitory activity was purified from the homogenate by the combination of HPLC with reversed-phase mode. Octapeptide with the ACE inhibitory activity was purified and its amino acid sequence was determined (Val-Phe-Pro-Met-Asn-Pro-Pro-Lys). A search for sequence homology in databases revealed that the same sequence existed in the primary structure of the porcine skeletal muscle myosin heavy chain. The ACE inhibitory activity (IC_{50}) against the synthesized octapeptide was determined as 66.0 uM.

In the dairy industry, many physiologically functional foods have been developed. Asic studies on the tertiary function of milk components and on physiologically functional dairy prdoducts have been extensively conducted (Arai, 1996). However, there have been few such studies on meat products. Although many low-fat and low-salt meat products have been developed, there have been no efforts to introduce physiologically functional properties into meat products. We have reported recently that the concept of probiotics (cultures of live microorganisms that benefit the host by improving properties of indigenous microflora) has great potential in the meat industry (Arihara *et al*., 1998; Sameshima *et al*., 1998). *L. rhamnosus* FERM P-15120, the strain selected in this study, is a probiotic lactic acid bacteria isolated from human intestinal tract (Sameshima *et al*., 1998). Therfore, fermented meat products prepared with this strain are expected to have both probiotic and antihypertensive properties.

By using bioactive components, properties having potential health benefits can be introduced into meat products, thus improving the nutritional value of the products. Utilization of ACE inhibitory activity and substances from meat proteins may lead to the development of new healthy meat products.

Conclusions

This study demonstrated that peptides with ACE inhibitory and antihypertensive activity may be generated from meat by bacterial fermentation. Furthermore, fermentation of meat by lactic acid bacteria resulted in the generation of the ACE inhibitory peptide. The results of this study suggest that ACE inhibitory and antihypertensive activities generated by fermentation could be utilized to develop physiologically functional foods. Although bioactive peptides, such as ACE inhibitors, have not yet been utilized in the meat industry, meat products with such acitivity could open up a new market in the near future. It is expected that increasing interest will be shown in basic research and potential applications of bioactive peptides for meat products.

FATTY ACID CONTENT AND COMPOSITION OF MUSCLE LIPIDS OF GOAT KIDS FED SUNFLOWER OIL SUPPLEMENTED DIET

Banskalieva, V.[1], Marinova, P.[1], Renerre, M.[2], and Tzvetkova, V.[3]
[1] Institute of Animal Science, Kostinbrod, Bulgaria
[2] INRA, Center de Recherches de Clermont-Theix, France
[3] Institute of Cryobiology and Food Technologies, Sofia, Bulgaria

Background

Consumers, becoming more health conscious, are increasingly paying attention to quality aspects of meat, particularly to lean meat. Goat meat is a good source of lean meat due to its very little intramuscular fat content. However, the leanness of goat meat may be a disadvantage in promoting goat meat products, which may have inferior juiciness, palatability, "mouth feel", and tenderness. Therefore, a shift in the partitioning toward deposition of more inter- and intramuscular fat would increase carcass quality as well as consumer acceptance. High concentrate diets enhanced mostly internal fat (Bas *et al*., 1982), but did not influence muscle composition (Muller *et al*., 1985) in goat kids. Using diets rich in 18:2 showed a decrease of the total lipid content and an increase in the amount of phospholipids (PL) in muscles of calves and lambs (Jenkins and Kramer, 1990; Ponnampalam *et al*. 2001). In contrast, in our previous study with kids (Marinova *et al*., 2001), sunflower oil supplemented diet increased the intermuscular fat and total fat content in all meat cuts.

However, not only fat content, but also its fatty acid profile affects the quality of meat. The interest in fatty acids with respect to consumer health lies in the proportions of polyunsaturated (P) and saturated (S) fatty acids, their ratio (P/S), the ratio of n-6/n-3 fatty acids, as well as the content of cholesterol. In addition to the beneficial effects of polyunsaturated fatty acids, the conjugated linoleic acid (CLA) isomers have received much attention for their potential health promoting effects. Vegetable oils as natural sources of the essential linolenic and linoleic acids (being precursors of CLA) are now attracting increased research attention. Feeding calves and lambs diets supplemented with unprotected sources of 18:2, resulted in an increase of muscle PL fraction, but decreased the n-6/n-3 ratio (Jenkins and Kramer, 1990; Ponnampalam *et al*. 2001). Recently it was demonstrated that an unprotected sunflower oil supplemented diet significantly increased CLA content in the triacylglycerol (TG) fraction of various lamb tissues (Peterson at al., 2002). However, no data related to the effect of vegetable oils on the lipid content and composition in goat muscles are available.

Objectives

The object of this study was to examine the effect of dietary enrichment of n-6 fatty acids (sunflower oil) on the content and fatty acid composition of muscle triacylglycerols and structural phospholipids, as well as cholesterol level, in growing goat kids.

Material and methods

Two groups of five male kids (age 3 months) were fed iso-nitrogenous diets for 21 days, as described in a previous paper (Marinova *et al.,* 2001). The diets contained either no added fat (control), or sunflower oil (2.5% of as-fed basis weight of concentrate) (experimental). Samples from *M. longissimus dorsi* (LD)*, M. semimebranosus (*SM) *and M. supraspinalis* (SP) were taken after slaughter at 24h *post mortem*, and lipids were extracted according to the method of Bligh and Dyer (1959). Aliquots of the lipid extracts were submitted to cholesterol and phospholipid assays, using the methods of Sperry and Webb (1950) and Bartlet *et al*.(1959), respectively. Methyl esters of PL and TG isolated by preparative TLC, were obtained using a 0.01% solution of sulfuric acid in dry methanol at 47^{o}C for 14h, as described by Christie (1973). The fatty acid composition of the lipid fraction as well as the content of TG, were analyzed by gas chromatography using triarahidin as an internal standard. The effect of treatment (control ν sunflower oil supplemented group) was subjected to Student's test for determination of significance.

Results and discussion

The intramuscular fat (i.f) content, and the contents of the single lipid fractions distinguished between the three muscles (Table 1). In m.SP, where the total fat content was highest, the concentrations of PL and cholesterol were also higher, but the TG level lower, compared with the other two muscles.

Table 1. Contents of intramuscular fat, phospholipids, triacylglycerols and cholesterol in M. *longissimus dorsi, M. semimembranosus and M. supraspinalis,* of goat kids in response to feeding sunflower oil

Muscles	*M. longissimus dorsi*		*M. semimembranosus*		*M. supraspinalis*	
			Groups[a]

TG [c]	2.15± 0.29	3.33± 0.41	1.44±0.19	3.19±0.62	1.29±0.13	3.79±0.78

[a] Control: no added sunflower oil; experimental : sunflower oil supplemented diet (2.5% of weight of concentrate as fed-basis) ; [b] PL – phospholipids; mg/g fresh tissue; [c] TG – triacylglycerols" µ mol/g fresh tissue; * $P < 0.05$.

Sunflower oil supplementation tended to increase (although to a different extent in different muscles) all lipid fractions. Jenkins and Kramer (1990); Ponnampalam *et al*. (2001) also reported higher PL level after corn or sunflower treatment, but reduced muscle TG levels. Contrary to the negligible changes in PL fractions, the TG concentrations were increased by 55%, 120% and 193%, (Table 1), respectively for m.LD ,m.SM and m.SP.

[a] Control: no added sunflower oil; experimental : sunflower oil supplemented diet (2.5% of weight of concentrate as fed-basis) ; [b] UFA - Unsaturated fatty acids; *$P<0.05$.

The increase of fat in kids' muscle after sunflower oil treatment leads to an increase in the relative diameter of larger cells and to a corresponding decrease in that of the smaller cells, most noticeably in SP muscle (Marinova, 2003). Paterson *et al*. (2002) reported that sunflower oil supplementation, as a source of unprotected 18:2, resulted in a significant increase of CLA content in different lamb tissues, and suggested that the biological activity of CLA may be more related to deposition of fat rather than to specific effects on PL alterations. The increased intramuscular fat could have a beneficial effect on the marbling of lean goat meat, although the tendency of getting more cholesterol would have to be considered.

Similarly to other livestock species reared for meat production, the major fatty acids in TG muscle of kids were 16:0, 18:0 and 18:1 (Table 2). The sum of unsaturated fatty acids (UFA) did not differ between the three muscles, although small variations in the proportions of 14:0, 18:0 and 18:2 were observed. In experimental animals, the only significant changes ($p<0.05$) were the reduction in the proportions of 16:1 in LD and 16:0 in SM muscles. The reduction of 16:0 in SM was apparently compensated for by an increase of

18:0 and 18:2 contents. Paterson *et al*. (2002) reported similar changes with sunflower oil in the rib muscle of lambs. Sunflower oil also tended to decrease the proportion of 18:1 in SP muscle, while increasing 18:0 in all three muscles. However, in SM muscle, no increase of 18:2 was observed in the other two muscle TG fractions. It may be speculated that blood flow delivered different amount of 18:2 to different muscles, or, the decreased proportion of 18:2 in LD and SP muscles was due to a conversion of 18:2 to CLA, which substitutes 18:2 in TG molecules, as was suggested by Peterson at al. (2002). Unfortunately we were not able to determine the CLA content.

FA profiles of PL in the three muscles of goat kids reflected the metabolic type of muscles (Table 3). The highest proportion of 16:0, and the lowest proportion of 18:2 were found in LD, whereas no differences in the content of 18:1 were observed between muscles. The linoleic acid concentration in the three muscles was higher than that reported for muscle PL of goats of different breeds and ages (Banskalieva *et al*., 2000). The SP muscle being oxidative type had a higher level of PL (Table 1), as well as a higher proportion (29.6%) of polyunsaturated fatty acids (PUFA) than the LD and SM muscles of oxidative-glycolytic type (24.95% and 26.23%, respectively). The n-6/n-3 ratios in the LD, SM and SP were 7.98, 8.94 and 8.74, respectively, ie. higher than the minimum of 4.0 officially recommended. High n-6/n-3 ratio with great variation (4.38 to 19.62) caused by differences in age, breed, muscles, diet, etc. have also been reported earlier in goats (Banskalieva, *et al*., 2000). The P/S ratios of 0.60, 0.67 and 0.79 of LD, SM and SP, respectively, were somewhat comparable to the recommended beneficial value of 0.7, indicating that as a meat producing species, goats have a rather optimal P/S ratio.

The sunflower oil treatment had no significant effect on the major fatty acids (16:0,18:0 and 18:1) in muscle PL fractions of kids. The relative proportion of 18:2 tended to increase in SM and SP resulting in a slight elevation in the total content of polyunsaturated FA in SM, but not in the other two muscles. However, an opposite tendency ie., decrease was observed in the proportions of 18:3n-3, 20:2n-6 and 20:4n-6. The increased P/S ratio reflects the net effect in the sum of polyunsaturated FA of a muscle. Despite the slightly diminished P/S ratios in LD and SP, they remained close to the recommended beneficial value of 0.7. The tendency of 20:4 to decrease may suggest that the activity of Δ6-desaturase (participating in conversion of 18:2 to 20:4) is affected, or some amount of 18:2 was converted to CLA (Peterson at al. (2002). Although small, the variations in the amount of n-6 fatty acids were compensated by a slightly increased incorporation

of some n-3 fatty acids in the PL fraction. As a result, the n-6/n-3 ratios tended to decrease in LD and SM, but not in SP muscle.

Conclusions

The results of this study show that the P/S ratio in PL fractions of the muscle of goat kids was comparable to the recommended beneficial value set for this ratio. However, the higher proportions of n-6 fatty acids resulted in the higher n-6/n-3 ratio compared to other species. Sunflower oil supplementation increased mostly TG fractions, which may have a positive effect on the marbling of goat meat. Only in the SM muscle of the treated kids, was a tendency of increased incorporation of 18:2 into the TG and PL fractions observed. Using an unprotected source of 18:2 did not change the P/S ratios in muscle PL fractions, but increased the value of n-6/n-3 ratio in SP, whereas in the other two muscles (LD and SM) an opposite tendency was observed.

ABOUT SOME REGULAR FEATURES OF CHANGE OF BEEF FAT FRACTIONAL COMPOSITION DURING FERMENTATIVE GLYCEROLYSIS

Berdutina A.V.*, Nikitina E.S., Mitaleva S.I., Karpo B.S., Trubnikova O.N.
GNU V.M.Gorbatov All-Russian Meat Research Institute, Moscow, Russia

Background

Beef fat having high level of saturated fatty acids has limited use in current food diets, because its frequent consumption can provoke occurrence of cancer. Therefore, the search for possible ways of incorporation of transformed beef fat into combined meat products with balanced fatty acid composition is an urgent problem. One way of resolving this problem is the creation of technology of enzymatic modification of beef fat in the mixture of lipids having high functional-technological properties that are needed in meat industry. Enzymatic glycerolysis changes the lipid composition of the fats, which leads to accumulation of fractions of mono- and diglycerides having wide use as food additives. It was interesting to study the kinetics of beef fat fractional composition change during enzymatic glycerolysis.

Objectives

The purpose of the work was to study kinetic regularities of accumulation and consumption of individual lipid fractions during glycerolysis of beef fat in the presence of enzymatic preparation Liposym TL IM.

Materials and methods

Sterilized melted beef fat, food grade glycerol, and enzymatic preparation Liposym TL IM (Novozymes company, Denmark) were used for investigations. Lyposym TL IM is a granulated enzymatic preparation of purified 1,3 specific lipase immobilized on silica gel from Thermomyces lanuginosus, being produced during deep cultivation of GM strain Aspergillus oryzae. The preparation is mechanically stable, is intended for use in technological processes with batch loading, and has an activity of 175 IUN/g. As a unit of interesterification Novo (Interesterification Unit Novo, IUN) was taken the amount of enzyme, transforming 0.01% mass of tristearin per min during interesterification of soy oil by completely hydrogenized soy oil in a ratio 73: 27 (mass.%) at 70ºC in the absence of solvents.

Glycerolysis was carried out in a thermostatted glass reactor provided with a three-blade stirrer with constant rotation speed. Molar ratio fat-glycerol varied from 1:1 to 1:10, whereas the enzyme-substrate ratio E:S was changed in the range from 1:100 to 1:5. During investigation of kinetic characteristics of the process of glycerolysis was carried out at 45, 50, 55, 60, as well as 70ºC, periodically taking out samples for analysis of fractional composition by the method of thin-layer chromatography. Plates with the developed spots were scanned with the help of the system GelVue 2, by the area of the spots' percentages of fractions of tri-, di monoglycerols and fatty acids in the mixture of lipids were calculated. Calibration curves were constructed according to commercial standards Sigma.

Results and discussion

From literature it is known that the ratio of triglycerides to glycerol is the determining factor in obtaining different fractional composition of lipids. The amount of glycerol supplied to the reactor significantly influenced the yield of target fractions of mono- and diglycerides, The highest yield of fractions of mono- and diglycerides in this case was observed with mole ratio fat-glycerol 1:5, and did not increase with further increase of glycerol fraction in reaction mixture, which allows to recommend this ratio as the optimum. The process of enzymatic glycerolysis should be carried out with enzyme-substrate ratio that allows the achievement of maximum yield of target fractions with minimum doses of enzyme. The calculated enzyme-substrate ratio constituted 1:40 (mass.).

To clarify the influence of temperature on the velocity of glycerolysis, the dependencies of concentration change of separate lipid fractions in time were studied [1,2].

Fig. 1a shows experimental kinetic curves of the destruction process of triglycerides. Graphical differentiation of the above dependencies allowed to construct differential kinetic curves in co-ordinates (dP/dt; t), where the value dP/dt reflects the rate of destruction of triglycerides at the given time period (Fig.1b). We could with high correlation coefficients to approximate the curves with broken lines containing two rectilinear areas: horizontal and inclined, which may be considered as areas characterizing two stages of the process of glycerolysis. Observing the constant rate of change of triglycerides concentration at the first stage we can suppose that the number of elementary acts of triglycerides interaction with the active centers of enzymes per unit of time is also the constant value. Therefore, one can conditionally call the first stage as the stage of the effective work of the enzyme. In this case the break on differential curves will correspond to the time of effective work of enzyme, and the value of (dP/dt) on the first stage can be interpreted as the effective velocity of triglycerides destruction. The values of effective lengths of glycerolysis process were obtained by extrapolation of differential kinetic curves on abscissa axis.

The view of dependencies of triglycerides concentration change from time allowed us to suppose that the process of their destruction can be described by the equation of reaction of pseudo-first order. To check this supposition kinetic curves of Fig. 1a were linearized in semi-logarithmic co-ordinates. Determination of the value of inclination angle tangent of obtained straight lines allowed us to calculate values of effective constants of triglycerides destruction rates (Table 1).

From Table 1 it follows that the largest time period of effective operation of enzyme was at 45ºC and constituted 50 min, however, this temperature did not ensure high reaction rate. Temperature increase up to 60ºC led to the increase of effective initial rate 10-fold, and the time of the effective work of enzyme decreased to 5 min. Further temperature growth caused decrease of the rate of change of triglycerides concentration. Comparing experimental and differential curves of triglycerides conversion at 60ºC (Fig.1a and b) one can suppose that after 10-15 min the process of triglycerides hydrolysis was balanced by the process of their synthesis that was also evidenced by stabilization of concentration of triglycerides at 60ºC at the level 30%, i.e. 1.3 –1.5 times higher than at 45-55ºC.

The above approach was applied for description of kinetic curves of change of free fatty acids fraction concentration. The time of effective work of enzyme as determined from analysis of dependencies of the change of free fatty acids accumulation velocity was 2 times higher, than in the case of triglycerides destruction (Table 1).

Kinetic dependencies of monoglycerides fraction accumulation are interesting for discussion. Since in the system simultaneously occurred the processes of glycerolysis and autolysis, then one can consider formation of monoglycerides, on the one hand, as a result of synthesis from glycerol and free fatty acids, and on the other hand, as a result of incomplete hydrolysis of tri- and diglycerides. Simultaneously with the accumulation of monoglycerides the process of their hydrolysis to glycerol and fatty acids could also occur, therefore, the description of monoglycerides formation mechanism and the calculation of kinetic parameters of processes of their synthesis and destruction is a complex problem.

Fig.2(a) shows dependencies of change of mass share of monoglycerides fraction from time at different temperatures. Unlike triglycerides and fatty acid fractions there are no clear and simple dependency of monoglycerides yield from temperature. Thus, at temperatures 45-55ºC during the first hour the concentration of monoglycerides increased, and during the second hour: at 45ºC – decreased, at 50ºC – stabilized and at 55ºC continued to rise. At 60ºC the increase in monoglycerides concentration took place only during first 20 minutes, after which the growth stopped and total yield did not exceed 4-5%. At 70ºC during first 15 minutes there was no monoglycerides fraction at all, but then their concentration began to increase slowly, reaching only as little as 3%.

The process of monoglycerides formation looks more vividly on differential kinetic curves, presented in Fig. 2b. It is interesting to note that effective time for enzyme work, during which there was observed constant velocity of accumulation of monoglycerides fractions actually did not depend upon the temperatures in the interval 45 – 60ºC and constituted 15-20 minutes. The most effective initial velocity of accumulation of monoglycerides was marked at 50ºC , the least - at 60ºC. The dependencies dP/dt = f(t) constructed at 50-60ºC (Fig.2b) were satisfactorily approximated by broken line from three lengths. The appearance of

medium length on differential curve was associated with the fact that after the stage with constant velocity of monoglycerides formation, with the above temperatures there was an abrupt decrease of the velocity by 2 or more times during 5-10 min. Further the velocity of monoglycerides formation decreased much slower, which was seen from the third area of differential curve.

The process of monoglycerides accumulation at 45ºC, 50ºC and 55ºC was satisfactorily described by the reaction equation of pseudo-first order. The values of effective constants of monoglycerides accumulation velocities are presented in Table.1.

The dependence of accumulation of diglycerides fraction from temperature was of more complex nature.. The highest yield of diglycerides was reached at 55ºC, in 2 hours. Comparatively high values of diglycerides concentrations, about 22%, and correspondingly low yield of monoglycerides at 70ºC, can, probably be explained by two predominating processes: triglycerides hydrolysis on the first stage, and also the synthesis of diglycerides from monoglycerides and fatty acids. The absence of clear correlation between the yield of diglycerides fraction and glycerolysis temperature, is probably associated with multiple elementary acts leading to their formation and destruction.

Conclusions

As a result of investigations were determined the conditions of glycerolysis of beef fat in the presence of preparations Lipozym TL IM which ensure production of modified fat with maximum content of fractions of mono- and diglycerides. Optimum conditions of glycerolysis: correlation fat-glycerol 1:5 (mol.), correlation enzyme-substrate 1:40 (mass.), at temperature of 53-58ºC. Under the above conditions modified beef fat was obtained with the fractional lipids composition as follows: monoglycerides – 27-32%, diglycerides – 26-31%, triglycerides – 25-30%, free fatty acids – 7-12%. Such composition of the product allows to speak about good prospects of use of modified fat as a component of a stabilizing functional additive for production of emulsified meat products.

ASSESMENT OF EFFICIENCY OF CHICK-PEA USE FOR SELENIUM ENRICHMENT OF STEER BEEF AND POULTRY MEAT

Chernukha, I.M.[1], Belyakina, N.E.[1] and Gorlov, N.F.[2]

[1] The V.M. Gorbatov All-Russian Meat Research Institute, Russia, 109316 Moscow, 26 Talalikhina St.
[2] The Volgograd Research and Technological Institute of Meat-and-Dairy Cattle Breeding and Animal Husbandry Products Processing, 400086 Volgograd, 6 Rokossovskogo St., Russia

Background

Interest of researchers to selenium – microelement essential for normal activity of an organism – has increased lately. Activity spectrum of selenium inside the organism is rather wide. It fulfils catalytic, structural and regulatory functions; interacts with vitamins, enzymes and biological membranes; is involved in reduction-oxidation processes; fat, protein and carbohydrate metabolism.

To enrich feeds with selenium, various selenium-containing additives, primarily organic selenium compounds, are being used widely in animal husbandry. Moreover, plants with a high content of selenium are known, such as coconuts (8100.0 μg/kg), pistachio nuts (4500.0 μg/kg), soybeans (600.0 μg/kg), wheat bran (1100.0 μg/kg), edible boletuses (1000.0 μg/kg), daily selenium requirement for man being 70 μg. Chick-pea (*Cicer arietinum L.*) has a selenium content of ~700 μg/kg (Table 1).

The main form of digestible selenium in vegetable food is selenium-methionine. It is assimilated 5-10 times better than other forms of selenium. For this reason, plants are considered the priority sources of selenium.

Objectives

The objective of these investigations was to compare the capacity of cattle and poultry tissues as well as organs to accumulate selenium of both vegetable and chemical origin.

Materials and methods

Broiler chicken and young bulls kept on feeds (42 and 90 days, respectively), containing DAFS-25TM (diacetophenonilselenide) preparation and chick peas as selenium-enriching additive, served as the object of investigations.

Samples were analyzed using the following methods:
- selenium content – by fluorimetric method;
- iron content – according to GOST (State Standard) 26928-86;
- total amino acid composition – by Mure and Shtein on LC 3000 automatic amino acid analyzer ("Eppendorf-Biotronic", Germany);
- fatty acid composition – by Folch method on HP 6890 gas chromatograph ("Hwelett Packard");
- color (a-redness) – with "Spectroton" spectrocolorimeter;
- protein, fat, moisture content, and pH – by generally accepted methods.

Results and discussion

Investigation of physical-chemical indices of poultry and beef meat did not show significant difference between test and control groups in terms of moisture, protein and ash content. However, the fat content was significantly lower in broiler chicken meat compared to beef.

As far as selenium content in muscular tissue is concerned, the groups differed from each other (Table 2). Increase in selenium content of poultry meat of the test group was found, the maximum amount being determined for meat and skin samples – by 46.7% higher, compared to the control sample, and by 14.5% higher, compared to the skinless sample. It is obvious, that selenium from chick-pea was assimilated by broiler chicken organism, and accumulated in tissues. Connective tissue, in this case, had higher accumulative capacity, in comparison with the muscular tissue.

Identical data were obtained for red meat. Fattening of Aberden Angus steers on 10 % chick peas diet also resulted in a certain increase of selenium content in muscular tissue. In three months of fattening the amount of selenium in meat of the test group became 33.8% higher than that of the control group.

For comparative study on efficiency of use of diverse-origin biologically active substances, degree of synthetic (DAFS-25, 1st test group) and natural (chick peas, 2nd test group) selenium accumulation was investigated. In the process of fattening it was established, that up to the 15-months' age steers of the 2nd test group outweighed (in live weight) animals of the control group by 19.6 kg (P>0.99), and those of the 1st test group, by 12.8 kg (P>0.95). The average daily gain in live weight of steers by groups was 926.0 ± 10.75, 967.0 ± 11.62, and 1 057.5 ± 10.24 g for the control, 1st and 2nd test groups, respectively. Yield of main carcass tissues is given in Table 3. Steers of the 2nd test group, exceeding analogues of the control and the 1st test group by 13.1 kg, or by 7.3% (P>0.99), and by 8.9 kg, or 4.8% (P>0.95), were characterized by the highest content of muscular tissue in carcasses. However, at the same time, the content of interior fat increased by 4.1 kg, or 39.8%, and by 1.8 kg, or 14.3%, respectively.

The chemical composition data reliably confirmed a higher fat content in meat samples of the 2nd test group, compared to analogues of the control and the 1st test group, by 9.9% (P>0.999) and 8.4% (P>0.999), respectively.

Results of investigations of selenium and iron content in steer meat are of interest (see Table 2). It was established that the maximum increase in selenium content (by 34%), compared to the control, was observed when fattening with chick-pea, whereas the fattening with DAFS-25 resulted in a correspondent increase of 15%. Reduction of iron level both in poultry and steer meat of test groups was surprising considering that the iron level was equal in all feeds. Results of investigations of selenium in steer liver, heart and *longissimus dorsi* demonstrated that the level of selenium content in the heart muscle, when fattening both with chick-pea and DAFS-25, was practically the same or slightly higher, in contrast to selenium level in muscular tissue, where it was increased with the increase of its ingress into the organism. Selenium level in liver of the test animals did not exceed that of the control ones. This may be an indication of non-accumulation or obtaining its optimal level even during usual fattening.

Results of investigation of color characteristics of the steer back *longissimus dorsi* after freezing, storage in the frozen state for 24 hours and the consequent defrosting showed, that during the first day the maximum value of the redness index was noted in control, and the minimum, in samples with DAFS fattening, what correlates with the data on iron content. In 3 days the above index decreased to the same level in all samples. In 5 days decrease was in progress. At the same time, the redness index of meat samples of steers obtaining feed with chick-pea was the highest, while in control samples it decreased by 62%, in samples with DAFS-25 fattening – by 54%, and in samples with chick-pea fattening – by 41%, that is, these samples were decolored more slowly, compared to the others. This may be explained by the high selenium content, which perhaps exhibited antioxidant properties.

Conclusions

Comparative evaluation of effect of diets with chick-pea and DAFS-25 selenium-containing preparation on gain in live weight, meat quality and selenium accumulation by organs and tissues of farm animals and poultry demonstrated the following:
- selenium assimilation from chick-pea was more effective, compared to DAFS-25 additive;
- the maximum selenium accumulation took place in muscular tissue;
- the presence of selenium positively affects the stability of meat colour.

In the future, further investigations on selenium influence over iron assimilation by animal organism, as well as study on technological characteristics of meat products manufactured from such meat, are planned to be carried out. In this way, a possibility of meat selenium enrichment in the animal lifetime was shown. Usage of natural selenium-containing plants is preferable in this case.

COMMON DIETS: NUTRITION, AND OBESITY

Chikere Kingsley Ruben

University of Ibadan, Oyo State-Nigeria 4, Abiola street, off Oduduwa Road, Oworonshoki, Lagos 234001-Nigeria

Scientific data suggest positive relationships between a vegetarian diet and reduced risk for several chronic degenerative diseases and conditions, including obesity, coronary artery disease, hypertension, diabetes mellitus, and some types of cancer. Vegetarian diets, like all diets, need to be planned appropriately to be nutritionally adequate.

Position statement
It is the position of The American Dietetic Association (ADA) that appropriately planned vegetarian diets are healthful, are nutritionally adequate, and provide health benefits in the prevention and treatment of certain diseases.

Vegetarianism in Perspective
The eating patterns of vegetarians vary considerably. The lacto-ovo-vegetarian eating pattern is based on grains, vegetables, fruits, legumes, seeds, nuts, dairy products, and eggs, and excludes meat, fish, and fowl. The vegan, or total vegetarian, eating pattern is similar to the lacto-ovo-vegetarian pattern except for the additional exclusion of eggs, dairy, and other animal products. Even within these patterns, considerable variation may exist in the extent to which animal products are avoided. Therefore, individual assessment is required to accurately evaluate the nutritional quality of a vegetarian's dietary intake.
In addition to the health advantages, other considerations that may lead a person to adopt a vegetarian diet pattern include concern for the environment, ecology, and world hunger issues. Vegetarians also cite economic reasons, ethical considerations, and religious beliefs as their reasons for following this type of diet pattern. Consumer demand for vegetarian options has resulted in increasing numbers of foodservices that offer vegetarian options. Presently, most university foodservices offer vegetarian options.

Health Implications of Vegetarianism
Vegetarian diets low in fat or saturated fat have been used successfully as part of comprehensive health programs to reverse severe coronary artery disease (3,4). Vegetarian diets offer disease protection benefits because of their lower saturated fat, cholesterol, and animal protein content and often higher concentration of folate (which reduces serum homocysteine levels) (5), antioxidants such as vitamins C and E, carotenoids, and phytochemicals (6). Not only is mortality from coronary artery disease lower in vegetarians than in non-vegetarians (7), but vegetarian diets have also been successful in arresting coronary artery disease (8,9). Total serum cholesterol and low-density lipoprotein cholesterol levels are usually lower in vegetarians, but high-density lipoprotein cholesterol and triglyceride levels vary depending on the type of vegetarian diet followed (10).

Vegetarians tend to have a lower incidence of hypertension than non-vegetarians (11). This effect appears to be independent of both body weight and sodium intake. Type 2 diabetes mellitus is much less likely to be a cause of death in vegetarians than non-vegetarians, perhaps because of their higher intake of complex carbohydrates and lower body mass index (12).

Incidence of lung and colorectal cancer is lower in vegetarians than in non-vegetarians (2,13). Reduced colorectal cancer risk is associated with increased consumption of fibre, vegetables, and fruit (14,15). The environment of the colon differs notably in vegetarians compared with non-vegetarians in ways that could favourably affect colon cancer risk (16,17). Lower breast cancer rates have not been observed in Western vegetarians, but cross-cultural data indicate that breast cancer rates are lower in populations that consume plant-based diets (18). The lower estrogen levels in vegetarian women may be protective (19).

A well-planned vegetarian diet may be useful in the prevention and treatment of renal disease. Studies using human being and animal models suggest that some plant proteins may increase survival rates and decrease proteinuria, glomerular filtration rate, renal blood flow, and histologic renal damage compared with a non-vegetarian diet (20,21).

Nutrition Considerations for Vegetarians

Plant sources of protein alone can provide adequate amounts of essential amino acids if a variety of plant foods are consumed and energy needs are met. Research suggests that complementary proteins do not need to be consumed at the same time and that consumption of various sources of amino acids over the course of the day should ensure adequate nitrogen retention and use in healthy persons (22). Although vegetarian diets are lower in total protein and a vegetarian's protein needs may be somewhat elevated because of the lower quality of some plant proteins, protein intake in both lacto-ovo-vegetarians and vegans appears to be adequate (16).

Plant foods contain only nonheme iron, which is more sensitive than heme iron to both inhibitors and enhancers of iron absorption. Although vegetarian diets are higher in total iron content than non-vegetarian diets, iron stores are lower in vegetarians because the iron from plant foods is more poorly absorbed (23). The clinical importance of this, if any, is unclear because iron deficiency anemia rates are similar in vegetarians and non-vegetarians (23). The higher vitamin C content of vegetarian diets may improve iron absorption.

Although plant foods can contain vitamin B-12 on their surface from soil residues, this is not a reliable source of B-12 for vegetarians. Much of the vitamin B-12 present in spirulina, sea vegetables, tempeh, and miso has been shown to be inactive B-12 analog rather than the active vitamin. Although dairy products and eggs contain vitamin B-12, research suggests that lacto-ovo-vegetarians have low blood levels of vitamin B-12. Supplementation or use of fortified foods is advised for vegetarians who avoid or limit animal foods (24).

Because vitamin B-12 requirements are small, and it is both stored and recycled in the body, symptoms of deficiency may be delayed for years. Absorption of vitamin B-12 becomes less efficient as the body ages, so supplements may be advised for all older vegetarians.

Lacto-ovo-vegetarians have calcium intakes that are comparable to or higher than those of non-vegetarians (25,26). Calcium intakes of vegans, however, are generally lower than those of both lacto-ovo-vegetarians and omnivores (26). It should be noted that vegans may have lower calcium needs than non-vegetarians because diets that are low in total protein and more alkaline have been shown to have a calcium-sparing effect (27). Furthermore, when a person's diet is low in both protein and sodium and regular weight-bearing physical activity is engaged in, his or her calcium requirements may be lower than those of a sedentary person who eats a standard Western diet. These factors, and genetic influences, may help explain variations in bone health that are independent of calcium intake.

Because calcium requirements of vegans have not been established and inadequate calcium intakes are linked to risk for osteoporosis in all women, vegans should meet the calcium requirements established for their age group by the Institute of Medicine (28). Calcium is well absorbed from many plant foods, and vegan diets can provide adequate calcium if the diet regularly includes foods rich in calcium (29). In addition, many new vegetarian foods are calcium-fortified. Dietary supplements are advised for vegans only if they do not meet calcium requirements from food.

Diets that do not include fish or eggs lack the long-chain n-3 fatty acid docosahexanoic acid (DHA). Vegetarians may have lower blood lipid levels of this fatty acid, although not all studies are in agreement with this finding (34,35). The essential fatty acid linolenic acid can be converted to DHA, although conversion rates appear to be inefficient and high intakes of linolenic acid interfere with conversion (36). The implications of low levels of DHA is not clear. However, it is recommended that vegetarians include good sources of linolenic acid in their diet.

Figure 1 below presents food sources of nutrients that are often of concern for vegetarians.

Iron	Milligrams per serving
Breads, cereals, and grains	
Whole wheat bread, 1 slice	0.9
White bread, 1 slice	0.7

Lippincott-Raven; 1994.* Provisional Table on the Content of Omega-3 Fatty Acids and Other Fat Components in Selected Foods, 1988. *Ibadan Oyo State: Nafdac Dept of [a]Red Star Yeast and Products, a division of Universal Foods Corp, Ikeja, Lagos.*

Conclusions

Diets that are high in carbohydrate and low to moderate in fat tend to be lower in energy. The lowest energy intakes were observed for those on a vegetarian diet. The diet quality as measured by HEI was highest for the high carbohydrate groups and lowest for the low carbohydrate groups. The BMIs were significantly lower for men and women on the high carbohydrate diet; the highest BMIs were noted for those on a low carbohydrate diet.

Background

In recent years, consumers have become more concerned about dietary fat and cholesterol associated with meat consumption, since these compounds are referred to as playing important roles in predisposition of human coronary disease (Salvatori *et al*. 2004), obesity and cancer (Chizzolini *et al*. 1999; Erickson, 1998). The Maronesa, an autochthonous cattle breed reared in the north part of Portugal is used for meat production uniquely based on calves produced under Protected Denomination of Origin (PDO). This type of veal is perceived as healthy due to the friendly extensive system applied on animal production, and is highly appreciated for its extraordinary eating quality.

A number of different factors, such as muscle location, muscle fibre type composition, sex and nutritional status, have been reported to influence the content of cholesterol and fat in meat. According to Calkins (2003) the amount of fat and the fibre characteristics of the muscle may contribute to the eating quality experienced by consumers.

Objective

The aim of this study was to evaluate the lipid composition, and the content of total collagen and haem pigment in various muscles with respect to muscle fibre types in Maronesa-PDO meat.

Material & Methods

About 1 hour after slaughter, samples from *Longissimus dorsi* (Ld), *Supra spinatus* (Ss) and *Biceps femoris* (Bf) of eight Maronesa calves of both sexes, with ages ranging from 6 to 9 months were taken for histochemical analysis. Transverse serial sections (10μm) were cut in a cryostat at –24ºC and stained for myofibrillar ATPase after pre-incubation at pH 4.45 as described by Brooke & Kaiser, 1970. The succinic dehydrogenase protocol described by Sheehan & Hrapchak (1987) was also used to define fibre metabolic properties. The percentage of each fibre type was calculated from a minimum of 400 units, by counting the total number of each type and dividing it by the total number of fibres. Differentiation into type I, type IIa and type IIb was based on staining intensity.

Samples for chemical analysis were collected 24 h after slaughter. Total lipids were extracted by the procedure of Folch *et al*. (1957) and then separated into neutral and polar fractions as described by Juaneda & Rocquelin (1985). Cholesterol was determined by HPLC according to Roseiro *et al*. (2002). Total collagen was measured following the ISO 3496:1994 procedure.

The samples were analysed for pigment content according to Hornsey (1956). Results were expressed as mg haematin/100g wet tissue, using a standard curve of a commercially available haematin instead of the factor used by Hornsey (1956).

Data were analysed using one-way analysis of variance (ANOVA) and significant differences were determined using Tukey´s HSD post hoc test requiring a probability value of less than 5 % ($p<0.05$) (Statistica 6.0-StatSoft Inc., 2001).

Results & Discussion

Muscle fibre type composition and metabolic profile

Fibre type composition and metabolic profile of the analysed muscles are indicated on Table 1. The Ss muscle showed a mean percentage of type I fibres significantly lower (P<0.01) than the other two muscles, yet it was the most oxidative unit of the three. This could be due to the fact that oxidative pattern is not only determined by fibre type I content but also by the incidence of such type of metabolism among types IIa (Zerouala & Stickland, 1991) and IIb fibres. On the other hand, the percentage of glycolytic fibres, classified by SDH procedure, was much lower than that of type IIb fibres, classified by ATPase. Ruusunen & Puolanne (1997) made a similar observation. These authors, by using NADH method to evaluate metabolic fibre type profile, reported that some IIb fibres analysed by the myosin ATPase method were in fact oxidative by metabolism.

According to the histochemical analyses, all studied muscles can be considered, predominantly, having oxidative metabolism. This may be related to the age of the animals. Fiedler *et al.* (1998) observed a decrease in the proportion of the oxidative fibres and concomitantly an increase in the glycolytic metabolism of the muscle along growth. Similarly, Johnston *et al*. (1981) showed that Ld and Bf muscles from older animals presented predominantly glycolytic metabolism. Nevertheless, in our case, Ld muscle showed lower mean percentage of IIb and a higher mean percentage of IIa fibers than those observed by Guinot *et al*. (1992), for Friesian-Holstein calves (carcass weight of 105-120). These results suggest that weight at slaughter may not have an important effect on muscle fibre type profile and that this issue may be affected to a larger extent by other factors such as breed, diet and handling. A study from Roseiro *et al* (2004) on Barrosã calves of similar age and weight at slaughter showed muscles with lower oxidative metabolism, higher percentage of type IIb and lower percentage of type IIa fibres than those of Maronesa calves.

Table 1. Cholesterol and intramuscular fat contents of different muscles of Maronesa calves.

	Muscle			F-value	P
	Ld	Bf	Ss		
Intramuscular characteristics					
Total lipids (g/100g)	1.38^{b}	1.48^{b}	1.80^{a}	8.11	*
Neutral lipids (g/100g)	0.71^{b}	0.73^{b}	1.02^{a}	3.10	*
Polar lipids (g/100g)	0.66^{b}	0.79^{ab}	0.84^{a}	3.65	*
Cholesterol (mg/100g)	48.50^{b}	51.50^{ab}	62.20^{a}	2.79	*
Haem pigment (mg/100g)	19.61	19.89	21.23	0.31	Ns
Total collagen (mg/g)	6.45^{b}	11.89^{ab}	13.38^{a}	3.95	*
ATPase (pH 4.6)					
Fibre type I (%)	21.42^{a}	24.99^{a}	16.69^{b}	3.60	*

In same row, means with different letters are significantly different. * p<0.05; ** p< 0.01; ns not significant.

Intramuscular chemical characteristics

As presented in Table 1, the amount of intramuscular fat, cholesterol and collagen was affected by anatomical location (P<0.05). The Ss muscle, the most oxidative among the analysed, showed significantly higher total (1.80 mg/100g) and neutral (1.02 mg/100g) lipid contents than Ld (1.38 and 0.71 mg/100g, respectively) and Bf (1.48 and 0.73 mg/100g, respectively). In relation to the polar lipids and cholesterol, Ss muscle also presented higher mean values (P<0.05) than LD muscle but did not differ significantly from those obtained from the Bf.

The oxidative fibres have greater aerobic metabolism, which is supported by lipids. For this reason they contain higher levels of intra-fibre lipids than their glycolytic counterparts. Although other authors have observed no significant differences in cholesterol content between muscles with distinct anatomical location

(Cifuni *et al*., 2004; Bohac & Rhee, 1988), Browning *et al*. (1990) did find differences among them, as we did. As previously reported, the content of total lipids, phospholipids and triacylglycerols depend on the metabolic type of muscles. The oxidative muscles contain more lipids and more triglycerides than the glycolytic ones (Alasnier *et al*., 1996).

Total haem pigment is an indicator of the redness of muscle and is closely related to its oxidative activity (Meynier & Gandemer, 1991). Although there were no significant differences in the oxidative activity between muscles, the Ss muscle, the most oxidative one, showed mean haem pigment content higher than Ld and Bf muscles.

As presented in Table 1, the collagen content of muscles was ranked as Ss>Bf>Ld. The same tendency for Bf and Ld muscles was observed by Seideman (1986). Beatty *et al.* (1966) found that the proportion of white fibres in the muscles were positively correlated to their collagen content. In this study, despite the small number of animals involved, the Ss and Bf muscles presented a higher proportion of white fibres (IIb) than Ld suggesting a possible relationship between these two issues. According to Kirchofer *et al*. (2002), muscles with increased type IIb fibres have more connective tissue and are less tender than muscles with more type I fibers. Many researchers have reported significant relationships between collagen content of the meat and its tenderness. However, the usefulness of collagen as a predictor of meat tenderness is still controversial. Muscles with more α-white fibres had more connective tissue, less intramuscular fat, and were less tender than muscles with more β-red fibres (Calkins *et al*. 1981).

Background

Horsemeat is not a traditional raw material for production of canned meat products for children. Pediatricians recommend beef for infants because it corresponds best to their nutrient status.
But it is known that horsemeat has pronounced dietetic properties. Protein of horsemeat by its amino acid balance is not inferior to beef. Horse fat is easily melted (melting point of lamb fat – 44-55^{0}C, beef fat – 40-50^{0}C, pork fat – 33-46^{0}C, horse fat – 30-43^{0}C), contains more than 50% of unsaturated fatty acids, among them - up to 20% linoleic and linolenic which are indispensable.
Horsemeat possesses hypoallergenic properties, high therapeutic efficiency in cases of celiac diseases, lactase deficiency and ability to decrease cholesterol level in blood that was confirmed by many clinical tests, carried out by technologists of the Institute together with pediatricians and specialists in nutrition.
Besides, horsemeat is more wholesome from hygiene point of view because horses are not sensitive to parasite diseases as well as to spongiform encephalopathy.

Objectives

The evaluation of nutrients adequacy, biological value of horsemeat as compared to beef and pork and substantiation of usefulness of horsemeat for child nutrition.

Materials and methods

Calculation of amino acid and fatty acid balance was carried out according to computer technique of Lipatov N.N. /1/ as compared to the reference - mature woman's milk.
Medical and biological evaluation of canned pork and horsemeat samples for children was carried out at the Chair of ecology of a man and environment hygiene of the I.M.Sechenov Moscow medical academy with the use of growth-mass and biochemical indices (Sukhanov B.P., 1987, Korolev A.A., 1997) on model groups of animals: growing white male rats of Vistar line with the initial body weight 70±5 g during 28 days. Biological value was judged from the value of coefficient of protein efficiency /2/. The content of available lysin was determined by the method of binding of color "orange", based on combination of two reactions: the first one between negatively charged group of azo dye and positively charged main nitrogen containing groups of lysin, histidine, arginin and the end groups of food proteins suspended in acid medium; the second reaction of propionilation of free amino groups of lysin with propionic anhydride, providing their blocking. The content of available lysin was determined by difference of the amount of dye for the first and second reaction.
Determination of taurin was carried out on liquid amino acid analyzer Biotronic LC-5000.

Results and discussion

A characteristic of amino acid balance of meat raw materials proteins is presented in Table 1.

Table 1.

№	Trimmed meat	Indispensable amino acids, g/100 g of protein									Cmin, %	Rp, Un.	σ, g/100g of product
		Protein, %	iso	leu	lys	meth+cys	phen+tyr	thre	trp	val			
1	Horse meat	19.5	4.6	9.8	7.5	4.0	8.6	4.6	1.5	5.2	78.16	0.84	6.96
2	Beef	18.7	4.2	7.95	8.54	3.87	7.81	4.32	1.13	5.86	75.33	0.79	9.18

Mature woman milk		1.4	4.5	9.0	7.0	3.9	8.6	4.0	4.6	5.0	100.0	1.0	0

As follows from presented data the protein of horsemeat as evaluated with the help of such indices of amino acid composition as minimum score (Cmin), coefficient of utility (R_p), coefficient of comparable redundancy (σ), shows rather high amino acid balance and is not inferior to beef and pork.

To describe the amino acid composition more completely investigations for determination of taurin - non-protein amino acid that is essential for infants - were carried out. Taurin is formed from sulfur-containing amino acids – methionine and cystine. It is a part of bile acids, relates to non-volatile compounds of meat and comes to the organism with foods of animal origin. Vegetable foods (vegetables, fruit, cereals etc.) and milk do not contain taurin. For children of this age conjugation of bile acids with taurin is typical, because taurin conjugates do not deposit under the conditions of acid medium in proximal part of small intestines, thus assisting in better fat absorption. Thus, with sufficient supply of taurin with foods biological value of protein increases at the expense of economic use of sulfur-containing amino acids, and assimilatiom of fats improves as well. The investigations carried out demonstrate a higher level of taurin in horsemeat - 134±5.3 mg/100g of product as compared to beef - 102±3.0 mg/100g of product.

Characteristic of fatty acid balance of fat in different kinds of meat is presented in Table 2.

Table 2.

Fatty acid composition of horsemeat as evaluated from the coefficient of fatty acid balance, by the content of sums of saturated, monounsaturated and polyunsaturated fatty acids (I = 1 … 3) and especially linoleic, linolenic and arachidonic (i = 1…6) is not inferior than the fat of beef and pork and can be acknowledged as highly adapted to fat of woman's milk.

Table 3 presents the composition of elements of beef, pork, horsemeat which are used for production of canned foods for children.
As is seen from Table 3, by its microelement composition horsemeat is close to beef, but contains more iron and copper which take part in the process of blood forming, which is a positive factor in curing and prophylactics of anemia.
Results of medical and biological evaluation of canned pork and horsemeat are presented in Table 4.
Analysis of data presented in Table 4 shows that canned horsemeat is not inferior by its biological value to canned pork and beef, and the available lysin tends to increase.
According to clinical tests carried out under the supervision of Dr. Sc. (Med.) Ladodo M.S and Dr. Sci. (Med.) Borovik T.E. high therapeutic efficiency of horsemeat is shown in curing of patients suffering food allergy, anemia, different forms of malabsorbtion of intestines.

Conclusions

Comparative evaluation has shown that horsemeat by its food and biological value is not inferior to beef and pork and can be used not only for healthy children of early age, but also in curative nutrition of children suffering food allergy, anemia, different forms malabsorbtion of intestines.

EFFECTS OF MODIFICATION OF FATTY ACID COMPOSITION OF ANIMAL PRODUCTS ON ADOLESCENT FATTY ACID INTAKE IN BELGIUM

[1]De Smet, S., [2]Matthys, C., [2]Bilau, M., [3]Van Camp, J., [4]Warnants, N., [1]Raes, K., [5]Sturtewagen, G. and [2]De Henauw, S.

Background

Over the last decades, much research has been devoted to the potential of modifying the fatty acid composition of animal food products, to better meet human nutritional guidelines. This research has mainly focused on increasing the content of polyunsaturated fatty acids (PUFA), aiming at increasing the P/S ratio (polyunsaturated/saturated fatty acids), on lowering the ratio of n-6/n-3 PUFA and on increasing the content of fatty acids with reported beneficial effects, e.g. long-chain PUFA and conjugated linoleic acids (Raes et al., 2004). There is little doubt that n-3 fatty acids are important in human nutrition (Connor, 2000).

There is growing interest in the animal feed industry to implement strategies fulfilling these objectives. However, the impact of such strategies on the actual fatty acid intake patterns of human population groups, and consequently the potential human health benefits, remain unclear. An assessment of the impact of strategies to modify the fatty acid composition of foods of animal origin on the fatty acid intake pattern of human populations is therefore desirable (Gibney, 1999). The outcome of such assessment could assist in evaluating the potential health benefits, which in turn need to be outweighed against the extra costs for implementing these strategies in the animal industry and against alternative strategies. A preliminary study was carried out in this regard, using human food consumption data and alternative fatty acid composition data of animal food products.

Objectives

To examine the impact of alterations in the n-6/n-3 PUFA ratio of animal foods on the pattern of fatty acid intake in the Belgian population. An alternative fatty acid composition profile for the major animal foods and two scenarios of implementation compared to a standard situation were considered.

Materials and methods

Food consumption data

Consumption data from a survey done in 1997 in a random sample of Flemish adolescents (aged 13-18 years; 129 boys and 212 girls) from the region of Ghent in Belgium were used. The dietary assessment method used was a 7-day diary, which was completed according to a standardised protocol. The database-architecture for this survey was generated on the basis of a commonly used Dutch dietary assessment tool, providing a detailed level of entries for food items (n=745 recorded in this study) (Unilever, 1992). A number of 527 foods contained fat following the food composition tables and were further used in this study.

Food composition data and fatty acid composition of animal products

Nutrient composition data routinely used in Belgium are those from the Belgian and the Dutch food composition tables (NEVO, 1993; NUBEL, 1992, 1995). However, differentiated data on the n-6 and n-3 PUFA are not available at the level of detail wanted in this study. The following approach was therefore adopted. The fat content of all food items was taken from the local food composition tables and was assumed to remain constant for the various scenarios analysed in this study. The origin of the lipid fraction was determined according to vegetable, land animal or marine origin or combinations thereof. The lipid fraction of land animal origin was further specified according to beef, pork, poultry, milk, eggs, sheep and horse. Subsequently, fatty acid content of the food items was obtained by linking the fat content and the contribution of the various lipid fractions to fatty acid proportions. For vegetable and marine fat sources, fatty acid proportions were taken from the McCance & Widdowson's and USDA food composition tables.

For land animal fat sources, two fatty acid composition profiles were considered for beef, pork, poultry, milk and eggs in the different scenarios envisaged in this study, i.e. a 'standard' and a 'n-3 enriched' fatty acid profile (Table 1). Because of the low intake of sheep and horse meat in Belgium, no alternative fatty acid composition was considered for these meats. Fatty acid composition was defined in terms of the sum of saturated fatty acids (SFA), the sum of monounsaturated fatty acids (MUFA), C18:2n-6 (linoleic acid, LA), C18:3n-3 (α-linolenic acid, LNA), C20:4n-6 (arachidonic acid, AA) and the sum of the long-chain n-3 PUFA C20:5n-3 (EPA), C22:5n-3 (DPA) and C22:6n-3 (DHA). The data were derived from a range of literature sources and from own information (for references see review of Raes et al., 2004). Values for the n-3 enriched profile were considered target values that could be obtained in commercial practice if feeds are including LNA rich sources, e.g. linseed and grass, at rather high levels that, however, do not compromise animal performances. The fatty acid composition of the meats was based on estimated contributions of intramuscular fat and subcutaneous fat (mainly for pork) and the differences in fatty acid composition between these fat depots. The use of fish oil or algae to increase the content of long-chain n-3 PUFA was not considered, hence higher levels of these fatty acids are resulting from elongation and desaturation of LNA.

Table 1. Standard (stand) and n-3 PUFA enriched (n-3) fatty acid profiles of the land animal fats assumed in this study (% w/w of total fatty acids)

	Beef		Pork		Poultry		Milk		Eggs		Sheep	Horse
	Stand	n-3	Stand	n-3	Stand	n-3	Stand	n-3	Stand	n-3	Stand	Stand
SFA	39.0	38.0	39.0	37.0	30.0	28.0	68.0	58.5	31.0	30.0	36.0	36.0
MUFA	39.0	38.0	39.0	37.0	38.0	36.0	25.0	32.0	41.5	39.0	35.0	34.0
C18:2n-6 (LA)	8.5	8.5	14.0	14.0	17.0	14.0	1.5	3.0	20.0	17.5	6.0	13.0
C20:4n-6 (AA)	1.5	1.5	0.4	0.4	3.0	3.0	0.0	0.0	2.0	1.0	2.2	1.7
C18:3n-3 (LNA)	1.0	2.0	1.5	5.0	2.5	7.0	0.5	1.3	1.0	7.0	1.5	7.5
LCn-3 (EPA, DPA, DHA)	0.5	1.0	0.3	0.5	2.0	4.5	0.0	0.0	1.5	2.5	2.8	1.6

Scenarios and calculations

Descriptive statistics and distributions for the intake of SFA, MUFA, LA, AA, LNA and LCn-3 PUFA were calculated for three scenarios, 1/ standard fatty acid composition of all land animal fats (Stand), 2/ n-3 enriched pork only (Pork+), 3/ n-3 enrichment of all land animal fats (All+). Scenario 2 and 3 correspond to a situation where all fattening pigs and all beef cattle, fattening pigs, poultry, dairy cows and layers, respectively, are fed diets high in LNA to achieve the fatty acid composition assumed in Table 1.

Results and discussion

Mean values for the intake of summarized and individual fatty acids in the different scenarios are given in Table 2. Mean values correspond reasonably well with data from an earlier study on the fatty acid composition of the Belgian diet, albeit in different population groups (Staessen et al., 1998). As expected, the largest changes in the mean fatty acid intake were observed for LNA and the LCn-3 PUFA. For LNA, the intake in g/p/d increased by 18% and 36% in the Pork+ and All+ scenario, respectively, compared to the standard scenario. The corresponding values for the relative increase of the LCn-3 PUFA intake are 6.5% and 35%. These changes were accompanied by a 6% decrease in the SFA intake in the All+ scenario, and relatively small increases in the intake of MUFA in the All+ scenario and in the intake of LA in the Pork+ and All+ scenario.

Table 2. Mean values for the fatty acid intake in the Standard, Pork+ and All+ scenario (gram/person/day, g/p/d and Energy%, E%)

Scenario	Standard		Pork+		All+	
	g/p/d	E%	g/p/d	E%	g/p/d	E%
SFA	35.8	14.4	35.6	14.3	33.6	13.5
MUFA	29.2	11.7	29.0	11.6	30.2	12.2
C18:2n-6 (LA)	14.1	5.65	14.5	5.83	14.7	5.90
C20:4n-6 (AA)	0.24	0.10	0.24	0.10	0.22	0.09
C18:3n-3 (LNA)	2.16	0.87	2.57	1.04	2.99	1.21
LCn-3 (EPA, DPA, DHA)	0.29	0.12	0.32	0.13	0.41	0.17

When the mean intake values are compared to nutritional recommendations (De Hoge Gezondheidsraad, 2003), none of the scenarios meet the criterium of SFA Energy% (E%) < 10. All scenarios meet the criteria MUFA E% > 10 and LA E% > 2. The mean value for the LNA E% is lower than the recommended value > 1 in the standard scenario, but exceeds this value in the Pork+ and All+ scenario. The recommended value for EPA+DHA E% > 0.3 was clearly not met in any of the scenarios. In addition, DPA was included in our data, making a significant contribution to the sum of the LCn-3 PUFA in land animal products. The average n-6/n-3 ratio dropped from 6.6 to 5.4 and 4.6 in the Pork+ and All+ scenario compared to the standard situation.

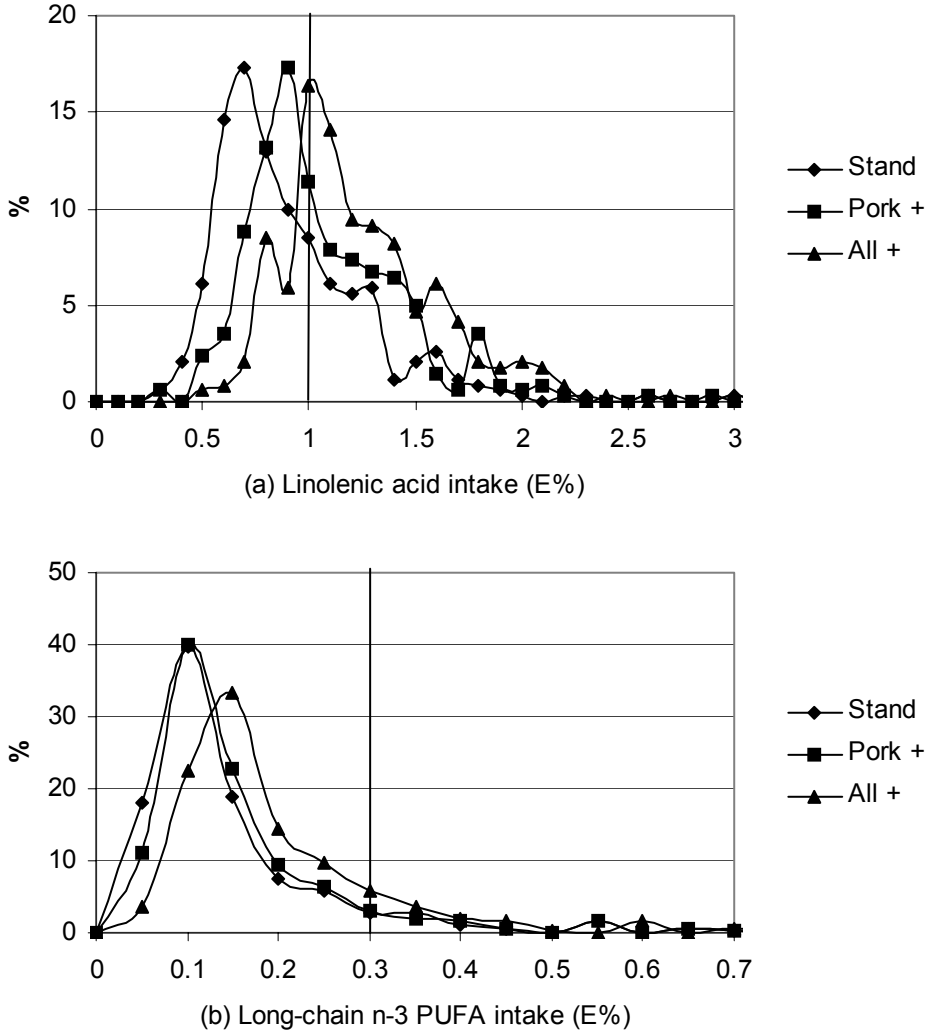

Figure 1. Distribution of the adolescent average daily intake of (a) LNA and (b) LCn-3 PUFA for the three scenarios (Energy%, E%). Vertical lines represent recommended minimum intake values.

The population distributions of the intake of LNA and LCn-3 PUFA are shown in figure 1. Interestingly, the largest increase in intake of these fatty acids occurs at the lowest intake levels. At high intake levels, there is almost no change, illustrating probably that a high intake of LNA and LCn-3 PUFA is not derived from land animal products, but from vegetable food sources and fish, respectively. High intake levels of the LCn-3 PUFA are only observed in a small part of the population, corresponding to the low average fish consumption in Belgium (De Henauw and De Backer, 1999). Staessen et al. (1998) calculated that meat was the most important source of n-3 PUFA in the Belgian diet. Hence, for a low-fish consumption population like in Belgium, strategies to increase the content of n-3 PUFA in land animal foods may be worthwhile. This may be even more valid in view of the increasing share of fish derived from aquaculture and the expected shift in fish feeding practices towards more n-6 fat sources.

This preliminary study has to be considered as a simulation study and an extrapolation to actual food intake patterns in the entire Belgian population is therefore speculative. Furthermore, the outcome of this kind of

assessment exercises is strongly determined by the assumptions made that may be debated at several points. Particularly the changes in fatty acid composition of the land animal fats in the alternative scenarios that were assumed may largely affect the outcome, e.g. a quite high reduction in the SFA content of 'n-3' milk was assumed, which may be responsable for the large drop in SFA intake in the All+ scenario. Similarly, the moderate increase in intake of LCn-3 PUFA in the Pork+ scenario compared to the relatively large increase in the All+ scenario may be due to a larger increase for the content of LCn-3 PUFA that was assumed for eggs, poultry and beef compared to pork. In addition, it is not very likely that an altered animal nutritional strategy will be adopted by the whole sector. Some modelling would be interesting in this respect, taking into account distributions in fatty acid composition instead of fixed mean values. Nevertheless, this preliminary study has shown the potential of this approach to evaluate the effects of alternative feeding strategies in the animal industry on human intake patterns. The potential impact on human health of these shifts in fatty acid intake is of course difficult to establish. In several human clinical studies using land animal foods with modified fatty acid composition following changes in the animals' diets, significant changes in the fatty acid composition of plasma and erythrocytes have been demonstrated (Sim and Nakai, 1994; Stewart et al., 2001; Weill et al., 2002). Hence, modification of the fatty acid composition of land animal foods may be a useful approach.

Conclusions

In this simulation study using Belgian food consumption data for adolescents, a relatively large but achievable enrichment in n-3 PUFA of either all pork or all major land animal products was calculated to increase the average daily intake of α-linolenic acid by 18% and 36%, respectively, and of the sum of long-chain n-3 PUFA by 6.5% and 35%, respectively. Although the outcome is largely affected by the assumptions that are made, this kind of assessment may help in evaluating the potential impact of new animal feeding strategies on human dietary intake and consequently on human health.

Background

The fatty acid composition of intramuscular fat can be influenced by factors such as diet (Rhee, 2000), breed (Robelin, 1986), age (Link et al., 1970) and the level of fatness of animals (Nürnberg et al., 1998). On the other hand, the fatty acid composition influences the nutritive value and the palatability of the meat. In relation to the nutritive value, consumption of saturated fatty acids (SFA) has been associated with an increase of plasma cholesterol and plasma low density lipoprotein levels, which are linked at the same time to a major risk of coronary heart disease. Conjugated linoleic acid (CLA), which arises from microbial hydrogenation of dietary linoleic acid in the rumen, exhibits anticarcinogenic properties when is included in the diet at low levels (French et al., 2000). Additionally, meat flavour is influenced by the saturation rate of fatty acids (Purchas et al., 1979). The polyunsaturated fatty acids (PUFA) are more susceptible to oxidation than monounsaturated fatty acids (MUFA), their oxidation is primarily responsible for the oxidative meat flavour deterioration (Gatellier et al,, 2001).

Objectives

The purpose of this study was to analyse fatty acid composition in commercial lamb types representing different production systems from Spain, German, United Kingdom and Uruguay to assess the extent of "natural" dissimilarity in their fatty acid composition.

Materials and methods

Five groups of 20 lambs slaughtered at usual commercial weight were used from four countries: Spain, United Kingdom, Germany and two types of Uruguay, heavy and light lambs, which are representative of their typical production system conditions. Spanish lambs were from Rasa Aragonesa breed, produced in an intensive-housed system, weaned and kept on concentrates and cereal straw *ad libitum* until slaughtering. The carcass weight was 10.2 ± 0.2 kg. British lambs were Dorset breed, mainly reared on a grass-based system, using strategic concentrate supplementation, being carcass weight 22.8 ±1.7 kg. German lambs were commercial lambs (crossbreed between Merino Landschaf x Suffolk or Schwarzköpfe); with a carcass weight of 23.2 ± 3.6 kg. They were reared on grass complemented with concentrate. Uruguayan lambs were from Corriedale breed, they were raised under extensive improved grazing conditions, producing two types of lambs; the carcass weight of light and heavy lambs were 11.1 ± 1.4 and 19.6 ± 2.2 kg., respectively.

Intramuscular fat was extracted from *longissimus lumborum* muscle (Hanson and Olley, 1963). Methyl esters of the samples were formed according to Morrison and Smith (1964), using nonadecanoic acid (19:0) prior to saponification as internal standard. Chromatographic analysis of methyl esters was performed using a Perkin-Elmer gas chromatograph (Perkin-Elmer, USA). Fatty acids were identified from standards and quantified using the internal standard.

One-way ANOVA was performed using GLM procedure from the Statistical Analysis System package (SAS, 1996). Differences between the means were determined using the Student-Newman-Keuls test. PRINCOMP procedure was used to principal component analysis, the variables were standardized.

Results and discussion

The least square means of the fatty acid composition (expressed as proportion by weight of total fatty acids) of the lambs and fatty acid ratios from typical production systems of the countries studied are shown

in table 1 and 2, respectively. Spanish and Uruguayan light lambs showed the lowest intramuscular fat proportion (2.41% and 3.05%, respectively) related to the lowest weights and ages at slaughtered in comparison with the rest of the lamb types, where the Uruguayan heavy lambs had the highest intramuscular fat proportion (5.92%) with intermediate position to United Kingdom (4.32%) and German lambs (4.25%).

Spanish lambs showed the highest proportion of C18:2 and lowest of C18:0, while the Uruguayan and German lambs had the highest percentage of C16:0. The proportions of C18:3 and C20:5 were higher with grass fed lambs (mainly Uruguayan) compared with lambs reared intensively using concentrates (Spanish and German lambs). These differences in fatty acid composition could be mainly related to differences in the feeding production system (grass or concentrate). Thus, Díaz et al. (2002) found lambs fed with concentrate showed lower percentage of C18:0 and higher C18:2 than lambs fed with pasture. Grass contains high levels of C18:3, precursor of the *n*-3 fatty acids series, while concentrate generated high level of 18:2 precursor of *n*-6 fatty acids series (Rhee, 2000).

The CLA isomer, *cis-9, trans-11 18:2*, was detected in all the lambs types evaluated. However, Spanish lambs had only 0.40 % of the total of fatty acids, while the other lambs, showed more than twofold (0.94 % and 0.79 % for light and heavy Uruguayan lambs, 0.97 % for German and 1.05 % for British lambs). French et al. (2000) showed the linear increment of intramuscular CLA concentration when the proportion of concentrate in the diet decreased. The high concentrations of rapidly fermentable sugar and soluble fibre of forage creates a rumen conditions which promotes a greater production or decreased utilization of CLA by the rumen (Kelly et al., 1998).

The highest P/S ratio was for Spanish lambs, due to their lower proportion of SFA and higher of PUFA. It could be due to differences in feed, age and fatness level. Thus forage stimulates ruminal activity promoting the biohydrogenation of the fatty acids, which in turn, increases the concentration of SFA (Choi et al., 1997). Link et al. (1970) showed in muscle that the proportion of PUFA decreased with increasing animal age and concomitant increases in intramuscular neutral lipid deposition. The increment of SFA with age and decrement of PUFA could be the reason why older animals (German, British and Uruguayan heavy lambs) showed low PUFA proportions and P/S ratio. With regard to fatness Nürnberg et al. (1998) found a negative relationship between fat content and PUFA, and Marmer et al. (1984) found that triacylglycerols, which increased with fatness, are less unsaturated than phospholipids in muscle membranes. The ratio *n*-6/*n*-3 was very high in Spanish lambs (8.42) related to the other lambs (lower than 2.5). According to Kemp et al. (1981), the use of concentrate resulted in raised concentrations of *n*-6 PUFA and grass diets increased *n*-3 PUFA.

Principal component (PC) analysis was performed on intramuscular fat to study the relationship between fatty acid percentages and to examine the relationships between the types of lambs compared. Figure 1 displays the projection of the fatty acid data in the plane defined by the two first principal components (PC). The first PC explained 34.97 % of the variability of the fatty acid composition. This component was mainly characterized by C18:2, C20:4 in the right hand side and antithrombotic relation (ATT) in the left one; where these variables were placed far from the origin of the first PC. The second PC explained the 21.50 % of the variability, it was defined by long chain fatty acids (C22:5, C22:6 and C20:5) and in the opposite direction by MUFA, which were placed far from the origin of the second PC. However, Bas and Morand-Fehr (2001), using PCs analysis to study fatty acid composition, found that the first two PC explained about 45% of the total variance in subcutaneous and intramuscular fat, and about 60% in perirenal adipose tissue. The projection of the fatty acid data in the plane defined by the two first principal components of the five groups studied is shown in figure 2. Spanish lambs were clearly separated from rest of lamb types and were placed on the right hand, close to short chain fatty acids and *n*-6. The Uruguayan light lambs were located down in the figure, close to long chain fatty acids, whereas Uruguayan heavy and British lambs are slightly moved on the left side, where ATT, C18:0, SFA and CLA lay and German lambs were located between Spanish lambs and the other three groups.

Conclusions

The Spanish lambs fed with concentrate had lowest SFA proportion and higher PUFA proportion, therefore they had a better ratio P/S compared with the rest of the lambs types. The Uruguayan light lambs were similar to Spanish lambs in relation to PUFA proportion, and Uruguayan heavy, German and British lambs showed similar proportions of CLA, SFA and PUFA as well as P/S. Uruguayan heavy lambs had lower *n*-6/*n*-3 ratio in comparison with the German lambs, being the United Kingdom lambs placed between them.

EFFECT OF ROSEMARY EXTRACT ON THE FORMATION OF HETEROCYCLIC AROMATIC AMINES IN FRIED BEEF PATTIES

Monika Gibis, Ute Jautz and Albert Fischer

University of Hohenheim, Institute of Food Technology, Department of Meat Technology, D-70593 Stuttgart, Germany

Background

Epidemiological studies have shown that the daily diet can be responsible for various types of cancer. Heterocyclic Aromatic Amines (HAA) are especially found in the crust of fried meat and fish. These substances are formed during the Maillard reaction from creatinine, carbohydrates and amino acids. Several HAA have been shown to be carcinogenic in long-term animal studies on rodents and non-human primates (Adamson et al., 1990). The International Agency for Research on Cancer has classified several HAA as possible human carcinogens and recommends the reduction of these compounds in exposure of humans (IARC, 1993). Besides the important physical parameters such as temperature and heating time, natural antioxidants should inhibit the formation of HAA, because free radicals are involved in the complex Maillard reaction and the formation of HAA.

Objectives

The objective of this study was to examine the possibility of reducing the formation of HAA in beef patties by using a commercial rosemary extract. Additionally, the beef patties were tested for sensory parameters such as taste, smell, juiciness and colour.

Materials and methods

Preparation of beef patties

Plain beef, roughly desinewed and defatted, was coarsely minced through a 3 mm plate. 1.2 % salt and the liquid extract of Rosmarinus officinalis (Tab.1) (Flavor Guard LO W/S, Chr. Hansen, Germany) in concentrations of 0.5, 0.75, 1.0 and 2.0 g/kg were added to the minced beef, respectively. The control batch was prepared without the extract. After mixing 80 g ± 1 g of the material, the beef patties (16 mm thick x 85 mm diameter; estimated fat content of 12 %) were formed with a special mould.

Heating devices

The patties were put between two pieces of tin foil, which were coated with sunflower oil. The two grill plates of a double contact grill (Nevada-grill, Neumärker, Hemer, Germany) produce a temperature of 230 °C. The patties were immediately fried on both sides simultaneously for 5 min to a core temperature of 72 °C and to a surface temperature < 190 °C at the end of the frying process.

Colour measurement of beef patties

One hour after heating, the L*(brightness)-, a*(redness)- and b*(yellowness)- values were determined by using a Chromameter CR 200 (Minolta, Ahrensburg, Germany).

Determination of HAA

The method of HPLC analysis with some modifications was based on the method described by Gross and Grüter (1992). The quantification was carried out with an external calibration (Norharman and Harman) or standard addition (MeIQx, 4,8-DiMeIQx, PhIP).

Sensory test

Sensory testers evaluated colour, juiciness, taste and smell of the fried samples with a scale from 0 (very unpleasant) to 6 (very pleasant). After frying, the samples were frozen for a week and reheated in a microwave for the sensory test.

Determination of weight loss during frying

The beef patties were weighed before and 1 hour after heating.

Results and discussion

There are different kinds of rosemary extracts in trade. Some of these extracts are in powder form and contain maltodextrin as carrier. These extracts were not suitable for our investigations because maltodextrins as carbohydrates can influence the Maillard reaction and the HAA formation consequently (Skog and Jägerstad, 1990). The different extracts also include strongly differing concentrations of carnosol, carnosolic acid and other antioxidant compounds such as phenolic diterpenes. These substances have a very high antioxidant potential and inhibit the warmed-over flavour in the patties, which were frozen and reheated in the microwave. The rosemary extract used was a water dispersible liquid, which contains lecithin and polyglycerides as emulgators. But the extract contains a lower content of carnosol and carnosolic acid (Tab. 1), while the products in powder form contain up to 17 %.

Figure 1 shows the effect of the used rosemary extract on the formation of HAA. PhIP was the only compound significantly reduced by adding the rosemary extract. The lowest concentration had approximately the same effect on the PhIP formation as the highest. The lowest used concentration was the recommendation of the extract producer for patties. Higher concentrations of the rosemary extract in the patties showed no further reduction effect on PhIP. The three highest concentrations of extract addition increased the amount of the MeIQx formation slightly. The PhIP content was reduced by 64 % in the average of all used extract amounts. Norharman and Harman were found in all beef patties but the contents increased with higher addition of rosemary extract.

The colour (Fig. 2) and the weight loss of the patties showed no significant differences between the batches with or without extract. Figure 3 shows the result of the sensory evaluation. All patties were evaluated equally pleasant as the controls without rosemary extract. The taste of the patties with extract was described pleasantly spicy. Even the higher amounts of extract addition did not result in over-spiced products.

Some authors have reported reductions in the content of HAA in fried ground beef patties as a result of adding oleoresin rosemary (Balogh et al., 2000). In this study, rosemary oil, when used in two concentrations (1 % and 10 % based on fat content), reduced PhIP formation by 44 % in fried meat. Contrary to these findings, some authors have reported that the formation of PhIP increases slightly with the addition of rosemary flavour. Additionally, no correlation could be found between the oxidative properties of the flavours and the formation of PhIP (Zöchling et al., 2002).

Conclusions

In the present study, only the content of PhIP decreased significantly with the addition of commercial rosemary extract. All other HAA, especially Norharman and Harman, increased slightly with the addition of rosemary extract. The PhIP content in the fried beef patties was reduced by 64 % in the average of all used extract amounts. The flavour and colour of the patties with rosemary extract were found pleasant.

THE EFFECT OF GENDER ON THE MEAT QUALITY CHARACTERISTICS OF KUDU *(TRAGELAPHUS STREPSICEROS)*

Hoffman, L. C.

Department of Animal Sciences, University of Stellenbosch, P Bag X1, Matieland 7602, South Africa.

Background

The kudu, one of Africa's most majestic animals shows strong sexual dimorphism, the male bears enormous spiral horns, which attains full length (≈120 cm) at six years of age, reaches a larger size (≈250 kg live weight) than the female (≈180 kg live weight) and is more predominantly adorned with manes of hair on the back and neck. Kudu are predominantly browsers, but will occasionally graze. Kudu occur throughout the savannah regions in central Africa south of the equatorial forests, through East Africa to Ethiopia, Sudan and Chad down to the Eastern Cape (South Africa), and are common throughout bushveld areas where there are stands of bush, they do not occur in open grassland and forest. Within South Africa, this species is hunted regularly for local consumption, particularly in the form of biltong (slices of meat, lightly salted and air-dried, similar to jerky). Of the R843m generated by the game industry in South Africa during 2000, 53.4% was generated by the biltong hunting industry and a further ≈3% by the game meat industry (Bothma, 2002). Kudu meat is also a regular item in most South African restaurants that serve game meat and is also frequently exported (Hoffman & Bogalke, 1999).

Objectives

Although this species is consumed regularly, very little data seems to have been published as pertaining to the muscle chemical composition and other quality attributes of its meat. In the present investigation, the proximate and fatty acid chemical composition of the *M. longissimus dorsi et lumborum* of eighteen animals are presented.

Materials and methods

Eighteen kudu were harvested early in the evening during winter in the Tussen die Riviere Nature Reserve in the Free State Province, South Africa. Of these, eight were males (varying in live mass from 111 to 179 kg) and ten females (live mass from 68 to 152 kg).

Standard harvesting techniques were utilised (Hoffman, 2003) with the animals all being killed instantaneously with a head shot using a .270 calibre rifle fitted with a telescopic sight. Live mass was recorded on the hot carcasses after being bled, approximately 60 min *post mortem*. The animals were then eviscerated, skinned and cleaned, followed by the removal of the head, gut and other edible and non-edible parts of the body. These included the kidneys, liver, lungs, internal fat as well as the leg from the hoof to the knee. The carcasses were then moved into a cooling facility overnight. The dressed carcasses were removed from the cooler (set at 4°C) early the next morning (≈12 h *post mortem*) and weighed for calculation of the dressing percentage and for removal of the muscle samples for chemical analysis. For chemical analysis the *M. longissimus dorsi et lumborum* (MLD) was removed from between the 12th and 13th rib to between the 4th and 5th lumbar vertebra.

The lean meat samples (MLD) were placed in polyethylene bags, vacuum-sealed and placed in a freezer at –20°C until further chemical analyses could be carried out. Proximate analysis was conducted on the MLD samples. After removing the subcutaneous fat and superficial connective tissue, the frozen muscle samples were cut into smaller portions, minced three times through a 2 mm sieve to ensure homogeneity, and analysed chemically. Total percentage moisture, protein and ash were determined according to standard AOAC methods (AOAC, 1997). The moisture content was analysed by drying a 2.5 g sample at 100°C for a period of 24 h. The protein (N x 6.25) content was determined by the block digestion method (AOAC, 1997), while ashing was done at 500°C for a period of 5 h. The total fat content was determined by extracting the fat with a 2:1 mixture of chloroform:methanol (Lee, Trevino & Chaiyawat, 1996).

The fatty acid content was determined using the same method described by Tichelaar *et al*. (1998). After thawing the meat, the lipids in a 2 g sample were extracted with chloroform/methanol (CM 2:1; v/v). All the extraction solvents contained 0.01% butylated hydroxytoluene (BHT) as an antioxidant. A polytron mixer (Kinematica, type PT 10-35, Switzerland) was used to homogenize the sample within the extraction solvent. Heptadecanoic acid (C17:0) was used as an internal standard to quantify the individual fatty acids. A sub-sample of the extracted lipids was transmethylated for 2 h at 70°C using methanol/sulphuric acid (19:1; v/v) as transmethylating agent. After cooling, the resulting fatty acid methyl esters (FAME) were extracted with water and hexane. The top hexane phase was transferred to a spotting tube and dried under nitrogen. The FAME were purified by TLC (silica gel 60 plates) and analysed by GLC (Varian Model 3300 equipped with flame ionisation detection) using a 60 m BPX70 capillary columns of 0.25 mm internal diameter (SGE, Australia). Gas flow rates were, hydrogen, 25 ml/min; and hydrogen carrier gas 2-4 ml/min.

Temperature programming was linear at 3°C/min, with an initial temperature of 150°C, a final temperature of 220°C, an injector temperature of 240°C and a detector temperature of 250°C. The FAME in the total lipids were identified by comparison of the retention times to those of standard FAME mixture (Nu-Chek-Prep Inc., Elysian, Minnesota).

A standard analysis of variation was performed on the various parameters measured and differences were tested for by means of student's t-test using SAS version 8.2 (SAS, 2002) statistical software.

Results and discussion

Due to the fact that non-trophy status bulls (young animals) were cropped, there was no significant difference for the live weight (121.30±10.531 vs 137.79±7.680 kg), carcass weight (72.40±6.684 vs 79.25±4.709 kg) or dressout percentage (59.55±0.942 vs 57.45±0.651 %) between the females and males respectively. This value is similar to the 58% reported for other game species such as the impala (Hoffman, 2000). The proximate chemical composition of the MLD is shown in Table 1. None of the parameters differed significantly between the sexes and the low lipid values indicate that kudu meat could be considered as a healthy lean meat.

Table 1. The average (±se) chemical composition of the *M. longissimus dorsi et lumborum* of female and male kudu.

Parameter	Female (n=10)	Male (n=8)	Pr > |t|
Moisture (%)	74.15 ± 0.285	74.49 ± 0.162	0.3420
Protein (%)	24.29 ± 0.278	23.58 ± 0.181	0.0591
Lipid (%)	1.56 ± 0.093	1.58 ± 0.056	0.8802
Ash (%)	1.29 ± 0.021	1.23 ± 0.032	0.0897

In Table 2 the fatty acid content of the MLD is shown. The following fatty acids were not detected: C22:0, C22:4n-6, C24:0 and C24:1n-9. Only two of the longer chained polyunsaturated fatty acids (C20:3n-6 and C20:%n-3) differed between the females and males, the later having a higher concentration each time. Of the kudu muscle's fatty acids, 37% were saturated, 22% monounsaturated and 41% polyunsaturated. The level of arachidonic acid was particularly high (≈8%) and was 0.47 mg per 100 g meat. The kudu had a very high mean desirable fatty acid (stearic acid plus all unsaturated fatty acids) content of 83%. The mean polyunsaturated to saturated ratio (1.12) were all well above the recommended 0.45 advocated by the British Department of Health (Enser *et al*., 1998). The n-6:n-3 PUFA ratio (2.34) was also well below the British department of Health's recommended figure of 4.

Table 2. The mean (±se) fatty acid content (%) of the *M. longissimus dorsi et lumborum* of female and male kudu.

Fatty acid	Female (n=10)	Male (n=8)	Pr > |t|
C16:0	17.53 ± 0.688	16.10 ± 0.343	0.1058
C16:1n-7	0.70 ± 0.129	0.52 ± 0.054	0.2637
C18:0	20.00 ± 1.157	19.72 ± 1.086	0.8642
C18:1	21.94 ± 1.455	19.91 ± 0.967	0.2873
C18:2n-6	19.03 ± 1.313	20.53 ± 0.786	0.3701
C18:3n-3	4.67 ± 0.383	4.85 ± 0.395	0.7463
C18:3n-6	0.08 ± 0.028	0.05 ± 0.026	0.4774
C20:0	0.20 ± 0.035	0.11 ± 0.418	0.1147
C20:1n-9	0.10 ± 0.030	0.06 ± 0.033	0.3313
C20:2n-6	0.12 ± 0.032	0.15 ± 0.083	0.7227
C20:3n-6	0.92 ± 0.049	1.14 ± 0.050	0.0076
C20:4n-6	7.74 ± 0.455	8.44 ± 0.376	0.2702
C20:5n-3	2.50 ± 0.256	3.17 ± 0.147	0.0492
C22:5	2.42 ± 0.150	2.75 ± 0.139	0.1349
C22:6n-3	2.06 ± 0.2391	2.50 ± 0.227	0.2022

Conclusions

The chemical composition of kudu *M. longissimus dorsi et lumborum* indicates that this meat could be classified as nutrient dense. Of particular interest is the high protein (≈24 g per 100g meat) and low fat content (≈1.5 g per 100 g meat) of the meat. The fatty acid profile of the meat is also very advantageous for human consumption by being highly unsaturated (≈ 63%) with a positive n-6:n-3 ratio. Eighty-three per cent of the fatty acid found in the meat could be classified as being desirable for human consumption. Analysis of the levels of Vitamin E and other anti-oxidants will be of value to see how prone towards rancidity the meat is. Similarly, the effect of the low lipid content on consumer acceptability (flavour, juiciness, etc) requires elucidation. Further research is also required on the amino acid and mineral profile of this meat.

Background

Ante mortem and *post mortem* factors influence nutritive value of beef (Seideman *et al*., 1989). Production patterns and the grading system in Venezuela differ from those applied in the U.S.A. Therefore, notorious differences in beef chemical composition and quality might be expected. Based on the wide variation in palatability of Venezuelan beef, the hotels, restaurants and other food service institutions (HRI) have been purchasing imported U.S. Choice or Select beef. Beef imports from U.S.A. have been banned since January 2004 because of the BSE issue. If import resumes, it is anticipated that consumer preference towards U.S. beef will continue. Top quality, well-marbled U.S. beef generally has a thick cover of fat that an increasing number of consumers find repelling. These consumers are either concerned with diet/health issues or are simply typical, price-oriented Venezuelans, who always look for lean beef, with no plate waste. The Venezuelan diet-health oriented, high-income market niche, could be satisfied by a national product if nutrient compositional advantages were guaranteed. To our knowledge, differences between Venezuelan and American beef in proximate and mineral composition have not been scientifically proven. The only available report (Huerta-Leidenz, 1998) compared beef *longissimus* from both origins indicating nutrient reference values from indirect sources; this is, without performing simultaneous analyses of samples under the same laboratory conditions.

Objectives

a) To compare marbling levels, proximate and mineral composition of top-graded Venezuelan and American beef samples commonly used by restaurants of Venezuela; and
b) To examine the variation in marbling levels and chemical composition due to muscle.

Materials and methods

Procurement of high-quality, imported U.S. beef samples

Twenty wholesale Beef Loin, Top Sirloin Cap (Coulottes) and 10 Beef Rib, Ribeye, Lip-On (Ribeyes) cuts were procured frozen in boxes labeled as "Choice or higher" (CH-or-Higher), and transported to Universidad del Zulia (LUZ). Upon arrival, marbling scores were individually assigned. One 2.54cm thick steak was fabricated and kept frozen (-20ºC). To be prepared for chemical analyses, partially thawed steaks were trimmed to zero fat cover (and other surrounding muscles in the case of ribeye). *Longissimus dorsi thoracis* (LDT) and *biceps femoris* (BF) muscles, from ribeyes and coulottes, respectively, were ground for homogenization with a Black & Decker™ food manual processor. Ground muscles were packed by duplicates in plastic Zip-lock™, bags and immediately stored at -20ºC until chemical analyses.

Venezuelan samples of known production history.

A first group of Venezuelan samples were derived from 18 steers of known genetic history (9 F1 Angus and 9 ¾ Brahman) semi-intensively fed during 60d. Animals were slaughtered and hot carcasses were graded (Decreto Presidencial 1896, 1997). In each breed type two carcasses were graded as Optima ("AA") and seven carcasses were graded as Excelente ("A"). At 72 h *post-mortem* ribeyes and coulottes were removed. Steak fabrication and preparation for chemical analyses was similar to the U.S. beef steaks.

Venezuelan samples of unknown production history

Twenty coulottes (10 "A" and 10 "AA") and 20 Ribeye roasts (10 "A" and 10 "AA") were purchased fresh from different butcher stores and supermarkets of Maracaibo city. Both types of retail cuts were reduced to 2.54cm thick steaks and the marbling level was determined with marbling photographs. Steak fabrication and preparation for chemical analyses was similar to the U.S. beef steaks.

Chemical analyses

Except for total lipids (by the Folch *et al.,* 1957 method), proximate analysis was performed according to the A.O.A.C. (1997). Except for phosphorus (by the A.O.A.C., 1997 method), mineral analyses were conducted by atomic absorption and/or atomic emission with ashing procedure (A.O.A.C, 1997), following the analytical methods described by Perkin-Elmer (1994).

Statistical analyses

Marbling scores and proximate compositional data were subjected to a simple one-way analysis of variance (ANOVA) to test differences due to grade (SAS, 1996). ANOVA of mineral contents included the effects of muscle, grade and the two-way interaction. The least squares means (LSMEANS) were separated by Tukey-Kramer´s test (SAS, 1996).

Results and discussion

Marbling levels

ANOVA detected effect (P=0.0001) of carcass grading on marbling level of BF and LDT samples (mean values are not shown in tabular form). Mean marbling levels in domestic BF samples were described as "Traces", while IMPORTED counterparts averaged a higher (P<0.01) "Small" amount of marbling. Top quality ("AA") domestic LDT exhibited "Slight" amounts of marbling, higher (P<0.05) than the "Traces" level described for the second-quality Venezuelan ("A") LDT, but still inferior (P<0.05) to the "Moderate" level found in CH-or-Higher LDT.

Proximate composition

Highly significant effects (P<0.001) of carcass grade on moisture and total lipid contents of BF and LDT were detected. Variation of protein content in BF samples was detected at P<0.10. CH-or-higher BF and LDT samples had lower (P<0.0001) moisture and higher lipid contents when compared to A and AA domestic samples (Table 1 and 2). To our knowledge there are no available reports in Venezuela regarding to the effect of carcass grade on proximate composition of the retail cuts under study.

Table 1. Least square means ± standard error for proximate composition of *biceps femoris*

Component (g/100g of fresh tissue)	Grades[a]		
	A (n=24)	AA (n=14)	Choice-or-higher (n=20)
Moisture	74.35 ± 0.30 [b]	74.27 ± 0.40 [b]	71.71± 0.34 [c]
Ash	1.22 ± 0.02	1.18 ± 0.03	1.20 ± 0.02
Protein	20.46 ± 0.15	20.36 ± 0.21	19.94 ± 0.15
Total lipids	3.46 ± 0.43 [b]	4.18 ± 0.57 [b]	6.01 ± 0.48 [c]

[a] Abbreviations of commercial terminology used to designate quality grades for beef carcasses in Venezuela and U.S.A. Letters A and AA corresponds respectively, to the second ("Excelente") and first ("Optima") quality grades in Venezuela (Decreto 1896, 1997); CH-or-Higher corresponds to imported U.S. boxed beef labeled as "Choice or higher".
[b,c] different letters in the same row indicates significant differences (P<0,05)

Table 2. Least square means ± standard error for proximate composition of longissimus dorsii thoracis

	Grade[a]		
Component (g/100g of fresh tissue)	A (n=24)	AA (n=14)	Choice-or-higher (n=10)
Moisture	74.68 ± 0.32 [b]	74.03 ± 0.42 [b]	68.17 ± 0.52 [c]
Ash	1.13 ± 0.01	1.14 ± 0.02	1.10 ± 0.02
Protein	21.87 ± 0.12	21.48 ± 0.16	21.94 ± 0.19
Total lipids	1.96 ± 0.38 [b]	2.99 ± 0.50 [b]	7.97 ± 0.60 [c]

[a] Abbreviations of commercial terminology used to designate quality grades for beef carcasses in Venezuela and U.S.A. Letters A and AA corresponds respectively, to the second ("Excelente") and first ("Optima") quality grades in Venezuela (Decreto 1896, 1997); CH-or-Higher corresponds to imported U.S. boxed beef labeled as "Choice or higher".
[b,c:] LSMEANS bearing different letters in the same row indicate statistical difference (P<0.05).

Mineral composition

ANOVA detected significant effects (P<0.05) of muscle and carcass grade on the mineral content.

Muscle effects

Except for Mg, P and Na, ANOVA detected the effect of muscle (P<0.05) on variation of most individual minerals under study (Table 3).

Table 3. Least Square means ± standard error for the mineral content of fresh, lean muscles.

	Muscle				
	Biceps Femoris		*Longissimus dorsi thoracis*		
Mineral (mg/100g of fresh tissue)	n		n		P value
Ca	58	6.8 ± 0.18	48	7.4 ± 0.21	0.026
Fe	58	2.4 ± 0.03	48	1.9 ± 0.04	0.001
Mg	54	23.3 ± 0.22	47	23.4 ±0.26	NS
P	58	197.0 ± 1.00	48	198.1 ± 1.14	NS
K	56	347.0 ± 2.02	45	354.3 ± 2.33	0.021
Na	58	61.3 ± 0.71	48	59.4 ± 0.81	0.09
Zn	58	3.8 ± 0.06	48	3.5 ± 0.06	0.002
Cu	58	0.04 ± 0.004	48	0.02 ± 0.004	0.001

NS = Non significant (P> 0.1)

Grade effects

Table 4 shows adjusted LSMEANS for the mineral content of muscles according to grade. "Choice or higher" samples showed higher Ca, Fe and Zn and lower P and K as compared to domestic samples. Mineral content did not vary (P>0.05) across Venezuelan grades. Mineral concentrations for domestic samples coincide with that presented in a previous report (Huerta-Leidenz *et al*., 2003).

Conclusions

Both imported and domestic beef muscles are highly nutritious foods and good sources of protein, Fe, P and Zn; Venezuelan beef steaks should have comparative advantages in the diet/health market niche due to their exceptional leanness.

Table 4. Least Square means ± standard error for the mineral content of 100g of fresh, lean sample, according to carcass grade.

Mineral (mg/100g of fresh tissue)	Grade[a]					
	A		AA		CH-or-higher	
	n		n		n	
Ca	48	6.0 ± 0.20 [b]	28	6.6 ± 0.26 [b]	30	8.6 ± 0.26 [c]
Fe	48	2.1 ± 0.04 [b]	28	2.0 ± 0.05 [b]	30	2.4 ± 0.05 [c]
Mg	43	23.9 ± 0.25 [b]	28	23.2 ± 0.31 [bc]	30	22.9 ± 0.32 [c]
P	48	201.4 ± 1.07 [b]	28	199.1 ± 1.40 [b]	30	192.0 ± 1.44 [c]
K	44	360.7 ± 2.24 [b]	27	349.9 ± 2.86 [b]	30	341.3 ± 2.87 [c]
Na	48	60.3 ± 0.76 [b]	28	60.8 ± 0.99 [b]	30	59.9 ± 1.02 [b]
Zn	48	3.3 ± 0.06 [b]	28	3.5 ± 0.08 [b]	30	4.2 ± 0.08 [c]
Cu	48	0.030 ± 0.004 [bc]	28	0.034 ± 0.005 [b]	30	0.021 ± 0.005 [c]

[a] Abbreviations of commercial terminology used to designate quality grades for beef carcasses in Venezuela and U.S.A. Background

According to the U.S Meat Export Federation, in 2002 Venezuela took up the third position among the leading markets for U.S. beef in Central and South America. Currently, Venezuela has kept a ban on imports of U.S. beef due to its BSE status. Substitution of high quality U.S. beef in the Venezuelan HRI trade is a clear opportunity but a serious challenge for national beef producers. Some Venezuelan cattlemen, particularly from the Zulia State regions, have been modifying traditional practices (genetics, gender, feeding, and management) to offer competitively, young steer carcasses that grade in the high-quality Venezuelan standards (Decreto 1896, 1997). Despite all these particular efforts, there is a lack of information about how well this new concept of "high-quality" Venezuelan beef will compare in consumer acceptance to imported U.S. beef of the top USDA grades.

Objectives

The purpose of this study was to compare particular samples of high-valued HRI beef cuts of different background (domestic vs. imported) in cookery traits, consumer sensory ratings, and shear force values, according to grade.

Materials and methods

Procurement of high-quality, imported U.S. beef samples. A total of 12 wholesale Beef Loin, Top Sirloin Cap (IMPS/NAMP 184D, commonly referred as Coulottes) and 10 Beef Rib, Ribeye, Lip-On (IMPS/NAMP 112A, commonly referred as Ribeyes) cuts (NAMP, 1997), were procured from the two major food trading companies of Venezuela. The U.S. wholesale cuts were individually vacuum packaged, imported in boxes labeled as "Choice or higher" (CH-or-Higher) and kept in frozen storage (-20ºC). U.S. wholesale cuts were transported to Universidad del Zulia and three 2.54 cm thick steaks were fabricated and kept frozen (-20ºC) until further analyses.

Procurement of high quality, domestic samples. Twenty steers of known genetics (10 F1 Red Angus and 10 ¾ Brahman) were selected to represent a unique "high-quality" domestic beef sample produced in a particular zone of Zulia State. The steer group was placed on pastures during the stocking phase. The semi-intensive fattening (concentrate supplementation) phase lasted 60 d. The group was subjected to typical industry procedures. At 24 h post-mortem, chilled carcasses were evaluated and graded according to Venezuelan (Decreto Presidencial 1896, 1997) and USDA standards (USDA, 1989). Ribeyes and coulottes were removed from the right side of each carcass 48h postmortem. Three 2.54cm-thick steaks were identified, vacuum packaged, and immediately stored at 4ºC during 15 d for aging. When the aging period was completed, samples were blast frozen at -20ºC. Frozen samples were transported in a refrigerated truck to LUZ. Upon arrival, the samples were stored in home freezers during 20 d until further analyses.

Cookery, sensory evaluation and shear force determinations. Sample preparation, cooking procedures and cooking equipment followed those guidelines described by AMSA (1995). Sensory evaluation of the LDT samples was conducted with 69 consumers. Sensory evaluation of the BF samples was conducted two days after with 77 consumers. Overall first impression, flavor, and tenderness were surveyed by using hedonic, non-descriptive, 1-to-9 rating scales (1= Dislike very much; 9= Like very much). Additionally, flavor intensity was evaluated by a descriptive, non-structured hedonic scale (1= Insipid; 9= Strong). Warner-Bratzler shear force determinations (WBS) of LDT and BF samples were conducted simultaneously during two days.

Statistical Analyses.
Carcass data. A simple one-way analysis of variance (F-test) to test differences due to breed type was conducted (SAS, 1996).
Cookery and sensory data. Muscle data were subjected to analysis of variance (ANOVA) by SAS (1996) using cold carcass grade as the main effect, and consumer panelist as a block. The least squares means (LSMEAN) were separated by Tukey-Kramer´s (SAS, 1996). The proportion (%) of consumers indicating rating values of 6 or higher for the overall first impression was used as a measure of acceptability.
WBS data. The effects of grade, muscle and the two-way interaction were analyzed and LSMEANS were separated by Tukey-Kramer´s test (SAS, 1996). The proportion of Tender (WBS value = <3.88 kg), Intermediate (WBS value = 3.88 to 4.98 kg) and tough (WBS value = >4.98 kg) steaks, were determined using tenderness thresholds values (Huerta-Leidenz and Rodas-Gonzalez, 1998).

Results and discussion

Carcass quality of the samples. F1 Red Angus steer carcasses were younger (A^{84} ± 2.91 vs. B^{01} ± 2.91; P=0.0006) according to their skeletal maturity, and trended to exhibit an overall better fleshing as compared to the ¾ Brahman steers. While 70% of the F1 Red Angus carcasses fell in the top quality Venezuelan grade, none of the cold ¾ Brahman carcasses did. Ribeye marbling scores of F1 Red Angus (Practically devoid^{94} ± 27.1) and ¾ Brahman steers (Traces^{70} ± 27.1) were not different (P> 0.05). Average marbling levels for the samples of U.S. "Choice or higher" beef used in the present study, were Small^{98} ± 26.24 and Moderate^{59} ± 32.39, for BF and LDT muscles, respectively.
Cookery traits. Table 1 shows LSMEAN values for cookery traits according to grade and muscle. BF Choice-or higher samples required less (P<0.05) time to reach the endpoint temperature. LDT samples showed similar cooking times to longissimus samples derived from Venezuelan "A" bulls (Malaver et al., 2000). Percentage of cooking loss did not vary across breed types or grades. The greater (P<0.05) weight losses of the U.S. beef steaks are attributed to their larger sizes.
Consumer Sensory Evaluation. Table 2 shows LSMEANS for consumer ratings of sensory traits of LDT and BF according to grade. Consumers assigned higher (P<0.01) ratings to the U.S. imported LDT in all sensorial traits under study. The fact that U.S. CH-or-Higher LDT samples obtained the highest (P<0.001) consumer ratings for flavor and flavor intensity was unexpected. It is commonly believed that many Latin American consumers; accustomed to the strong flavor of relatively old, grass-fed beef, are not pleased with the taste of U.S. beef, due to its bland flavor. In regard to BF muscles, non-significant differences in tenderness were found between the BF steaks graded AA and their Choice-or-higher counterparts.
Level of consumer acceptability. Table 3 shows percentages of consumer acceptability of LDT and BF according to grade. CH-or-higher LDT exhibited the highest level of acceptability (80%). Level of acceptability for each grade, calculated by pooling sensory data from both muscles showed (not presented in tabular form) the highest acceptability level --approximately 67% of 146 evaluations-- was reached by the CH-or-Higher beef. No previous consumer preference studies had been conducted in Venezuela to compare beef from different origins.
Shear force determinations and tenderness classes. No significant variation (P> 0.05) in WBS values due to muscle, or to muscle x grade was detected; therefore, muscle data were pooled. LSMEANS values for WBS by grade, were decreasing in the sequence A >AA> CH-or-Higher, with a significant difference between the top-quality, Venezuelan AA grade and its U.S. counterpart (Table 4). It is noteworthy to indicate that no tough steaks were detected for any sample of the three grades (Table 4). An outstanding proportion (94%) of tender steaks was exhibited by the CH-or-Higher samples.

Conclusions

The use of imported Choice-or-higher BF and LDT cuts is highly justified based on the high consumer acceptability level observed herein. The inferior and unacceptable tenderness impression ratings of Venezuelan grade A BF and LDT steaks, prevents its use in gourmet-type restaurants.
Similar tenderness ratings between the Venezuelan top quality AA and Choice-and-higher, BF steaks, does not necessarily indicate that they can be used interchangeably in the HRI trade, because the first impression and flavor of AA steaks were rated as unacceptable (<6 points). The shorter cooking time of "Choice and higher" BF steaks is another important consideration for food service operators.
Due to the low number of observations and the very specific nature of the samples under study, the present findings must be taken as preliminary.

Lab. of Animal Origin Food Science, School of Agricultural Biotechnology, Seoul National University,
* Dept. of Public Health, College of Veterinary Medicine, Seoul National University, Seoul, 151-742, Korea

Background

Recently, the interest in the composition of food has been increased because potential anti-carcinogens and other therapeutic agents of food have been reported (Messina et al, 1994; Gibbs et al., 2004). Of particular interests in nutrition and food science are bioactive peptides that are present in the amino acid sequence of food proteins. These peptides are inactive within the sequence of the parent proteins but can be released by enzymatic proteolysis, for example, during gastrointestinal digestion or during food processing. Also, they are produced partly by the hydrolytic action of commercial enzymes (Gibbs et al., 2004). Once they are liberated in the body, the peptides may act like regulatory compounds. Thus, these peptides could be the potential health enhancing nutraceuticals for food and pharmaceutical applications. (Meisel, H.1997). From the nutritional point of view, meat contains many valuable components and biologically active substances (Korhonen et al., 1998). Arihara et al.(2001) reported that ACE inhibitory peptides were purified from porcine skeletal muscle proteins. However, very few studies have been done on beef protein (Jang et al., 2000). In this respect, we separated ACE inhibitory peptides from beef protein hydrolysates by enzyme hydrolysis and suspected that these peptides may have other biological activities.

Objectives

The aim of this study was to separate ACE inhibitory peptides from beef protein hydrolysates using seven commercial enzymes and investigate whether these ACE inhibition active peptides have any other biological activities, such as cytotoxic activity, antimicrobial activity, and machrophage stimulating activity.

Methods

Protein digestion was carried out with 7 enzymes, thermolysin at pH7.5 and 37°C, proteinase K at pH7.5 and 37°C, pepsin at pH3.0 and 37°C, protease at pH7.5 and 37°C, trypsin at pH 7.6-8.0 and 25°C, tyrosinase at pH6.5 and 25°C, and papain at pH6.2 and 25°C for 8 hours. The enzymatic hydrolysates were purified further with ultrafiltration and gel filtration. Of each hydrolysate, the fraction with the highest inhibitory activity was selected and identified by RP-HPLC. The amino acid sequence of those peptides was revealed by protein sequencer and the biological activities were determined. The ACE inhibitory activity was measured by a method described in our previous report (Jang et al.,2001). Antimicrobial activity was examined against six pathogens, *Escherichia coli, Staphylococuus aureus, Salmonella thyphimurium, Pseudomonas aeruginosa, Bacilus cereus,* and *Listeria monocytogenes* with tryptic soy agar (Difco. U.S.A). The sensitivity of pathogen to the peptides was determined by the disk diffusion method (Ponce et al., 2003) The diameter of the inhibition halos were as: not detected for diameters less than 8 mm; sensitive (+) for diameters 9-12 mm; very sensitive (++) for diameters 13-18 mm and extremely sensitive (+++) for diameters larger than 19mm. The cytotoxic effect of the peptides was assayed in vitro against MCF-7(breast cancer cell), AGS(stomach cancer cell), and LLC(lung cancer cell) by using the MTT assay (Carystinos, et al.,2001). Percent cell viability of test samples was determined as : % Cell Viability = (average OD for test group/average OD for control group) x 100. To acquire tumor cytotoxicity, machrophages should be activated by stimulants such as lipopolysaccharide. The activated macrophage secreted tumor necrosis factor, interleukin-1 (IL-1), and nitric oxide as soluble effectors. In this respect, the nitrite formation was taken as an index of the macrophage (RAW 264.7) stimulating activity (Miwa et al., 1990). Nitric oxide production was estimated by measuring the accumulation of the stable NO metabolite, nitrite, in the culture supernatants using the Griess assay (Green et al., 1982).

Results and discussion

Four peptides were separated from the hydrolysates for 8hrs incubation with 7 enzymes. The ACE inhibition activities of the separated peptides 1155, 325, 1152, 714, and 1134 were 14.64%, 34.77%, 25.09%, 31.66%, and 53.36%, respectively (Tab. 1). Their IC_{50} values were 117.27, 64.27, 52.92, 50.35, and 75ug/ml. The peptide 714 showed that the smallest concentration needed to inhibit 50% of ACE. Although the structure-activity relationships of many bioactive peptides have not yet been fully established, peptides with a defined bioactivity are known to have common structural features. Structure activity correlations among different peptide inhibitors of ACE indicate that binding to ACE is strongly influenced by the C-terminal tripeptide

sequence of the substrate.(Meisel, H.1997). These peptides characterized were studied for biological activity. A wide variety of organisms produce antimicrobial peptides as a primary innate immune strategy. Typically, peptides that are relatively short(less than 100 amino acids), positively charged, and amphiphillic acid are reported to be active against bacteria, fungi, viruses and protozoa(Farnaud, et al., 2004).
Table. 2 shows the effects of peptide 1155 on 6 pathogens. All the treated concentrations of peptide 1155 showed a sensitive inhibition on *S.typh., B.cer., E.coli, and L.mono* but not *S.aureus and P.aeru*. Peptide 325 showed very sensitive inhibition activity, especially on *E.coli* and *P.aeru* with concentration of 200 and 400ug/ml (Tab.3). However, peptide 1152 was very sensitive to *P.aeru*., only with 200ug/ml and 400ug/ml. Peptide 714 showed sensitive activity to *E.coli* at all treated concentrations(Tab.4). From this result, small peptides (3-4 amino acids), 1152 and 325 in particular, resulted in very sensitive activity to *P.aeru.* but the reason was not clear. Bellamy et al.(1993) suggested that the antimicrobial activity of lactoferricin and synthetic analogs seems to be correlated with the net positive charge of the peptides. These cationic peptides kill sensitive microorganisms by increasing cell membrane permeability.
The cytotoxic effect of separated peptides on breast cancer, lung cancer, and stomach cancer was measured by MTT assay. Peptide 325 showed a slight decrease of MCF-7 cell viability dose dependently(Fig. 1). The peptide 325 reduced cell viability by 85% at 400ug/ml of concentration. However, the rest of peptides showed no significant decrease of cell viability. Fig. 2. shows the effect of separated peptides on stomach cancer(AGS) cell. When 400ug/ml of peptide 325 and peptide 1155 were added into the AGS cell, the viability was decreased by 75% and 25%. The peptide 1155 showed significant reduction by up to 20%. However, peptide 714 seemed to act as a nutrient to AGS cell where it increased viability of AGS cell. Also, peptide 325 showed 4% reduction, while the other peptides had no cytotoxic effect on LLC(Fig. 3). Peptide 325 inhibited viability of those 3 tumor cells. Thus, this peptide was selected to investigate NO production by stimulation of machrophage. To investigate machrophage stimulation activity, 100, 300, and 1000ug/ml of peptide 325 were treated at machrophage. However, nitric oxide was not produced in all treatments(data not shown). Miwa et al.(1997) examined if nitric oxide formation by macrophage was stimulated with water extracts from meats and offal. They suggested that a water extract of beef didn't produce nitric oxide. Low concentrations of NO from activated macrophages are beneficial as, along with other reactive nitrogen intermediates, they are responsible for cytostatic and cytotoxic activity against infectious organisms and tumor cells (Komutarin, et al., 2004). However, overproduction of NO has been found to be associated with various disease such as septic shock, autoimmune disease, chronic inflammation by increasing vascular permeability, and the extravasations of fluid and proteins at the inflammatory site (Moncada, et al., 1991; Komutarin, et al., 2004).

Conclusions

ACE inhibitory peptides Separated from beef hydrolysates by enzymes were found to have cytotoxic activity on tumor cells and antimicrobial activity on 6 pathogens while macrophage stimulating activity was not shown.

A NEW METHOD FOR QUANTIFICATION OF APOLAR HETEROCYCLIC AROMATIC AMINES WITH PLANAR CHROMATOGRAPHY

Ute Jautz[1], Gerda Morlock[2], Monika Gibis[1], Wolfgang Schwack[2], Albert Fischer[1]

[1]University of Hohenheim, Institute of Food Technology, Dept. of Meat Technology, D-70599 Stuttgart, Germany
[2]University of Hohenheim, Institute of Food Chemistry, D-70599 Stuttgart, Germany

Background

Heterocyclic Aromatic Amines (HAA) are among the most potent mutagenic substances [1]. Around 20 different HAA at low µg/kg level can be identified in food. During the heating process at high temperatures, these substances are formed in meat from the precursors creatine, creatinine, amino acids and sugars. The concentrations depend on the way of preparation, heating time and temperature [2].

Objectives

HAA are typically quantified by liquid or gas chromatography with detection by UV-absorbance, fluorescence or mass spectrometry [3]. The objective of this study was to develop a new method to determine HAA, which have very similar chemical structures.

Materials and methods

Materials

The standard substances Glu-P-1, Glu-P-2, AαC and MeAαC were purchased from Toronto Research Chemicals, Ontario, Canada; Harman and Norharman from Sigma-Aldrich, Taufkirchen, Germany; HPTLC plates silica gel 60 F_{254} (20 x 10 cm) from Merck, Darmstadt, Germany.

Stock solutions

Standards were dissolved in methanol/NH_3.

Instruments

For sample application, the dissolved substances were sprayed in bands by Automatic TLC sampler 4 (ATS 4, Fig. 1). Afterwards, the plates were repeatedly developed in the same direction by the Automated Multiple Development System (AMD 2, Fig. 2). Drawn by capillary forces the developing solvent (mobile phase) migrated through the layer (stationary phase) over a defined distance. Densitometric evaluation of the developed plate was done by TLC Scanner 3 under UV 366 / > 400 nm. The DigiStore documentation system, i.e. Reprostar 3 with digital camera, made it possible to take a photo of the plate. The software winCATS controls all mechanical and electronic functions of the instruments. All TLC instruments were developed by CAMAG, Muttenz, Switzerland.

Results and discussion

Several affecting parameters had to be investigated to find optimal conditions to separate the six apolar and fluorescent HAA. In trade, various plates are available. These differ in material, thickness, particle size, pH-value, fluorescence indicator and binders. Furthermore, the optimal solvent or solvent mixture had to be found. The separation of the bands depends also on the number of gradient steps and migration distance. Moreover, basic, acid or neutral preconditioning between each gradient step changes the activity and pH-value of the layer. This can influence the separation and the focus of several bands. A five-step development to a migration distance of 40 mm each with the solvent mixture of 98 % diethyl ether and 2 % methanol, turned out to be the optimal condition to separate the substances (Fig. 3).

In Figure 4, pictures of plates after the chromatographic development are shown. Each standard is applicated separately as well as in a mixture of three standards. Mix A consists of Glu-P-1, AαC and Norharman, and mix B of Glu-P-2, MeAαC and Harman. The densitometric scan in Figure 5 shows the separated peaks and the possibility to quantify the substances by peak height or area.

Fluorescence measurement is a very sensitive detection method and has a lower detection limit compared to UV-absorbance. However, the point of time at which the evaluation is done is of vital importance. It was observed that fluorescence emission is not stable. A degradation of fluorescence was detected when plates were not stored in darkness but in daylight or artificial light, respectively. Compared with Figure 4a, Figure 4b shows the decline of fluorescence after 48 hours.

It is also evident that the decrease of fluorescence was different for each substance (Fig. 6a). Fluorescence intensity of AαC and MeAαC decreased faster than those of Glu-P-1 and Glu-P-2. The curves of Harman and Norharman first increased, then decreased. Figure 6b indicates that degradation could be avoided by storing the plates in total darkness.

There were also two great advantages to mention. On one hand, the presented method was very rapid. The multi-step development lasted about 45 minutes, i.e. less than 3 minutes per each determination was necessary, when 16 bands were applied on one plate. On the other hand, the method was cost effective. Only 45 mL of solvent per plate was needed, i.e., less than 3 mL per determination. The cost for the HPTLC plates used was less than 5 euros per plate.

Conclusions

The results show that it was possible to separate six fluorescent HAAs on one HPTLC plate. Moreover, it was found important that quantification by fluorescence took place immediately after developing the plate, because of the degradation fluorescence.

It was shown that modern planar chromatography was suitable for a screening test. Further aims may include the separation of the 15 most frequent HAAs found in meat on one HPTLC plate, as well as their quantification. At the present study, only standard substances were used. To what extent meat matrix may complicate the determination of HAAs, remains, thus, to be investigated.

HEME IRON AND B VITAMINS AS QUALITY MARKERS IN COOKED MEATS

Lanzi S., D'Evoli L., Salvatore P., Aguzzi A., Nicoli S., Marletta L. and [1]Lombardi-Boccia G.
National Institute for Food and Nutrition Research – Rome, Italy, [1]lombardiboccia@inran.it

Background

Meat consumption greatly contributes to the daily intakes of both heme iron and B vitamins in the diet (Lombardi-Boccia et al., 2003; Lucarini et al., in press). Meat represents the main source of highly available iron. An accurate knowledge of the levels of heme iron in meats and diets is of great importance because of the significant difference between heme and non-heme iron in bioavailability. As far as the vitamin B complex is concerned, meat is one of the main sources of niacin in the average Italian diet (Lucarini et al., in press), one serving of pork provides the daily thiamine requirement (LARN, 1996). Thermal processes which meat undergoes represent an important factor strongly affecting the nutritional value of meats and meat-based dishes. Losses of both heme iron and B vitamins occur during cooking processes of meat, and therefore, the amount of these micronutrients ingested may vary greatly.

Objectives

The present study focuses on how different cooking procedures (frying, stewing, roasting, "escalope") influence the retention of heme iron and B vitamins (thiamine, riboflavin, niacin) in meat cuts of beef, veal, chicken and turkey. Furthermore, the possibility of using heme iron and /or B vitamins as markers of the nutritional quality of cooked meats was also undertaken.

Materials and methods

The following meat cuts were analysed: beef (sirloin, fillet, roast beef, topside, flank), veal (fillet), chicken (breast, leg-lower part, leg-thigh, wing), turkey (breast, leg-lower part, leg-thigh). The meat cuts were cooked according to preparation protocols of some Italian recipes: poultry legs and wings were roasted in oven at 180°C for 50 min; breast and all the other meat cuts were hand-trimmed of all visible fat and fried (without the addition of fat or salt) in an iron-free pan with medium heat until red colour disappeared (beef fillet and roast beef were underdone); beef flank was stewed and turkey breast was also cooked as "escalope". To calculate weight loss, the cuts and the meat-based dishes were weighed before and after cooking, the latter after resting for 20 min at room temperature. Bones were removed, wherever necessary, and both raw and cooked meats were freeze-dried and then ground in a food blender (equipped with stainless steel blade) to ensure homogeneous and representative samples for analysis. Three samples for each meat cut and two preparations for each recipe (comprehensive of all the raw ingredients) were analysed for total iron, heme iron, thiamine, riboflavin and niacin content.

Iron content

Analysis of total iron were performed by ICP-Plasma on a Perkin-Elmer Optima 3200XL, following liquid ashing of the samples (4ml HNO3+1ml H2O2) in a microwave digestion system. Standard Reference materials: Bovine muscle (BCR 184, Community Bureau of Reference, Brussels) and Bovine liver (NBS 1577a, National Bureau of Standards, Gathersburg, MD 20899) were analysed to verify the accuracy of the analysis. Heme iron was determined following the analytical conditions described by Lombardi-Boccia et al. (2002a).

B vitamins

Thiamine and riboflavin were separated and quantified by HPLC after acidic and enzymatic (Takadiastase) hydrolysis of the samples, following the procedure described by Arella et al. (1996). Niacin was extracted following the method of Lahély et al. (1999) and quantified by HPLC following the method of Ward and Trenerry (1997). Identification of the correct peaks was performed by comparison with retention times of external standards: thiamine hydrocloride and riboflavin were obtained from Sigma Chemical Co. (St Louis, NO, USA), niacin was obtained from Fluka Chemie (Buchs, Switzerlands).

Results and discussion

The effect of heat treatments on total iron and heme iron content are presented in table 1. Cooked meats showed a higher iron concentration compared to the raw samples, this was due to the moisture losses occurred upon cooking. A previous study carried out on heme iron concentration in meats (Lombardi-Boccia et al., 2002b) showed that heat treatments did not cause losses in total iron content but modified the heme:non-heme iron ratio. Our present findings showed that frying caused losses in heme iron ranging from 3% (roast beef) to 24% (topside) (Tab.1). Less severe losses in heme iron content were found in poultry breast (both fried and cooked as escalope) (Tab.1). However, when meat was roasted (poultry meat), a substantial reduction in heme iron content was induced with losses ranging from 22% (turkey) to 43% (chicken wing) (Tab 1). The concentrations of B vitamins in raw and cooked meat cuts are presented in Table 2. Thiamine concentration varied greatly among cuts of the same species ($p<0.05$), in raw beef ranging from 0.02 mg/100g (sirloin) to a maximum of 0.14 mg/100g (flank). In the case of chicken and turkey, only breast samples were analysed, and the thiamine concentration was very low in both (Tab.2). Riboflavin content among cuts of beef varied from 0.09 to 0.17 mg/100g, fillet showing the highest concentration (Tab.2). Chicken breast showed the lowest riboflavin concentrations. Niacin content was almost identical in the various meat cuts of the same species. The highest amounts of niacin were found in poultry. The effect of cooking on the content of B vitamins in meat is also presented in Table 2. Heat treatments decreased the content of B vitamins. Among the vitamins analysed, thiamine was the most susceptible to thermal degradation, and ended up undetectable in most samples (Tab.2). Riboflavin, generally more resistant to heat, showed losses ranging from 37 to 60%. Comparable losses of riboflavin have been reported by Bodwell et al.(1986) and by Chan (1995). Complete retention of riboflavin was found in roast beef, a meat cut subjected to only a short cooking. Cooking induced less severe losses in niacin content, varying from 26% (turkey breast) to 42% (beef fillet). The values of thiamine and riboflavin found in literature (Bodwell et al., 1986; Chan et al., 1995, Leonhardt et al., 1997) are very similar to ours in both raw and cooked red meats, but markedly higher than ours in chicken and turkey breast.

Conclusions

This study updated some data concerning heme iron and vitamin B content in cuts of beef, veal and poultry and evaluated how cooking procedures affect their concentration. The knowledge of variations in the concentration of both heme iron and some B vitamins among raw and cooked meats is of utmost importance for two reasons: firstly, it allows the correct calculation of the actual nutrient intake at consumer level, and secondly, some of the micronutrients can be used as biochemical indicators of the nutritional quality of cooked meats. Our findings show in particular, that heme iron concentration vary greatly among the procedures analysed because its retention was strictly dependent on the severity of the heat treatment utilized. Therefore, heme iron concentration might serve as a useful index of the nutritional quality of cooked meats.

EFFECT OF SUPRANUTRITIONAL AND ORGANICALLY-BOUND DIETARY SELENIUM ON THE NUTRITIVE VALUE AND CASE LONGEVITY OF BEEF

[a]Lawler, T. L., [a]Marchello, M. J., [b]Taylor, J. B and [a]Caton, J. S.

Background

Elevated dietary selenium (Se) confers positive health benefits. Although some molecular forms are more potent than others (Ip et al., 2000; Finley and Davis, 2001), total Se intake must be three to ten fold the recommended dietary requirement for advantages, such as tumor inhibition, to be observed (Ip, 1998; Combs, 1999). As such, much effort has been devoted to identifying foods naturally high in or that can be readily enriched with Se (Finley et al., 1996; Lawler et al., 2004). Recently, we reported a 3.4-fold increase in the Se content of muscle from beef steers finished on a supranutritional organically-bound Se (2.7 mg·kg diet^{-1}) diets (Lawler et al., 2004). These diets did not negatively influence steer performance or carcass characteristics. Although some studies have documented the affects of inorganic versus organically-bound forms of dietary Se on the case life characteristics of meat, none have been conducted in beef describing the influence of supranutritional dietary Se. We hypothesized that skeletal muscle, from steers fed supranutritional Se as high Se grain, will have increased Se content, and not differ in nutritive quality and case longevity than muscle from steers fed adequate Se.

Objectives

Assess the nutritive value of *M. gastrocnemius*, and case longevity characteristics of *M. longissimus* from beef steers fed supranutritional dietary Se in the form of high Se wheat.

Materials and methods

Twenty crossbred beef steers (351 ± 24 kg initial body weight [BW]), individually fed (120 days) either 0.35 (n = 11; adequate; NRC, 1996) or 2.70 (n = 9; supranutritional) mg Se·kg BW^{-1}·day^{-1}, were utilized to assess the affects of supranutritional organically-bound Se on the nutritive value of the *M. gastrocnemius* (rear shank), and case longevity of the *M. longissimus* (strip loin; NAMP #180). The Se content of the adequate and supranutritional Se diets provided 9.5 and 65 mg·kg^{-1} BW·d^{-1}, respectively. Diets were similar in feed composition and nutrient content (25 % wheat, 39 % corn, 25 % grass hay, 5 % desugared molasses, and 6 % wheat middling based supplement; 14.0 % crude protein, 2.12 Mcal NEm·kg^{-1} DM, and 1.26 Mcal NEg·kg^{-1}; values expressed on a dry matter basis). High Se wheat (10.3 mg·kg^{-1}) directly replaced the adequate Se wheat (0.40 mg·kg^{-1}) to deliver the supranutritional Se treatment.

Immediately following slaughter (day 121), carcasses were placed in a cooler (4°C) for 48 hours. *M. gastrocnemius* samples (~3 g wet basis) were collected a 0, 6, 12, 24, 36 and 48 hours of the chilling period, wrapped in foil, snap frozen in liquid nitrogen and stored (-80°C) for subsequent analyses. The hour 0 *M. gastrocnemius* samples were analyzed for dry matter, ash, nitrogen, pH, lipids (AOAC, 1990), expressible moisture (Jauregui et al., 1981), and Se. Hydride generation atomic absorption spectrometry was used to analyze for Se following digestion of samples with nitric acid (Finley et al., 1996). All samples collected over time were analyzed for glutathione peroxidase (GSH-Px) activity. The coupled enzyme method of Paglia and Valentine (1967) was used to measure GSH-Px activity using H_2O_2 as the substrate and NADPH as the source of reducing equivalents. A BioRad assay kit (Hercules, CA) was used to determine protein concentrations (Quant microplate reader, Bio-Tek Instruments, Inc., Winooski, VT).

The *M. longissimus lumborum* was removed at the completion of the chilling period (48 hours), and two steaks (2.5 cm) were cut from the anterior end and weighed. Each steak was placed on a styrofoam tray, wrapped with a clear oxygen-permeable film, and displayed in a retail cooler (2.78ºC) for 12 days under fluorescent lighting with 150 lumens of light at the meat surface. Hunter L, a and b were measured daily with a Minolta CR-310 colorimeter (Minolta Corp., Ramsey, NJ) using a 50-mm diameter measurement

area, D65 light source with zero angle of reflectance. Additional subjective measurements were estimated using a scale from 1 (purplish red) to 8 (very dark red); a score of 3 was considered the ideal oxymyoglobin state. To measure drip loss, steaks were removed from their package and exudates on days 2, 4, 8, and 12, weighed, re-wrapped, and returned to the cooler. The amount of drip loss was determined as a percentage of initial weight. At the conclusion of the case life study, steaks were removed from the retail cooler, weighed, and cooked on flat grills to an endpoint temperature of 71 ± 3ºC. Internal temperature was evaluated using a digital thermometer placed in the approximate geometric centre of each steak. The steaks were weighed again after cooking, and cooking loss was calculated as a percentage of initial raw weight.

Nutrient values, moisture measurements and pH were analyzed as a completely randomized design, and drip loss, colour evaluations and GSH-Px data were analyzed as repeated measures using the mixed models procedure of SAS (v8.0; SAS, Cary, NC). The autoregressive order one and the spatial power law covariance structures were used for drip loss and colour evaluations, and GSH-Px activity analyses, respectively.

Results and discussion

M. gastrocnemius samples from steers fed high Se wheat diets had greater Se concentration and GSH-Px activity than the muscle from steers fed adequate Se (Table 1; $p < 0.05$). No sampling hour x treatment interaction was detected for GSH-Px activity throughout the chilling period ($p > 0.05$). This increase in muscle Se content was expected and consistent with other studies where organically-bound forms of Se were fed to barrows (Kim and Mahan, 2001) and steers (Hientz et al., 2001). The predominant form of selenium in high selenium grains and forages is selenomethionine (Olson et al., 1970; Djujic et al., 2000). This selenoamino acid is interchangeable with methionine during translation (Waschulewski and Sunde, 1988; Butler et al., 1989), resulting in Se being temporarily sequestered in the muscle and away from selenoprotein synthesis. However, once the rate of selenomethionine incorporation into protein has been saturated, Se would be released for selenoprotein synthesis at a rate equivalent to methionine/selenomethionine catabolisM. Compared to the 3.4-fold increase in Se concentration, the lack of proportional increase in GSH-Px activity confirms that the maximal responsiveness of GSH-Px synthesis to dietary Se is near or only slightly greater than adequate dietary requirements (Berggen et al., 1999). Although supranutritional Se had no influence on colour change ($p > 0.16$), steaks (*M. longissimus*) from steers fed the high Se wheat diets had less moisture lost (drip loss) over the 12-day case life study (Table 2; $p < 0.01$). This indicates that a supranutritional Se diet results in the mitigation of protein breakdown and subsequent release of water.

Conclusions

Supranutritional dietary selenium, from high selenium wheat, enhanced selenium concentration and glutathionine peroxidase activty of the *M. gastrocnemius*, and decreased drip loss from the *M. longissimus*. Caution should be used when assuming that enhanced Se concentration of a meat product will result in greater product stability during case display. This study clearly demonstrates the nutritive value of beef muscle products can be enhanced using feeds naturally high in selenium without negatively affecting the quality or case longevity of beef muscle.

Background

Poultry, especially chicken broilers and turkey, is one of the most widely consumed muscle foods in the world. Poultry meat is an important source of dietary energy and nutrients, providing high quality protein, essential fatty acids, vitamins, and highly bio-available minerals (D'Amicis and Turrini, 2002). Updated information concerning nutrient contents of poultry muscles is needed for the establishment of the nutritional value of both fresh and processed products, including ready-to-eat items. The amount, type and proportion of fatty acids as well as cholesterol in muscles are of particular health concern. These data are necessary for poultry processors in developing strategies to manufacture healthy products with desirable nutritional composition. Based on the wealth of literature on poultry muscle quality, one would assume that the nutritional value of poultry meat has been well established. In reality, this is a false assumption, because the results are in some cases based on whole poultry carcasses, and in other cases on specific muscles, and many times the data are incomplete or out-of-date.

Objectives

The aim of the paper is to present the nutritional value of poultry meat on the basis of the most up-to-date literature available and to point out the areas where more research is needed to advance out understanding of the subject.

Results and discussion

Chemical composition

The chemical composition of poultry breast (B) and thigh/leg (T/L) muscles was recently reviewed by Lesiow (2004) and is presented in Table 1. The richest in protein are B muscle of turkeys, broilers, geese and ducks, followed by T/L muscles of ducks, geese, turkeys and broilers. The fat content of B muscle, in an ascending order, is: turkey female, Pekin and Muscovy ducks, hens, broilers, turkey males, Mule ducks and geese, and for T/L muscle, the order is: Pekin, Mule and Muscovy ducks, hens, turkey, geese and broilers. B muscle contains more protein (0.4 to 3.8%) and less fat (0.29 to 5.07%) than T/L muscles. Moisture content of Pekin and Muscovy ducks is greater than of other kinds of poultry. Broilers, hens and Mule ducks have intermediate moisture content, while turkey and geese have substantially lower values. The B muscle of broiler, Pekin duck and goose has a higher percentage of moisture than their T/L muscles. The differences in chemical composition between males and females are also well documented (Lesiów, 2004, Table 1). Male broiler muscles have a higher moisture and ash content than do females. A lower moisture content and higher fat content are observed in turkey and Mule duck male B muscle when compared with females. A reverse trend, i.e., higher moisture and lower lipid contents, holds true for male and female B muscle of Pekin ducks. Muscovy duck and goose male B muscle has a higher fat content than the female counterpart. Turkey and Pekin duck male T muscle contains less fat than female T muscle. There is a lack of literature report on the chemical composition of Mule duck and goose T/L muscles.

The content of collagen influences nutritional and dietetic values of meat. Poultry B muscle contains less collagen (except for Pekin ducks) than T muscle (Table 1). As a protein of lower nutritive value, collagen is the lowest in turkey and goose and higher in broiler and Pekin duck muscles. Information is scarce about the collagen content in Mule and Muscovy duck muscles, and data available for geese were published in 1983-1984 (Bielińska et. al., 1984). The collagen content is sex dependent. Male broiler B and T muscles and turkey and goose T muscle contain more collagen than female muscles. The reverse is true for turkey and goose female B muscle.

Vitamins and Minerals

Broiler meat is an important source of niacin (PP) and vitamin B6, and duck and goose meat are rich in thiamine (B1) and riboflavin (B2). Broiler and turkey T/L muscles contain more vitamin B2 and less vitamins PP and B6 than B muscle. However, literature about vitamins in poultry meat dates back over 20 years and the content of vitamins in duck and geese is not presented for particular muscles but instead for the whole flesh (total amount of musculature in a carcass) (Hamm and Ang, 1984; Posati, 1979).

Mineral content of broiler and turkey B and T/L muscles has been reviewed (Lesiow, 2004). However, data for duck and goose meat are typically presented in relation to whole carcass flesh and are very often incomplete. Broiler and turkey T muscles are richer than B muscle in Fe (10.70 vs. 6.81 μg/g, and 11.87 vs. 5.01 μg/g) and Zn (15.27 vs. 6.65 μg/g, and 26.03 vs. 9.08 μg/g). This is due to the higher myoglobin and haemoglobin content and greater metabolic activity associated with the red muscle fibres. Turkey and broiler muscles are generally also rich in phosphorus and potassium. The mineral content of broiler B and L muscles is identical between sexes. There is no information about the possible influence of sex on the mineral content of the muscles of other poultry species. There is an interesting discrepancy (from 7.1% to 105%) in the mineral content of duck and goose flesh presented by Kunachowicz et. al. (2002) and Posati (1979), respectively.

Cholesterol and FFA

From the health and nutrition standpoint, it is important not to simply reduce the fatness and cholesterol content of carcasses but rather, to improve the FFA make-up, such as the proportion of n-3 fatty acids, in poultry muscles. The modern dietetics recommend the decrease of polyunsaturated PUFA n-6/n-3 ratio in human diet and to separately evaluate the content of linolenic acid, arachidonic acid, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) in foods (Okuyama et al., 1997).

The cholesterol content of poultry B muscle, in an ascending order, is as follows: broilers, hens and turkeys, Muscovy ducks, geese, Pekin and Mule ducks. The corresponding cholesterol content of broiler, turkey and goose T/L muscles is substantially less than in hens (Lesiów, 2004). The cholesterol content of B muscle is lower in broilers (by 56.5%) and turkeys (by 44.4-50.0%) than in their corresponding T/L muscles. On the contrary, the cholesterol level in goose B muscle is higher (by 20.5%) than in its T muscle. No data can be found on the cholesterol content of duck T/L muscles. B muscles of male turkey, goose and Mule duck show higher cholesterol content than their female counterparts.

The principal fatty acids in poultry muscles are oleic, palmitic and linoleic (Lesiów, 2004). In broiler, hen, Pekin and Muscovy ducks as well as goose, the lipids of B muscle are comprised of more saturated fatty acids (SFA), PUFA and less monounsaturated fatty acids (MUFA) than T/L muscle lipids (Table 1). Komprda et al. (2001) observed no differences in FFA composition between B and T muscles of turkey. However, the same research group reported later that turkey B muscle contained lower amounts of SFA, PUFA but more MUFA than T muscle (contrary to broilers) (Komprda et al., 2002). The PUFA n-6/n-3 ratio of broiler and turkey B muscle is lower in comparison with T muscle, whereas in hens, Muscovy ducks and geese the ratio is slightly higher in B than in T/L muscles. Pekin and Muscovy duck B muscle contains more SFA than other species of poultry (Lesiów, 2004). The percentage of MUFA is generally higher in goose B and T muscles and in duck T muscle compared to muscles from other poultry species. The most favourable ratio of PUFA n-6/n-3 is within broiler and turkey muscles, and then within hens, ducks and geese. Literature data within the duck species is difficult to compare due to variations in the age of the birds used in different studies as well as different production conditions employed. Turkey male B muscle has a higher MUFA content but lower SFA and PUFA, and turkey male T muscle has a higher SFA content but lower PUFA content than turkey female corresponding muscles. Goose male B muscle possesses a more favourable FFA profile compared to female B muscle as evidenced by the higher percentage of MUFA and lower level of SFA (Batura et. al., 1999).

Conclusions

It should be pointed out that the chemical composition and thus, the nutritional value of poultry meat is influenced by many production factors, such as diet (nutritional composition of the feed), the conditions in which the birds are grown, and the specific strains. For example, our previous studies (Xiong et al., 1993a,b) showed that broiler meat varied slightly in basic composition (protein, lipid, mineral and water) between

strain crosses. Therefore, evaluations of nutritional value of different poultry species should be done in the context of the ever-changing breeding technology that is likely to underscore strain-dependent variations in the meat composition. Results published by individual research laboratories are generally dealing with the whole poultry carcasses (e.g., mineral content in hen, duck and geese) or with specific muscles, and in some cases, the data are not complete (e.g., cholesterol and FFA content for different duck species) or up-to-date (e.g., vitamin content in turkey, duck and goose thigh/leg muscles). Further research is needed to fill in the gaps in the knowledge of the nutritional value of poultry muscles.

INTRODUCTION INTO FOODS COMBINATORICS

Lipatov N.N., Bashkirov O.I., Gevorgyan A.L.
Scientific Research Institute of child nutrition of RASKhN, Istra town, Russia

Background

The Food Combinatorics combines ideas of modern informatics, trophology, biophysical and chemical bases of food technology and particular technologies of multicomponent food products for special groups of population classified by age and metabolic state. Combinatorics is a science studying combinations of various objects (Encycloperia). ("Combination" is the term from Latin "combinatio"; it means combination – mutual arrangement of something.).

Objects of mathematical combinatorics are: all kinds of permutations, arrangements, and combinations. As applied to food processing industry, the notion of combinatorics is identified with arrangement, rearrangement, and combination of dominant characteristics of the objects of foods processing. Such objects are: raw materials; functional components; formulation mixtures formed from raw materials and functional components; half-finished products obtained at different stages of formulation mixtures processing; finished products which are the final purpose of the food protophysiological technology; diets which predetermine the effectiveness of its physiological technology including consumption, digestion, assimilation, and evacuation; technological processing, equipment for implementation of technological processes, parameters ensuring effective functioning of technological processes and equipment.

In addition, using the term "food combinatorics", the authors mean that it combines principles and methods of realization of results of designing of food products as material objects with predetermined characteristics created from separate elements, not providing these characteristics individually.

Objectives

The aim of the present work is to summarize personal notions of the author about an interdisciplinary field of knowledge - FOOD COMBINATORICS developed by them in recent years.

Materials and methods

All above-stated allows us to formulate the following definition:

THE FOOD COMBINATORICS is an interdisciplinary field of knowledge directed for studying and practical application of regular features of mutual influence of combinations of objects in the food production process.

Taking into account the experience and specifics of scientific and practical interests of the authors, one can state that the greatest attention is paid to the complex of problems connected with the quality improvement of baby foods prepared on the basis or with the use of components obtained in processing of meat raw materials, eggs, and milk.

Results and discussion

Medical and biological aspects of food combinatorics

On the whole, these aspects determine the complex of necessary and appropriate conditions providing possibility of quantitatively determined improvement of baby food quality through combinatory changes forming their alimentary adequacy of macro- and micronutrients and predetermine rightfulness of their assignment to so-called products of new generation.

The authors believe that the content of the paper, which follows hereinafter, will be better understood as logically tied links of the common methodological chain, if the following definition is given: Polycomponent baby foods of new generation are the safe products whose formulations comprise non-traditional for products

on meat, milk, cereals or fruit-vegetable bases some macro- or microfractionated components of these kinds of raw materials, as well as physiological functionally- methabolic ingredients added in amounts and ratios, assisting in the presence, apart from nutrient adequecy, of predetermined level of methabolic adequacy or special properties, and providing the absence of negative organoleptical perceptions in children, who are combined by determinated age, homeostasis or other signs.

As far as biological value of protein components contained in new baby foods is concerned, it should be noted, that apart from the conventional amino acid balance predetermined by the combinations of indispensable amino acids and in special cases dispensable amino-acids, the individual protein digestion is taken into account in the proposed methodology. In addition, while creating products, guaranteeing absence or minimum probability of occurrence of protein allergenic reaction, the most important are combinations of molecular-mass characteristics of almost all macromolecular and polypeptide components of total protein. At the same time, special attention is to be paid to the fact that these combinations depend on similar combinations in protein ingredients of the total protein and on the complex of processing technologies and parameters of their implementation.

In full measure, medical and biological aspects of the food combinatorics embrace the analysis, evaluation, and purposeful use of combinations and arrangements of factors, which predetermine nutrient and metabolic adequacy of such macronutrients of baby foods as fatty acids and carbohydrates, which have dominant influence on the food energetic value.

One of the most important part of medical and biological aspects is the study and practical realization of combinatory factors forming macro- and microelement adequacy of food products and diets containing them. Quantitatively the analysis of combinations not concerning the process factors and forming the food value on the whole can be accomplished with the help of mathematical models, developed by researchers headed by N.N.Lipatov (Jr.) (Academician of the Russian Academy of Agriculture).

In realization of these models by computers as applied to designing of foods for babies we used the rated values of the alimentary reference summarized in Table 1.

Table 1. Rated indices of the alimentary reference for babies up to one year

Nutrients	Content	Nutrients	Content
Indispensable amino acids:	g/100 g of prot.	Na	20.00
Isoleucine	4.60	S	11.20
Leucine	9.80	P	24.00
Lysine	7.50	Cl	54.4
Methionine+cystine	4.00	*Microelements:*	µg/1 g of protein
Phenylalanine+tyrosine	8.60	Fe	800.00

Tryptophan	1.50	Co	-
Valine	5.20	Mn	2.40
Histidine	-	Cu	32.00
Fatty acids:	g/100 g of fat	F	_
∑ UFA	41.78	Zn	240.00
∑ MUFA	43.03		
∑ PUFA including:	12.42	*Vitamins:*	mg/1g of protein
Linoleic	10.85	B_1	$3.2x10^{-2}$
Linolenic	0.62	B_2	$4.8x10^{-2}$
Arachidonic	0.95	B_6	$3.2x10^{-2}$
Macroelements:	mg/1 g of protein	B_{12}	$3.2x10^{-3}$
K	48.00	PP	$3.2x10^{-1}$
Ca	40.00	A	$4.8x10^{-2}$
Mg	4.00	E	$4.8.10^{-1}$

Conclusions

The authors hope that the International Association of scientists in the field of food technology (including the meat technology) would pay due attention to the present information and take an active part in discussions and further development of theoretical, experimental, and practical aspects of new interdisciplinary scientific direction - THE FOOD COMBINATORICS.

NON-TRADITIONAL IDEAS ABOUT ECOLOGICAL SAFETY AND NUTRITIONAL ADEQUACY OF FOODSTUFFS (INCLUDING MEAT-BASED ONES)

Lipatov N.N., Bashkirov O.I., Gevorgyan A.L.
Scientific Research Institute of Child Nutrition of RASHN, Istra town, Russia

Background

Analysis of available scientific literature about modern trends and prospects for quantitative evaluation of negative effects of indirect anthropogenic activities on ecology suggests that at the present time there is no appropriate informational-algorithmic support, sufficient for carrying out this evaluation, both on the whole and as applied to separate links of exotrophic chain "production of foods → storage → marketing → consumption → digestion → evacuation of catabolism products → utilization of all wastes".

As applied to foods and food processing, inadequate filling of this scientifically-intensive niche is largely caused by incorrectness, and as a consequence, "discrepancies" in terminology, phenomenological and noumenological notions and definitions, being the base for creation of computer-implemented versions of information-algorithmic support for calculation and analysis of dominant quantitative indices associated with ecology of foods.

Objectives

To fill this gap we offer herein for food scientists and food industry specialists the terms, definitions and criteria, being essentially our innovations.

Materials and methods

Terms and definitions

*Ecology** (definition from encyclopedia) – (from Greek oĭkos – house, dwelling, place of living and … logia) science about relations of plant and animal organisms and associations formed by them between each other and the environment.

*Ecology** (interpretation of the authors) – interdisciplinary science studying direct and (or) indirect mutual influence of a human organism in the process of his activities in places of living or location and different forms of existence of being there: animals, plants, micro organisms and organic, mineralorganic, mineral and field objects of natural or anthropogenic origin.

*Ecological safety** - notion as applied to food raw materials, technologies, devices, foodstuffs and their packaging combining necessary and adequate conditions providing absence or minimization of negative effects on the environment during production, processing marketing and use of listed objects.

*Food safety** - a group of indices which quantitatively characterize necessary and adequate conditions, eliminating probability of occurrence of pathological violations of physical, psychical and intellectual status of human organism, caused by components of raw materials and (or) ready products.

*Ecological purity** - (as applied to foodstuffs) = good ecological condition & food safety - is a total property of a particular food or products from the same assortment group characterizing their ability to have minimum effect on the environment during their production, storage, marketing and consumption and provide the absence of substances negatively influencing physical, psychical and intellectual status of a human organism.

*Nutrient (alimentary) adequacy** - a group of indices qualitatively and quantitatively characterizing contents and mutual balance of macro as well as micronutrients and their components in raw materials and final products.

*Metabolic adequacy** - a group of indices characterizing potential efficiency of use by the organism of nutrients as supplied to it by foodstuffs during their consumption, digestion and assimilation.

*Food value (adequacy)** - this is a potential ability, suggesting safety, of foodstuffs or raw materials used in their production to provide in their totality a material and energetic balance of the organism taking into consideration physiological and psychological requirements of the individual consumer or a group of consumers who are combined by their regional, national, age, professional or other signs.

Results and discussion

We have created the following set (1-6) of criteria:

Criterion of **relative ecological safety** of food processing

$$E_{П} = \left[\prod_{\alpha} \left(\frac{\Delta \mathrm{Ds}_{\alpha}}{\Delta \mathrm{Ds}_{\alpha 0}} \right) \cdot \prod_{\beta} \left(\frac{\Delta \mathrm{DA}_{\beta}}{\Delta \mathrm{DA}_{\beta 0}} \right) \cdot \frac{m_0}{m} \right]^{\frac{1}{\alpha + \beta + 1}} \qquad (1)$$

Where: $E_{П}$ - relative ecological safety of production of a particular food, units (with regards to base, reference); $_{\Delta}Ds_a$ – difference between high critical limit of the share of α-th contaminant and its actual pre-limit share in production effluents, corresponding to compared complexes of technological processes, % of ПДУ (Limit value, LV); $_{\Delta}DA_{\beta}$ - difference between top critical limit of the share of β-th contaminant and its actual pre-limit share in atmospheric emissions, corresponding to compared complexes of technological processes, % of LV; *m* - mass of unutilized production garbage, as accumulated in equal time periods in the implementation of compared versions of production processes, t. Index $_0$ corresponds to base (reference) version.

Rated criterion **of food safety**

$$S_{П} = \prod_{i}^{4} \left(1 - \prod_{ij} \frac{X_{ij}}{X_{ПДУij}} \right) * \left(1 - \max \prod_{ij} \frac{X_{ij}}{X_{ПДУij}} \right) \qquad (2)$$

Where: $S_{п}$ – rated food safety, share units; *i* = 1 = corresponds to a group of multiplicative indices of physical contamination of the product, $1 \le j \le k$; *i* =2 – corresponds to a group of multiplicative indices of chemical contamination of the product, $k + 1 \le j \le l$; *i* = 3 – corresponds to a group of multiplicative indices of radiological contamination of the product, $l + 1 \le j \le m$; *i* =4 – corresponds to a group of multiplicative indices of microbiological contamination of the product, $m + 1 \le j \le n$; X_{ij} corresponds to actual value of the unit ij-th index of contamination of the comparable product (corresponding unit of measurement). $X_{ПДУij}$ corresponds to limit value of the ij-th index of contamination. In the case when $S_{п} \le 0$ – the product **is not allowed** for consumption!

Criterion of **ecological purity**

$$e_{П} = (E_{П} \& S_{П})^{0,5} \qquad (3)$$

Rated criterion of **nutrient adequacy**

$$N_{П} = \left[\prod_{i=1}^{n} \mathrm{N}_i^{sign(1-N_i)\cdot\alpha_i} \right]^{0,5/n} \cdot \left[\mathrm{N}_{\min}^{\alpha_{\min}} \right]^{0,5} \qquad (4)$$

Where: $N_{П}$ - rated criterion of nutrient adequacy, share of units; N_i – determined rated *i*-th index of nutrient adequacy, share of units; $N_i = P/P_0$ – correlation of mass fractions of protein in comparable and reference objects; $N_2 = R_p$ - coefficient of rationality of amino acid composition (as $R_{p0} = 1$); $N_3 = L/L_0$ – ratio of mass fractions of fat in comparable and reference objects; $N_4 = \sum SFA/\sum SFA_0$; $N_5 \sum MUFA/\sum MUFA_0$; $N_6 = \sum PUFA/\sum PUFA_0$ -ratios of sums of saturated, monounsaturated and polyunsaturated fatty acids in the

compared and reference objects; $N_7 = C/C_0$ – ratio of mass fractions of carbohydrates in compared and reference objects; $N_8 = macr/macr_0$ – correlation of mass fractions of essential macroelements in compared and reference objects; $N_9 = micr/micr_0$ - ratio of mass fractions of essential microelements in compared and reference objects; $N_{10} = vit_A/vit_{A0}$ - ratio of mass fractions of essential water-soluble vitamins in compared and reference objects; $N_{11} = vit_L/vit_{L0}$ - ratio of mass fractions of essential fat-soluble vitamins in compared and reference objects; *Sign (1-Ni)* – function of sign; *Sign (*1-*Ni)* = +1, if *Ni* ≤*1* and *Sign (*1 – Ni) = -1, if *Ni >1;* N_{min} - index of nutrient adequacy, possessing minimum value; α_i – determined by expertise coefficients of weightiness of the *i th* index of nutrient adequacy, taking the values 0; 25; 0.5, 0.75; 1.0 (the less is the coefficient of weightiness, the less individual influence has the corresponding to it determined index of nutrient adequacy on its multiplicative value); α_{min} - coefficient of weightiness corresponding to $N_{min.}$

Rated criterion **of metabolic adequacy**

$$M_{II} = \left[\prod_i^n m_i^{sign(1-m_i)\cdot\beta_i}\right]^{0,5/n} \cdot \left[m_{min}^{\beta_{min}}\right]^{0,5} \quad (5)$$

where: M_{Π} – rated criterion of metabolic adequacy, share units; M_i – determined rated *i*-th index of metabolic adequacy; M_i –index of relative fractional adequacy of protein composition, share units; $M_2 = \pi$ – digestibility of protein in vitro, share units from initial tyrosine; M_3 …M_5 –ratio of: linoleic, linolenic and arachidonic polyunsaturated fatty acids in comparable and reference objects, shares of units; M_6 – ratio of assimilation of fat of comparable and reference objects, share of units; $M_7 = C_1/C_{10}$ – ratio of mass shares of metabolically hydrolyzed carbohydrates in comparable and reference objects, share of units; $M_8 = C_2/C_{20}$ - ratio of mass shares of metabolically non-hydrolyzed carbohydrates in comparable and reference objects, shares of units; $M_9 = Q/Q_0$ – ratio of energy value of comparable and reference objects, share of units; M_{10}…$M_{14} = S_1$ – relative organoleptic indices, share units; M_{min} - –index of nutrient adequacy, possessing minimum value; β_{min} - coefficient of weightiness, corresponding to M_{min}; β_i – determined by expertise coefficients of weightiness, taking up the values 0; 0.25, 0.5; 0.75; 1.0.

Criterion of **food adequacy**

$$K_{II} = (S_{II} \& N_{II} \& M_{II})^{1/3} \leq 1, \text{ share un.} \quad (6)$$

Conclusions

The authors of this paper hope that the above-stated ideas and criteria will allow to scientists and specialists, involved in the problems connected with ecological aspects of supply of people with high quality products to quantitatively interpret the obtained results.

Meat and Fat Research Institute, ul. Jubilerska 4, 04-190 Warszawa, Poland

Background

The interest of the aware consumers towards food products with specific health-promoting properties, is not decreasing (Bacers, Noll 1998). Food products, containing such components as dietary fibre (Cludesdale 1997, Cieślik, Topolska 2002) satisfy some of these expectations.

Wheat and oat fibre preparations of the newest generation are characterized by a neutral flavour (taste and smell) and a high water binding capacity. Owing to its chemical structure, dietary fibre may absorb water to its capillary system and distribute it throughout the whole volume of the product via a generated three-dimensional network. In this study, the network of fibres, created with added dietary fibre is introduced in the matrix of finely comminuted sausage batter.

Objectives

The aim of the undertaken work was to determine the role of the chosen dietary fibre preparations, applied as a fat replacer and as a functional additive in shaping of structure and quality of a model meat product.

Materials and methods

The studied dietary fibre preparations were: wheat (WF 600-30) and oat (HF 600-30), which were applied to finely comminuted cooked meat product. The evaluation of the application of the chosen dietary fibre preparations as fat replacers was carried out, exchanging 30 % of the formulation fat. Hydrated preparations were introduced to the batter at a preparation to water ratio of 1 to 3.5. The functional role of the dietary fibre preparations in the system of finely comminuted meat product was examined, introducing them as a functional additives at a quantity of ca 1.5 % of total batter weight.

The raw material of the model meat product consisted of the tendinous pork meat (21.4 %), lean beef meat (28.6 %), fine pork fat (21.4 %) and water (28.6 %). The control product had the same composition, but without added dietary fibre (variant K). The products were manufactured according to typical production technology of bologna sausage. The tins were filled with 400 g of sausage batter, cooked in water (75^{o}C) until core temperature of 72^{o}C was reached. After cooking, the tins were chilled in cold water and stored refrigerated at +4 – 6^{o}C until the test samples were collected.

After removal of fat and jelly, basic chemical composition of the products was analysed, ie., water, protein, fat, and sodium chloride. The energy value of the product, expressed in kcal/100 g, was also calculated. The binding capacity of the product was evaluated as cooking losses, as well as slice strengths determined mechanically with the Zwick apparatus, model 1445 MOPS (Tyszkiewicz, Olkiewicz 1991).

The texture profile was tested by the instrumental TPA method (Crystall et al. 1994) and hardness, springiness, gumminess, cohesiveness and chewiness were characterized. The parameters of the testing instrument were as follows: deformation – 80 %, speed of the test – 60 mm/min, thickness of the sample – 20 mm and diameter – 25.4 mm.

The rheological characteristics ie., plasticity, elasticity and fluidity, were determined by Continuously Stress-Relax Analysis (CASRA) method, with the application of Universal TestinG Machine (UTM) Zwick, model 1445 MOPS (Tyszkiewicz, Olkiewicz 1997).

The desirability of colour, taste and texture and overall palatability of the product were evaluated as well. The sensory evaluation was performed in a specific laboratory by a professional panel of 8 members. The facility meets the requirements of standard ISO 8589, and uses the computer system ANALSENS.

Two experimental series of production for all variants were carried out. Chemical composition, textural profile, and sensory evaluation were repeated twice for each experiment. The values of the remaining variables are the means of either 5 (cooking loss) or 10 (slice strength) repetitions. The results of the tests were subjected to one-way analysis of variance using Statgraphics for Windows ver. 3.1.

Results and discussion

The effect of the added dietary fibre (wheat - W, oat - O) preparation used as fat replacers (R) and as functional additives (F) on basic chemical composition of the model meat product is presented in Table I.

Table I. Effect of dietary fibre used as a fat replacer (R) and as a functional additive (F) on the basic chemical composition of model meat products

Application of dietary fibre preparation:	Variant	Water [%]	Fat [%]	Total protein [%]	Energy value [kcal/100g]	NaCl [%]
fat replacer (R)	K	63.9 ^{a}	23.7 ^{b}	10.3 ^{a}	254.6 ^{b}	1.45 ^{c}
	WR	66.7 ^{b}	19.5 ^{a}	10.5 ^{ab}	220.5 ^{a}	1.39 ^{b}
	OR	65.5 ^{ab}	20.2 ^{a}	10.6 ^{b}	226.0 ^{a}	1.33 ^{a}
	NIR	*1.8*	*2.1*	*0.2*	*19.1*	*0.03*
functional additive (F)	K	63.9 ^{c}	23.7	10.3	254.6	1.45
	WF	62.8 ^{b}	23.4	10.1	252.2	1.46
	OF	62.0 ^{a}	23.8	10.1	256.6	1.43
	NIR	*0.8*	*0.9*	*0.3*	*8.8*	*0.05*

Means in the same column with different superscript are significantly different (P≤0,05)

The dietary fibre preparations used as fat replacers (WR, OR) had a significant effect on lowering of fat content, energy value and NaCl content as well as on the increasing of the contents of water and protein of the product. The dietary fibre preparations, when introduced as functional additives (WF, OF), did not have any other significant effect on the basic chemical composition than lowering the water content of the product, as compared to the control variant.

Table II. Effect of the dietary fibres, used as a fat replacer (R) and as functional additive (F), on the binding capacity and textural parameters of the sausage.

Application of dietary fibre preparation:	Variant	Cooking loss [%]	Slice strength [N/cm^2]	Hardness [N]	Gumminess [N]	Chewiness [Nmm]
fat replacer (R)	K	3.84 ^{a}	3.08	71.4 ^{a}	11.9 ^{a}	53.14 ^{a}
	WR	6.91 ^{b}	3.07	84.6 ^{b}	14.6 ^{b}	65.1 ^{b}
	OR	8.83 ^{c}	3.22	80.6 ^{b}	13.8 ^{b}	63.1 ^{b}
	NIR	*1.57*	*0.52*	*6.5*	*1.4*	*8.6*
functional additive (F)	K	3.84	3.08	71.4 ^{a}	11.9 ^{a}	53.1
	WF	3.43	3.33	79.7 ^{b}	13.4 ^{b}	59.3
	OF	4.05	3.64	83.0 ^{b}	13.6 ^{b}	58.2
	NIR	*0.63*	*0.70*	*5.1*	*1.4*	*10.2*

Means in the same column of with different superscript are significantly different (P≤0,05)

Water binding capacity of the model product was evaluated in terms of cooking loss and slice strength (Tab. II). When used as fat replacers (WR, OR), the dietary fibre preparations caused a significant increase of cooking loss, yet a good slice strength not differing from the control product. The highest cooking loss was found in the product, in which dietary oat fibre replaced 30 % of the fat in the formulation. As functional additives (WF, OF), the studied preparations did not have any significant effect on water binding of the product.

When used as fat replacers (WR, OR), the dietary fibre preparations increased the textural measures of hardness, gumminess and chewiness significantly (Tab. II). Except for chewiness, this was also the case when fibre was used as a functional additive (WF, OF), they had a significant influence on the increase of hardness and gumminess. Products with added fibre (WR, OR, WF, OF) did not differ significantly from the controls for the remaining texture parameters, not found in the table.

Table III. Effect of dietary fibre as a fat replacer (R) and as functional additive (F) on the rheological characteristic

Application of dietary fibre preparation	Variant	Plasticity [x10^{5}N/m^2]	Elasticity [x10 $^{-6}$m^2/N]	Fluidity [x10^{-8}Nm^2/Ns]
fat replacer (R)	K	2.36	1.14	3.25
	WR	2.70	1.06	3.08
	OR	2.57	1.04	3.16
	NIR	*0.39*	*0.16*	*0.57*
functional additive (F)	K	2.36 ^{a}	1.14 ^{b}	3.25
	WF	2.60 ^{b}	1.01 ^{a}	3.26
	OF	2.66 ^{b}	0.99 ^{a}	3.07
	NIR	*0.16*	*0.12*	*0.50*

Means in the same column with different superscript are significantly different (P≤0,05)

The substitution of fat with dietary fibre did not have any significant effect on rheological characteristic of the products (Tab. III). The dietary fibre preparations, employed as functional additives (WF, OF) caused a significant increase of plasticity, with the simultaneous significant decrease of elasticity, in comparison to the control products.

Table IV. Effect of dietary fibre as a fat replacer (R) and as functional additive (F) on sensory parameters

Application of dietary fibre preparation	Variant	Colour desirability [c.u.]	Taste desirability [c.u.]	Texture desirability [c.u.]	Overall palatability [c.u.]
fat replacer (R)	K	5.0	5.3	5.2	5.6
	WR	5.0	5.3	5.4	5.5
	OR	5.2	5.0	5.1	5.2
	NIR	*0.7*	*0.5*	*0.4*	*0.6*
functional additive (F)	K	5.0	5.3^{ab}	5.2	5.6
	WF	4.8	5.0^{a}	5.3	5.3
	OF	5.2	5.4^{b}	5.4	5.5
	NIR	*0.8*	*0.3*	*0.4*	*0.5*

Means in the same part of column with different superscript are significantly different (P≤0,05)

In spite of their role in texture, the employed dietary fibre preparations did not play any significant role in sensory desirability (Tab. IV). The taste of the product containing oat fibre (OF) was preferred over that containing wheat fibre.

Meat products with a different type of dietary fibre preparation (wheat or oat) did not differ significantly from each other in terms of physiochemical parameters, texture, rheological or sensory properties.

For most characteristics evaluated, the products with added fibre did not differ from the control samples in quality. Also in earlier studies, in which wheat fibre of earlier generation was used as a fat replacer, Makała (2002a,b) found that the examined products had characteristics, such as structure, binding capacity and sensory desirability, similar to those of the controls. Dietary fibre used as a fat replacer produced better sensory quality than reported in the earlier protein - polysaccharide systems (Olkiewicz, Kostyra, Adamik 1998). A significant increase in cooking losses is a drawback of using dietary fibre preparations as fat substitutes, as also reported in earlier studies of Egbert (1991) and Keeton (1992).

To receive all benefits of added dietary fibre in meat products ie., desirable nutritional function as well as their favourable role in sensory quality, further studies are needed to optimize their application in fat substitution or functional administration.

Conclusions

1. Dietary fibre preparations used to replace 30% of fat caused a significant increase of cooking loss, whereas the slice strength and rheological quality did not differ from the control products.
2. The products containing 1.5 % of wheat or oat fibre were characterized by better binding capacity, sensory palatability and hardness than the control product. At the same time the product received nutritional value in the form of dietary fibre, which is known to promote the health of human gastro-intestinal tract.
3. Wheat and oat fibre may be used as fat replacers and functional additives without compromising the sensory and textural quality of finely comminuted cooked meat products.

Background

Colour and lipid stability in retail meats are very important quality characteristics, which influence consumer acceptability. Minced meats undergo oxidative changes and develop rancidity more quickly than intact muscle since grinding exposes more of the muscle surface to air and microbial contamination. Many attempts have been made to reduce pigment and lipid oxidation in meats through endogenous and exogenous treatment with antioxidants, in particular, vitamin E and vitamin C. Mitsumoto (2000) reported that dietary vitamin E supplementation for several weeks decreased oxidation of meat or fat in poultry, pork and beef and that exogenous vitamin C addition retarded pigment and lipid stability in ground pork and beef. In an increasingly competitive market, meat processors constantly strive to produce more healthy meat products. Tea catechins are polyphenolic antioxidants found in green tea, which possess a range of health promoting properties. Meat products containing natural antioxidants, as opposed to synthetic derivatives, are more desirable from a consumer viewpoint.

Tang et al. (2000) found that supplementation of poultry diets with tea catechins (300 mg/kg feed) retarded lipid oxidation in chicken meat compared to controls and dietary vitamin E (200 mg/kg feed) supplemented meat. To date, it is unknown whether tea catechin addition to meat products is as effective in maintaining meat quality as vitamin C.

Objectives

The aim of this study was to compare the effects of addition of tea catechins and vitamin C on the colous, lipid stability and sensory quality in cooked and raw beef as well as chicken patties.

Materials and methods

Fresh beef striploin and chicken breast muscles (~10 kg of each) were obtained from a local meat processing unit. Meat samples were vacuum packaged and stored at 0ºC for approximately 3 days prior to commencement of each trial. Tea catechins (TC) (80.15%) were obtained from Kinglong Natural Plant Products Industry Ltd., Changsha, Hunan, China. Sodium ascorbate (Vitamin C: VC) (99.0-101.0%) was obtained from Pfizer Ireland Pharmaceuticals, Ringaskiddy, Co. Cork.

Cooking and packaging

Beef and chicken samples were minced twice through a plate with 4 mm holes (mincer model P114L, Talsa, Valencia, Spain) following removal of all external fat and connective tissue. Following mincing, beef and chicken were assigned to one of the following five treatments: CNTRL, control meat; TC200, meat plus 200mg TC/kg muscle; TC400, meat plus 400mg TC/kg muscle; VC200, meat plus 200mg VC/kg muscle, VC400, meat plus 400mg VC/kg muscle. Sodium chloride (1%) was added to all samples.

Minced beef and chicken (125 g portions) were formed into patties using a meat former (Ministeak burger maker, O. L. Smith Co. Ltd., Italy) and stored overnight at 0ºC. Patties were cooked in a fan-assisted oven (model 10GN1/1, Zanussi Professional, Conegliano, Italy) at 180ºC until an internal meat temperature of 72ºC was reached, and subsequently held at 180ºC for a further 15 minutes. After chilling, cooked patties were placed in low oxygen permeable (<1cm^3/m^2/24hr/atm) polystyrene/ethylvinylalcohol (EVOH)/ polyethylene (PE) trays and flushed with 30% CO_2 : 70% N_2 using a vacuum sealing unit (VS 100, Gustav Müller & Co. KG, Homburg, Germany) equipped with a gas mixer (Witt-Gasetechnik GmbH & Co. KG,

Witten, Germany). Trays were covered and heat-sealed with a low oxygen permeable ($3cm^3/m^2/24hr$) laminated barrier film with a polyolefin heat sealable layer. Fresh raw beef and chicken patties were stored in 80% O_2 : 20% CO_2. All samples were stored for up to 7 days under fluorescent lighting (approximately 700 lux) at 4°C.

Colour determination

Surface colour measurements were determined using a CR-300 Chroma Meter (Minolta Co., Osaka, Japan) which consisted of a measuring head (CR-300), with an 8 mm diameter measuring area, and a data processor (DP-301). The chroma meter was calibrated on the Hunterlab colour space system using a white tile (D_{65}: Y = 94.4, x = 0.3172, y = 0.3339). Hunter *L** (lightness), *a** (redness) and *b** (yellowness) values were measured on days 1, 3 and 6 for cooked meats and on days 2 and 7 for raw beef and chicken.

Measurement of lipid oxidation

Lipid oxidation was measured by the 2-thiobarbituric acid distillation method of Tarladgis et al. (1960) as modified by Ke et al. (1977) and results were expressed as 2-thiobarbituric acid reactive substances (TBARS) in mg malonaldehyde (MDA)/kg meat.

Sensory evaluation

An untrained sensory panel of 8 to 11 people evaluated cooked beef and chicken patties after 1, 3 and 6 days of storage. Patties were placed on paper plates, reheated using a microwave oven at high power (800 W) for 30 sec and served to the panellists individually. Panellists were asked to evaluate sample colour, flavour, taste and tenderness on an 8-point scale ranging from extremely desirable (8) to extremely undesirable (1). In addition, panellists were asked to rank samples, in order of preference from best (1) to worst (5) separately for beef and chicken, in terms of overall acceptability.

Statistical analysis

Data were analyzed by the General Linear Models procedure of SAS (1988).

Results and discussion

Cooked patties

Both tea catechins treatments (TC200 and TC400) showed low ($P<0.05$) sensory colour scores (Fig. 1) and Hunter *b** values (10.2 and 9.9, respectively) in cooked meat patties compared to controls (*b** values: 13.2) and both vitamin C treatments (VC200 and VC400) (*b** values: 12.6 and 12.5, respectively). Tea catechins treatment (TC200) had low ($P<0.01$) Hunter *a** values (1.2) in cooked meat patties compared to controls (2.9) and both vitamin C treatments (VC200 and VC400) (3.3 and 3.0, respectively). Tea catechins treatments resulted in no significant differences ($P>0.10$) in the sensory flavour, taste, tenderness and Hunter *L** value in cooked meat compared to controls and both vitamin C treatments. Tea catechins treatments had no effects ($P>0.10$) on overall acceptability in cooked beef patties, but decreased ($P<0.001$) acceptability in cooked chicken meat during display compared to controls and vitamin C treatments. Neither of the vitamin C treatments significantly affected ($P>0.05$) sensory traits and Hunter colour values in cooked meat compared to controls. Tea catechins and vitamin C treatments effectively reduced ($P<0.001$) lipid oxidation in cooked meat patties compared to controls (Fig. 2).

Raw patties

Tea catechins treatment, TC400, showed lower ($P<0.01$) Hunter *b* values (6.6) in raw meat patties compared to controls (7.4). In contrast, the vitamin C treatment (VC200) resulted in the highest Hunter *b* values (7.7). Both tea catechins treatments (TC200 and TC400) greatly suppressed ($P<0.01$) lipid oxidation in raw meat patties compared to controls, and TC400 resulted in the lowest TBARS values (Fig. 3). Vitamin C treatments (VC200 and VC400) did not significantly reduce ($P>0.05$) lipid oxidation in raw meat patties compared to controls (Fig. 3).

Tea catechins have been recognized as efficient antioxidants by scavenging free radicals and chelating metal ions (Shahidi and Wanasundara, 1992; Tang et al., 2002). In the current study, tea catechins caused discoloration possibly by binding with the iron component of myoglobin, and delayed lipid oxidation by reacting with free radicals. Discoloration caused by tea catechins clearly reduced the visual appearance and overall acceptability of the meat patties by panellists. Maher et al. (2002) reported that addition of tea catechins (1000 mg/kg muscle) and rosemary (1000 mg/kg muscle) to minced beef greatly improved the colour and lipid stability under aerobic and modified atmosphere conditions compared controls. Tang et al.

(2001) reported that lipid oxidation in cooked chicken meat was more effectively controlled by the addition of tea catechins (300 mg/kg meat) than that in cooked beef, and that inhibition of lipid oxidation resulting from tea catechins was greater than that for vitamin E. In this study, tea catechins caused meat discoloration but inhibited lipid oxidation to a greater extent than vitamin C.

Meat

Beef was more susceptible ($P<0.01$) to oxidation as either cooked or raw than chicken meat. Raw meat stored in high oxygen conditions (80% O_2 : 20% CO_2) was more prone to lipid oxidation than cooked meat stored in anaerobic conditions (30% CO_2 : 70% N_2). Tea catechins and vitamin C treatments were effective ($P<0.001$) for lipid oxidation in cooked beef but not ($P>0.10$) in cooked chicken meat. Tea catechins treatments were effective ($P<0.05$) for lipid oxidation in raw beef compared to the control and vitamin C treatments but not ($P>0.10$) in raw chicken meat. Since chicken meat was very stable for lipid oxidation compared to beef in this study, neither tea catechins nor vitamin C could act well as antioxidants for lipid oxidation in cooked or raw chicken meat patties.

Conclusions

Addition of tea catechins caused discoloration in cooked beef and chicken patties, but effectively reduced lipid oxidation in cooked and raw beef patties. Further studies are necessary to elucidate the antioxidant mechanisms of tea catechins in muscle systems.

THE COMPOSITION AND OXIDATIVE STABILITY OF LIPIDS IN LONGISSIMUS MUSCLE FROM GRAZING CATTLE SUPPLEMENTED WITH SUNFLOWER OIL OR LINSEED OIL

Moloney, A. P.[1], Noci, F.[2], Monahan, F.J.[2], O'Grady, M.N.[3] and Kerry, J.P.[3]

Background

Manipulation of ruminant ration composition has been employed to enhance the concentrations of conjugated linoleic acid (CLA) and omega-3 polyunsaturated fatty acids (PUFA) in milk and meat. Compared with conventional indoor rations, consumption of grass, rich in n-3 PUFA, led to an improvement in the fatty acid profile of beef, by increasing PUFA and CLA concentrations, decreasing the n-6:n-3 PUFA ratio and decreasing the saturated fatty acid concentration (French et al., 2000). Enrichment of concentrate rations with plant oils, such as linseed oil or sunflower oil, also resulted in an increase in the concentration of CLA in bovine muscle (Enser et al., 1999, Noci et al., 2002). No information is available on the efficacy of such supplementation strategies for grazing beef cattle.

Strategies that improve the fatty acid composition must not impair other quality characteristics of beef. Appearance, specifically colour, is an important quality attribute influencing the consumer's decision to purchase. Increasing the PUFA concentration *per se* and/or increasing the concentration of longer carbon chain PUFA, predispose lipids to oxidation (Rey et al., 2001). Lipid oxidation is believed to be linked to muscle pigment oxidation and consequently to colour stability (O'Grady et al., 2001).

Objectives

The first objective of this study was to investigate the effect of plant oil supplementation of grazing cattle on the fatty acid profile of muscle, in particular the n-3 PUFA and CLA concentrations. The second objective was to determine the effect of alterations in the fatty acid composition on colour and lipid stability of beef.

Materials and methods

Forty-five Charolais crossbred heifers (mean initial bodyweight = 330 kg, s.d. 39.90) were blocked by initial bodyweight and, within block, randomly assigned to one of three dietary treatments (n = 15): unsupplemented grazing (GO); restricted grazing plus 2 kg/head/day of linseed oil-enriched meal (LO) or restricted grazing plus 2 kg/head/day of sunflower oil-enriched meal (SO). Concentrate and grass allowances were monitored at three-week intervals during a 5-month experimental period to achieve similar carcass weights across the treatments. Animals were slaughtered at a commercial facility, carcasses were chilled for 48 h at 4^{o}C, and the *M. Longissimus dorsi* (LD) was excised from each carcass. Intramuscular fat was extracted from muscle samples using chloroform and methanol (2:1 v/v), methylated at 50^{o}C for 20 minutes in alkaline and then acidic conditions and the fatty acid methyl esters obtained were analysed by gas chromatography (Supelcowax 100 m CP-Sil 88, Varian 3800). Vitamin E concentrations were measured as described by O'Sullivan et al. (2003).

Samples of LD collected 48h *post mortem* were vacuum packaged and stored at 4^{o}C for a further 24h prior to analysis. Samples were cut into steaks (25.4 mm thickness) and placed in retail display trays. Trays were over-wrapped with oxygen permeable film for aerobic storage or flushed with 80% O_2: 20% CO_2 for storage under modified atmosphere conditions. All samples were stored for up to 10 days at 4^{o}C under simulated retailed display conditions (616 lux fluorescent lighting). Colour measurements were made at 2 day intervals using a Cr-300 Chromameter (Minolta Co. Ltd., Japan) set on the CIE colour scale and reported as the 'a' redness value. Lipid oxidation was measured by the distillation method of Tarladgis et al. (1960) as modified by Ke et al. (1977) and results were expressed as 2-thiobarbituric acid reactive

substances (TBARS) in mg malondialdehyde/kg muscle. The data were analysed as a randomized block design using Genstat 6.0.

Results and discussion

Fatty acid data are summarised in Table 1. In general, the fatty acid composition of GO-fed cattle was similar to that previously reported by French et al. (2000). Compared to GO, SO-fed cattle had a higher concentration of C18:1 trans-11, C18:2, cis 9, trans-11 CLA, C20:4, total PUFA and n-6 PUFA but a lower concentration of C12:0, C18:3 and C22:5 and higher P:S and n-6:n-3 PUFA ratios. Compared to GO, LO-fed cattle had a higher concentration of C18:1 trans-11, cis 9, trans-11 CLA and n-3 PUFA and n-6:n-3 ratio but a lower concentration of C12:0, C20:4, C22:5 and C22:6. Compared to LO, SO-fed cattle had a higher concentration of C18:1 trans-11, C18:2, cis 9, trans 11 CLA, C20:4, C22:6 and n-6 PUFA, a lower concentration of C18:3 and a higher n-6:n-3 ratio.

Vitamin E (ug/g)	2.70^{a}	3.16^{b}	1.99^{c}	0.224	**

[1]NS = not significant; *,** and *** = P<0.05, P<0.01 and P<0.001, respectively; [2]SFA=total saturated fatty acids; MUFA = total monounsaturated fatty acids; PUFA = total polyunsaturated fatty acids; n-6 PUFA = sum of C18:2, C18:3n-6, C20:2, C20:3n-6, C20:4 and C22:2; n-3 PUFA = sum of C18:3n-3, C20:3n-3, C20:5, C22:5 and C22:6.

Vitamin E concentration was lowest in LO-fed cattle and highest in SO-fed cattle (Table 1). Since similar amounts were supplied by the concentrates this suggests greater metabolism and a possible greater requirement for Vitamin E in the diet that supplied the greatest amount of n-3 PUFA.

There was no effect of diet on colour stability of beef (Table 2). Muscle lipids tended to be more susceptible to oxidation in MAP (higher TBARS) than in aerobic packaging with muscle from SO-fed animals more stable than LO-fed animals (Table 2). Muscles from LO-fed animals had lower lipid stability compared to GO-fed animals on day 2 and 6 of display in MAP.

Table 2. Surface redness ('a' value) and lipid oxidation (TBARS) in *M. longissimus dorsi* from grazing cattle either unsupplemented (GO) or supplemented with sunflower oil (SO) or linseed oil (LO) stored in aerobic or in modified atmosphere packs (MAP).

[1]NS = not significant, * and ** = P<0.05 and P<0.01, respectively. Within packaging type and day, means with a common superscript do not differ significantly.

Conclusions

Supplementing grazing animals with plant oil-enriched concentrates resulted in a further beneficial effect on the fatty acid composition of muscle compared to grazing alone. Sunflower oil was more effective than linseed oil in increasing the concentration of CLA and TVA, but had a negative effect on the n-6:n-3 PUFA ratio. Linseed oil had a less pronounced effect on the CLA concentration than sunflower oil, but it also had a less negative effect on the n-6:n-3 PUFA ratio. While linseed oil supplementation caused a transient increase in lipid oxidation, this was not reflected in a loss in colour stability.

Background

The angiotensin I-converting enzyme (ACE) catalyses the formation of angiotensin II, a strong vasopresser, from angiotensin I, together with inactivation of bradykinin possessing hypotensive activity (Ondetti et al. 1977). Such dual effects of ACE inhibitors are contributory to their potent antihypertensive activity. Commercially available antihypertensive drugs such as captopril and enarapril are very potent ACE inhibitors. Recently, many ACE inhibitory peptides have been isolated from casein (Maruyama et al. 1985), sardine muscle (Matsui et al. 2000), dried bonito (Yokoyama et al. 1992), and porcine skeletal muscle (Arihara et al. 2001, Katayama et al. 2003 & 2004). However, there are few reports on deriving ACE inhibitory peptides derived from chicken bone extract.

Objectives

The objective of this study is to isolate and purify ACE inhibitory peptide derived from chicken bone extract.

Materials and methods

Materials and reagents

Chicken bone was obtained from ITOHAM FOODS Inc. Hippuryl-L-histidyl-L-leucine (HHL) was purchased from Nacalai Tesque (Kyoto, Japan). Commercial ACE (from rabbit lung) and trypsin were purchased from Sigma Chemical Co. (St. Louis, MO. U.S.A).

Preparation and hydrolysis of chicken bone extract

One kg of chicken bone was cut into about 3 cubic cm fragments using a saw, and heated under pressure at 121 ^{o}C for 30 min in an autoclave. The treated bone was suspended in 4 L of distilled water and boiled for 4 hours at 100 ^{o}C. The heated solution was filtered through a paper towel, and the filtrate was collected. Thereafter, the filtrate was centrifuged for 60 min at 10,000 x g to remove fat. The remaining solution was filtered again through a No. 5A filter paper (Toyo Roshi Kaisya Ltd., Tokyo, Japan), then the filtrate was lyophilized and used as chicken bone extract. Trypsin was used for hydrolysis of chicken bone extract. Five mg/ml of chicken bone extract was used as substrate. The ratio of enzyme to substrate was 1/100 (based on protein content). After 6 hours of hydrolysation at 37 ^{o}C (pH7.5), the solution was heated at 95 ^{o}C for 10 min to inactivate the protease. The solution was centrifuged for 10 min at 10,000g, and the supernatant was collected for experiments.

Purification of ACE inhibitory peptide

The chicken bone extract hydrolysate was fractionated by high-performance liquid chromatography (HPLC) with gel-filtration (column:TSK gel G2000SW$_{XL}$, 7.8 x 300 mm, Tosoh Co., Tokyo, Japan). Elution was performed with an isocratic elution of 0.2 M PBS (pH7.0) at a flow rate of 1.0 ml/min, after which the absorbance was detected at 225 nm (first HPLC run). The active fraction was collected, and rechromatographed under reversed-phase mode (column:Inertsil ODS-2 (octadecyl silica column), GL-Science, Inc., Tokyo, Japan). Elution was performed with a linear gradient of 0-35 % CH_3CN in 0.1 % TFA at a flow rate of 1.0 ml/min., after which the absorbance was detected at 225 nm (second HPLC run). The active fraction was again collected and rechromatographed under the same conditions except for the eluting solution. This time the elution was performed with a linear gradient of 8-14 % CH_3CN in 0.1 % TFA at a flow rate of 0.5 ml/min. Absorbance was again detected at 225 nm (third HPLC run). The active fraction was once again collected and rechromatographed under reverse-phase mode (column:Cosmosil 5PE-MS (phenyl

column), GL-Science, Inc., Tokyo, Japan). Elution was performed with an isocratic elution of 10 % CH_3CN (fourth HPLC run) and 5 % CH_3CN (final HPLC run) at a flow rate of 0.5 ml/min. This time the absorbance was detected at 215 nm.

Assay for ACE inhibitory activity

The ACE inhibitory activity was measured according to the method of Cushman and Cheung (1971) with slight modifications. This assay is based on the liberation of hippuric acid from hippuryl-L-histidyl-L-leucine (HHL) catalyzed by ACE. Six µl of sample solution was mixed with 20 µl of ACE (60 mU/ml) which dissolved in borate buffer (pH8.3), and with 50 µl of 7.6 mM HHL dissolved in 0.01 M borate buffer and 0.608 M NaCl. The mixture was incubated for 30 min at 37 ^{o}C. To terminate the enzyme activity, 554 µl of 0.1N HCl was added. To extract hippuric acid liberated from HHL by ACE, 1.5 ml of ethyl acetate was added and the tubes were vigorously shaken, and then centrifuged for 15 min at 1,000 x g. One ml of the ethyl acetate layer was dried for 10 min at 100 ^{o}C. Hippuric acid liberated by ACE was photometrically measured at 228 nm after ethyl acetate extraction. IC_{50} value was defined as the concentration of ACE inhibitors needed to inhibit 50 % of ACE activity.

Analysis of peptide

The amino acid sequence of the purified peptide was analyzed by a protein sequencer (Procise 492, Applied Biosystems, Foster City, CA, USA).

Synthesis of peptide

The peptide was synthesized by a solid phase method with a peptide synthesizer (Symphony, RAININ Instrument Co. Inc., Woburn, MA, USA).

Results and discussion

The plain chicken bone extract did not show ACE inhibitory activity, but its hydrolysate showed relatively strong activity with an IC_{50} value of 0.781 mg/ml. This level of activity is comparable to that of carnosine, which is a well-known substance with ACE inhibitory activity. The hydrolysate of chicken bone extracted by trypsin was fractionated by gel-filtration HPLC and the findings are shown in Fig. 1 (first HPLC run). Three fractions with the highest inhibitory activity (12-15 min) were further purified by reversed-phase HPLC (second and third HPLC run). Then the fraction with the highest inhibitory activity (26-27 min) was further purified by reversed-phase HPLC (fourth ie., the final HPLC run). From the single active fraction shown in Fig. 2 (final HPLC run), one peptide with a high ACE inhibitory activity was purified. The single purified peptide was sequenced by a protein sequencer. The amino acid sequence of the one ACE inhibitory peptide was determined, and the structure of the peptide was YYRA (Tyr-Tyr-Arg-Ala, MW 571.67). The IC_{50} value of this single isolated peptide was 33.9 µg/ml, and it showed a relatively high level of activity as do other ACE inhibitory peptides derived from foods. A search for sequence homology in certain databases (FASTA WWW service) demonstrated that the same sequence exists in the primary structure of Ig heavy chain V region (27-30 position) as shown in Fig. 3. Therefore, a novel ACE-inhibitory peptide not previously reported, was now introduced.

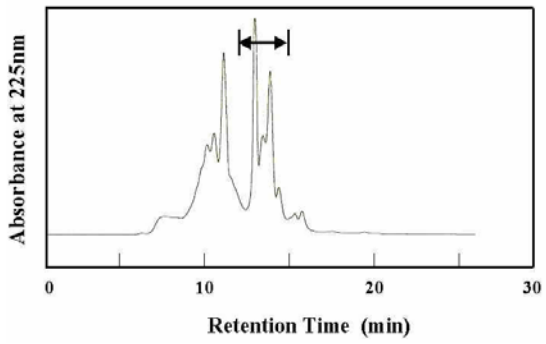

Fig. 1 Gel-filtration HPLC chromatograph (first HPLC run) Arrow indicate active fraction.

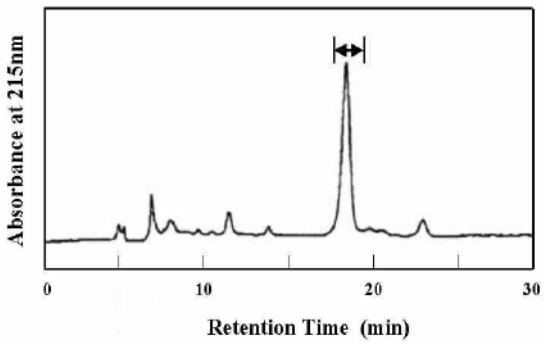

Fig. 2 Reversed-phase HPLC chromatograph (final HPLC run) Arrow indicate active fraction.

Fig. 3 Position of the peptide in the sequence (YYRA) of Ig heavy chain V region.

There are some peptides with potent inhibitory activity in vitro or when intravenously administered that are not active in vivo, when administered orally. It is thought that these peptides are digested into inactive peptide fragments or amino acids after oral administration. It is of great importance that the peptides have sufficient antihypertensive activities in vivo. Further studies are, thus, needed to measure the ACE activity using spontaneously hypertensive rats (SHR).

Conclusions

A novel ACE inhibitory peptide was isolated and purified from chicken bone extract. The amino acid sequence of the peptide was YYRA (Tyr-Tyr-Arg-Ala), which was of the origin of the Ig heavy chain V region (27-30 position). The result of this study suggests that ACE inhibitory peptides derived from chicken bone extract could be utilized in developing physiologically functional foods.

IDENTIFICATION OF SOURNESS-SUPPRESSING PEPTIDES IN COOKED PORK LOINS

Nishimura, T.[1], Okumura, T.[2], Morimatsu, F.[2] and Yamada, R.[2]

[1] Graduate School of Biosphere Science, Hiroshima University, Kagamiyama1-4-4 Higashi-hiroshima, 739-8528, Japan
[2]R& D Center, Nippon Meat Packers, Inc., 3-3 Midorigahara Tsukuba 300-2646, Japan

Background

It is well known that meat becomes more palatable with postmortem conditioning, which brings about not only tenderization but also improvement of flavor. The free amino acids and peptides that increase during postmortem aging play an important role in the improvement of meat taste (Nishimura, T., 1998). Some reports have indicated that there are peptides that change taste perception. It has been shown that dipeptides such as Gly-Glu, Pro-Glu and Val-Glu have a buffering action and improve the taste of Japanese sake. Glutamic acid-rich oligopeptides and casein hydrolysate have been reported to mask a bitter taste (Noguchi et al., 1975; Tamura et al, 1990). It has been reported that the addition of hydrolyzed wheat gluten to an umami taste solution enhanced its strength. A peptide fraction of MW 1,000-10,000 from beef vacuum-cooked at 60 ^{o}C for 6 hours has been reported to improve the taste of un-aged beef soup by suppressing its sourness（Ishii et al, 1995. Peptides enhancing umami in the presence of inosinic acids were also isolated from chicken hydrolysate by protease (Maehashi, et al, 1998). However, in the case of pork, there is little information on peptides that improve meat taste.

Objectives

The present work was conducted to identify the peptides that suppressed the sourness and improved the taste of vacuum-cooked pork loins after *post mortem* conditioning of 20 days at +4^{o}C. This study was also carried out to clarify the mechanism of sour taste suppression by the peptides.

Materials and methods

Preparation of peptide fractions

Pork loins were stored in the vacuum-packages at +4^{o}C for 20 days after slaughter, and the packages were heated in a water bath at 60^{o}C for 360 min. The ground pork loin was freeze-dried and the lipids were extracted with n-hexane. The ground lean muscle was then homogenized with a ten-fold volume of de-ionized water. The homogenate was centrifuged at 10,000×g for 20 min and the supernatant was collected. Ethanol was added (final concentration, 80%) to this supernatant, followed by centrifugation and then filtration. After evaporation and further freeze-drying of the filtrate, the LD muscle powder was dissolved in de-ionized water. The solution was ultrafiltrated through MW500 and 1,000 cut-off membranes (Amicon Co., Beverly, USA), and then freeze-dried. Each peptide fraction, Fraction Ⅰ (MW < 500), Fraction Ⅱ (MW 500-1,000), or Fraction Ⅲ (MW > 1,000), was obtained.

Sensory evaluation

Using a modification of the paired-preference tests, the changes in the strength of basic tastes on the addition of the peptide fractions were evaluated by a well-trained panel. The relative difference was expressed within a scale of -5 to 5 points, the point in the absence of a peptide fraction being taken as zero. Solutions of 0.2% lactic acid (sourness), 0.04% monosodium glutamate (umami), 0.001% quinine hydrochloride (bitterness), 0.5% sodium chloride (saltiness), and 1.0% sucrose (sweetness) were used as basic taste solutions for sensory evaluation.

Peptide analysis

Peptides were analyzed by HPLC on a reversed-phase column (Senshupack VP-318, Senshu Sci. co., Tokyo, Japan). The filtrate was applied on the column and eluted with a linear concentration (0-40%) gradient of acetonitrile containing 0.1% trifluoroacetic acid at 40 ^{o}C for 80 min. The flow rate was 1.0 ml/min and peptides were detected at 220 nm. The amino acid sequences of the peptides were determined with an ABI amino acid sequencer (Model 477A, Applied Biosystem Japan, Tokyo, Japan), and the molecular weights were measured with a mass spectrometer (TSQ 7000, Thermo Finnigan, San Jose, USA).

Assaying of binding to epithelial tissue of porcine tongues

The epithelial tissue containing foliate papillae was removed from the underlying dermis of fresh porcine tongue with a scalpel and fine forceps. After mincing with scissors, the epithelial tissue was homogenized with a ten-fold volume of 10mM Tris-HCl buffer (pH7.4) containing 10 mM $CaCl_2$ and 30 mM mannitol, and the homogenate was centrifuged at 30,000×g for 20 min. The precipitate was further homogenized with 10mM Tris-HCl buffer (pH 7.4) containing 100 mM mannitol, and the homogenate was centrifuged at 40,000×g for 20 min. This precipitate then served as the epithelium of porcine tongues.

The binding of radioactively labeled L-lactic acid (L-[U-^{14}C] lactic acid, sodium salt (120 Ci /m mol)) to the epithelium was measured. Sodium lactate solution (0.15 ml; 0.5%) containing labeled L-lactic acid and K-phosphate buffer (pH 7.2; 0.04 ml; 0.5M) was then added to 0.15 ml of epithelium solution (approximately 0.17mg protein/ml). Then, 0.16 ml of a peptide fraction solution or de-ionized water was added to this mixture, the final total assay volume being 0.4 ml. The same volume of 10 mM Tris-HCl buffer (pH 7.4) instead of the epithelium solutions was used as a blank. Each sample was incubated at room temperature for 10 min and then filtered rapidly through a 0.45μm cellulose acetate filter (Nihon Millipore Ltd., Tokyo, Japan). After filtration, the filter was immediately rinsed with 10 ml buffer 20 mM Tris-HCl buffer, pH） and the filter disc then placed into a bottle containing 5 ml of scintillation fluid (Aquasol^{TM}, New England Nuclear Co., Montpellier, USA). Then the radioactivity (C-DPM) of the samples was counted with a liquid scintillation counter (LSC-5100, Aloka Co., Mitaka, Japan). Each binding value was calculated by subtraction of the C-DPM value for the blank without epithelium from that with epithelium.

Assaying of binding to a synthetic lipid membrane with a taste sensor

The binding of sour taste substances to a synthetic lipid membrane composed of two types of lipids, dioctylphosphate and triocthylmethyl ammonium chloride, was measured with a taste sensor (SA401, Anritsu Co., Atsugi, Japan). A tartaric acid solution (1-10mM) containing 10 mM KCl was used as the sour taste solution. Using the taste sensor system, binding of tartaric acid to the membrane was relatively well reflected by the electric potential (mV) of the taste sensor. The electric potential of the tartaric acid solution with or without the peptide fraction was measured.

Results and discussion

Recovery of peptide fractions of pork

The amount of Peptide fraction I (MW < 500) in pork loins gradually increased as the storage period became longer, as did that of Fraction II (MW 500-1,000) up to 20 days. However, the amount of Peptide fraction III (MW > 1,000) remained unchanged throughout storage for 30 days. The result that peptides increased during storage for 20 days is in accordance with our previous study (Okumura, 1996). The amounts of peptides in fractions I, II and III from pork loins stored for 20 days were 30.2, 7.5 and 1.6 mg/g meat, respectively. With heating at 60°C for 6 hours after *post mortem* conditioning of two days, the amount of all three peptide fractions increased. However, in the pork stored for 20 days the fractions remained almost unchanged. Although we did not examine the reason for this, the fact that the activities of endogenous proteases in porcine muscle were lost during *post mortem* aging for 20 days may be responsible for the phenomenon.

Effect of addition of peptides fraction on basic tastes

The effect of added peptide fractions on the basic tastes were examined by sensory evaluation. Figure 1 shows that the sourness of a lactic acid solution by addition of Fraction II (0.074%) from pork loins stored at 4°C for 20 days was weaker than that without peptide fraction, while the addition of Fraction Ⅰ (0.37%) or III (0.016%) had little effect on sourness suppression. This indicated that some peptides in Fraction II suppressed sourness. The increase of these peptides during conditioning seemed to play an important role in the change of the sourness of unaged pork. Although the taste of beef taken from the carcass immediately after slaughter is sour and bloody, meat after conditioning at a low temperature has no such taste. Mild taste created during conditioning may be related to an increase in peptides. Therefore, it seemed that Fraction II masked the sourness or metallic taste of immediately *post mortem* pork meat and improved the taste during conditioning.

Purification and identification of the peptides suppressing sourness

In order to identify peptides suppressing sourness, the analysis of peptides in Fraction II of pork loins stored for 2 and 20 days at 4°C was performed. Figure 2 showed that the main peaks indicated by arrows presenting peptides (1), (2) and (3), were greatly increased during storage. On amino acid analyses of the peptides with

an amino acid sequencer and a mass spectrometer, peptides (1), (2), and (3) were identified as APPPPAEVHEVV, APPPPAEVHEVVE and APPPPAEVHEVHEEVH. These peptides were homologous to the peptide, APPPPAEVHEVHEEVH that was generated from troponin T in pork during *post mortem* conditioning. The structure of these peptides was similar to that of the peptide increasing during *post mortem* aging of beef. Many researchers have reported that troponin T was degraded by the activity of proteases during *post mortem* aging of chicken, porcine and bovine muscles at low temperature. The purified troponin T has also been shown to be degraded by calpain and cathepsin, indicating that the peptide APPPPAEVHEVHEEVH seems to be produced by the action of calpain and / or cathepsin. The clarification of the mechanism is the next problem to be resolved.

Using synthetic peptide, APPPP or APPPPAEVHEV, which are common amino acid sequences in the three peptides, the effect of these peptides on sourness was examined by sensory evaluation. The addition of APPPP to a lactic acid solution did not change the sour taste, whereas the addition of APPPPAEVHEV suppressed the sour taste. From these results, it was concluded that the three peptides containing common sequences in Fraction II suppressed the sour taste, and the increases in these peptides during conditioning delivered the mildness to the taste of meat. This is the first report that discovered the peptide suppressing sourness.

Mechanism of suppression of sourness on the addition of peptides

i) Binding assay of peptide using the epithelium of porcine tongue: The effect of concentration of peptide on the lactate binding to the epithelium was examined. The higher the concentration of Fraction Ⅱ added to the sample solution at pH 5 was, the lower was the amount of lactic acid binding to the epithelium (Fig. 3).

ii) Binding of tartaric acid to a synthetic lipid membrane: The binding of tartaric acid to a synthetic lipid membrane was also inhibited by the addition of peptide (3) in Fraction II, suggesting that Fraction II inhibited the binding of sour taste substances to the membranes of tongues. Furthermore, this inhibitory action depended on the concentration of Fraction II. It was concluded that the peptides of Fraction II derived from pork extract suppressed sourness through its interaction with sour taste channel or sour taste substances. That is, sour taste substances can not reach sour taste ion channel, because the peptide is either binding with sour taste substances or covering the entrance of sour taste ion channel (Fig. 4).

Conclusions

A peptide fraction (Fraction II; molecular weight 500-1000) from pork loins were cooked in vacuum-packages at 60°C for 6 hours suppressed sourness. Three peptides (APPPPAEVHEVV, APPPPAEVHEVVE and APPPPAEVHEVHEEVH) were isolated from Fraction II. These peptides seemed to suppress sourness through their interaction with sour taste channels or sour taste substances.

EFFECT OF MILK-REPLACER REARING *VS* NATURAL REARING ON FATTY ACID COMPOSITION OF SUCKLING LAMB LIVER

Osorio, M. T.[1], Bermejo, B.[1], López, O. A.[2], Zumalacárregui, J.M.[1], and Mateo, J.[1]

Background

"Castilla y León" is the region of Spain with the largest sheep stock –c.a. 6 millions–, from which approximately 2.5 millions are slaughtered annually for human consumption. The mayor part of these are suckling lambs 'lechales' –c.a. 60-70%– with age between 25-45 days and with a carcass weight of less than 7 kg, coming from milk production systems (Sañudo *et al*., 1998). The importance, value and quality of suckling lamb meat in 'Castilla y León' has been recognized and protected by a geographical indication: 'Lechazo de Castilla y León' (Council Regulation 2081/92/EC).

In general, in this region the suckling lambs are reared exclusively either with ewe's milk or with milk-substitute, although the last is being more widely used, especially in milk breeds. It appears that rearing suckling lambs, with one or the other type of milk has effect on several production aspects: economical –i.e. feed conversion, milk's price, cheese making, etc.–, meat quality –i.e. nutritional and organoleptic characteristics–, animal welfare and health (De la Fuente *et al*., 1998; Pérez *et al*., 2001; Napolitano *et al*., 2002), supporting the one or the other of both possibilities.

No studies on the fatty acids content of suckling lamb's liver have been found in the literature; however, there were found references dealing with the fat composition of older lambs (Enser *et al.*, 1998; Mir *et al.*, 2000; Moibi and Christopherson, 2001).

Objectives

The purpose of this study was to evaluate the effects of the type of rearing on the fatty acid composition of the liver of an autochthonous lamb breed from Spain (Churra). It was expected that fatty acid profile of fat depots from unweaned young lambs would really reflect the composition of the ingested milk (Bas and Morand-Fehr, 2000, Napolitano *et al*., 2002) –due to the fact that rumen metabolic development has not occurred at this early stage (Lane *et al*., 2000).

Materials and methods

Samples

Thirteen livers of 'lechales' from the Churra breed which were hand reared with milk-replacer and seventeen livers of Churra 'lechales' reared with ewe's milk were purchased from a local slaughterhouse. All samples were homogenised and kept frozen at -40 ºC prior to all analysis.

Fatty acid profile of liver

For analysis of fatty acids, the fat from aliquots of 35 g of liver was extracted according to the method described by Bligh and Dyer (1959). The methyl esters of fatty acids (FAME) from the fat were obtained by base-catalyzed transesterification with $NaCH_3O$ (Sehata *et al.* 1970). Gas chromatographic (GC) analysis were carried out using a Hewlett Packard 6890 Series GC System Chromatograph equipped with a automatic injector (HP 7683 Series Injector), and a Hewlett Packard 5973 Mass Selective detector. The column used for the separation was a Supelco 2-4136 Omegawax^{TM} 250 fused silica capillary column (30 m × 0.250 mm, 0.25 µm film thickness). The GC conditions were as follows: Initial oven temperature 50 ºC, held for 1 min, then programmed at 10 ºC min^{-1} to 150 ºC and held for 1 min, then 12 ºC min^{-1} to 180ºC, then 2 ºC min^{-1} to188ºC and held for 6 min, then 2 ºC min^{-1} to 220 ºC and held for 2 min, and finally 20 ºC min^{-1} to 260 and held for 7 min. Injector and detector temperature were 200 ºC and 300 ºC, respectively. The flow rate of the carrier gas (He) was 1 ml min^{-1} and 1 µl of solution was injected in the mode split, ratio 30:1, and the pressure was 16 psi.

The FAMEs were identified by using individual standards and by their mass spectrometry data obtained with a HP Mass Spectral Libraries (Hewlett Packard, revision D 01.00, 1998) as well as by their retention time found in literature. Quantities of FAMEs were calculated from the response factor of standards or, in case of those standards that were not available, from the response factors of their respective isomers. Results were expressed as percentage of weight of the identified peaks.

Statistical analysis
Fatty acid composition were analysed using ANOVA with one factor, rearing system.

Results and discussion

The fatty acid compositions of the liver from both types of feeding are shown in table 1. The most abundant fatty acids were C18:1, C18:0 and C16:0 and compared with other fatty depots of meat, a high percentage of polyunsaturated fatty acid was observed. These results are in agreement with those found in liver of older lambs in other studies (Enser *et al*., 1998; Mir *et al*., 2000; Moibi and Christopherson, 2001).

Liver from artificially reared lambs showed a lower content of saturated fatty acids ($P<0.001$) and a higher content of unsaturated fatty acids ($P<0.001$). The percentage of monounsaturated fatty acids was lower in the liver obtained from ewe-reared lambs ($P<0.001$) whereas no difference were observed for polyunsaturated fatty acids.

Saturated capric (C10:0), pentadecanoic (C15:0), palmitic (C16:0), margaric (C17:0) and stearic (C18:0) fatty acid contents were lower in the liver of lambs reared with milk substitute ($P<0.005$, $P<0.001$, $P<0.05$, $P<0.001$, and $P<0.001$, respectively). The amount of branched fatty acids was ten times greater in the samples of liver of lambs raised with ewe's milk ($P<0.001$) which can be attributed to the presence of these fatty acids only in ewe's milk. On the contrary, the monounsaturated oleic (C18:1) fatty acid contents were lower in the liver of ewe-reared lambs ($P<0.001$) whereas the cis-heptadecenoic fatty acid (C17:1) were higher ($P<0.001$), the same as the entire fatty acids with an odd number of carbon atoms.

The content of linoleic (C18:2), eicosadienoic (C20:2) and eicosatrienoic (C20:3) fatty acids were higher ($P<0.005$, $P<0.001$ and $P<0.05$, respectively) in the liver of lambs reared with milk substitute. On the other hand the content of linolenic (C18:3), arachidonic (C20:4) and eicosapentaenoic (C20:5) ($P<0.001$) polyunsaturated fatty acids were lower.

The P/S ratio was higher in lambs reared with milk substitutes ($P<0.001$) while the percentage of ω-3 polyunsaturated fatty acids was higher in lambs reared with ewe's milk ($P<0.001$).

The fatty acid profile of liver rather reflects the composition of the milk ingested by lambs. The rumen of suckling lambs is not functional yet and so the fatty acid composition of liver is similar to the fatty acid composition of ingested milk. According to Napolitano *et al.* (2002) milk substitutes showed a lower content of saturated fatty acids (60.2 *vs* 66.4%) and a higher content of monounsaturated (30.1 vs 20.1%) and polyunsaturated (9.7 vs 6.2%) fatty acids compared to milk from ewe. Most of the fat components of milk substitutes are derived from vegetables oils, which are characterised by a lower level of saturation compared to animal fats.

Conclusions

Substantial differences in fatty acid composition between liver from suckling lambs reared with ewe's milk and from those reared with milk-replacer were observed in this study. The liver of the lambs reared exclusively with ewe's milk showed a higher content of saturated fatty acids and a lower content of monounsaturated fatty acids than liver from artificially reared lambs. The nutritional characteristics of the livers of suckling lambs are influenced by the type of feeding.

MEAT PROTEIN-TANNIN INTERACTIONS: OBSERVED ANTIOXIDANT ACTIVITY AND POTENTIAL HEALTH BENEFITS

Pegg, R.B.[1] and Amarowicz, R.[2]

[1]University of Saskatchewan, Department of Applied Microbiology and Food Science, 51 Campus Drive, Saskatoon, SK, S7N 5A8, Canada; [2]Division of Food Science, Institute of Animal Reproduction and Food Research of the Polish Academy of Sciences, ul. Tuwima 10, PO Box 55, 10-718 Olsztyn, Poland

Background

A bearberry-leaf (*Arctostaphylos uva-ursi* L. Sprengel) extract was shown to be a good source of natural antioxidants and imparted strong antioxidant activity in model and meat systems (Pegg et al., 2001; Amarowicz et al., 2004). This observed activity stems chiefly from the polyphenolic constituents present in the extract (Amarowicz and Pegg, 2004). Polyphenolic-protein interactions are a matter of continuous research due to their importance in food: nutritional effects centre on the capacity of phenolics to bind and precipitate proteins. Tannins, which are complex secondary metabolites of plants widely distributed in foods and comprised of gallic acid esters or flavan-3-ol polymers, are most commonly responsible for such interactions with proteins. Tannins can form soluble and insoluble protein complexes; the formation depends not only on the size, conformation and charge of the protein molecules, but also on the molecular weight, length and flexibility of the tannins involved (Naczk et al., 2001a). The precipitation of a protein-tannin complex results from the development of a sufficiently hydrophobic surface on the adduct due to polyphenols binding to the protein surface and cross-linking of different protein molecules with the polyphenols. The bearberry extract is rich in tannins (~10%), which are partially responsible for the observed antioxidant activity in meat systems. Until recently, tannins have been basically considered as antinutrients in foods because they decrease the nutritional value of protein; however, it begs the question, "since the tannins function as antioxidants, do the complexes so formed in meat also do the same?"

Objectives

The objectives of this study were to verify the formation of protein-tannin complexes in meat and then to assess whether or not the antioxidant activity of the native tannin persisted in the protein-tannin complex.

Materials and methods

A crude bearberry-leaf extract was prepared according to Amarowicz et al. (2004) and then dechlorophyllized according to Pegg et al. (2003) on a silicic acid column using hexanes and 95% (v/v) ethanol as mobile phases. Dried extracts were stored at 4°C until used. The cooked pork systems were prepared and TBARS of the stored refrigerated products were determined according to the methods described by Pegg et al. (2001).

Isolation of Myosin

Myosin was isolated from chilled post-rigor knuckle muscle of hogs slaughtered at Mitchell's Gourmet Foods (Saskatoon, SK) and then shipped to the University of Saskatchewan 48 h post-mortem. A flow diagram for the isolation and purification of myosin from the muscle tissue is depicted in Fig. 1. All work was carried out in a refrigerated cabinet at 4°C. The modified Hasselbach-Schneider solution comprised 0.6 *M* KCl, 10 m*M* $Na_4P_2O_7 \cdot 10H_2O$ and 1 m*M* $MgCl_2$ in 0.1 *M* KH_2PO_4/K_2HPO_4 buffer, pH 6.4.

Production of Tannin-Protein Complexes from Porcine Myosin

Fifty milligrams of tannins (*i.e.*, obtained by Sephadex LH-20 chromatography of the crude ethanolic extract of bearberry: the first mobile phase used was 95% (v/v) ethanol to remove some polyphenolics {*i.e.*, arbutin and gallic acid} followed by the second, 1:1 (v/v) acetone:water; the acetone fraction collected was called "tannins") were dissolved in 50-mL distilled water. One hundred milligrams of isolated myosin were dissolved in 100 mL of a 0.20 M acetate buffer, pH 5.0, containing 0.17 M NaCl. The two solutions were mixed and allowed to stand at room temperature for 30 min. The reaction mixture was transferred to a 250-mL polypropylene centrifuge tube, centrifuged for 10 min at -2°C at 10,000 × *g* in a Beckman J2-HC centrifuge. The supernatant was carefully decanted. Precipitate adhering to the wall of the centrifuge tube was scrapped and the product was mixed with *ca.* 20-mL distilled water and then transferred to a small 50-

mL beaker. The contents in the beaker were lyophilized. The tannin content bound to proteins was determined by a colorimetric assay described by Hagerman and Butler (1978).

Results and discussion

The bearberry-leaf extract was found to be a rich source of tannins, comprising *ca.* 10% of the crude dechlorophyllized preparation, and possessed marked antioxidant activity in model and meat systems. Previous research in our laboratory has indicated that it contains both hydrolyzable and condensed tannins. When applied to meat systems, the tannins retarded lipid oxidation of the cooked products during storage. The effect was concentration dependent as depicted in Figure 2. At a 25-ppm addition level (sample B) the tannins offered little protection against oxidation of meat lipids (*i.e.*, only 35% inhibition of lipid oxidation by day 7), but when doubled, an efficacy almost equivalent to that of the synthetic antioxidant, *tert*-butylhydroquinone (TBHQ) added at the same level, was observed (*i.e.*, > 98% inhibition). This is quite interesting considering that the tannin constituents have considerably larger molecular masses than that of TBHQ (FW=166), which on a mole basis was added to the meat system in a far greater quantity. The question is, was the free-radical scavenging capability restricted to the free tannins in the meat meatrix or were those bound to protein in the form of protein-tannin complexes also capable of exhibiting antioxidant activity?

Tannins are notorious as protein precipitants and thereby decrease the nutritional value of food proteins. It is generally assumed that the resultant complex has limited or no value; however, is this really so? Tannins from bearberry-leaf extract were found to be strong precipitants of model proteins such as bovine serum albumin and fetuin (Naczk et al., 2001b); however, we wanted to investigate their interaction with meat proteins. As myosin is the dominant protein in muscle tissue, it was isolated from fresh meat used for the TBARS studies. Electrophoretic separation of the protein from the resultant product by SDS-PAGE confirmed that the isolated protein was indeed myosin of good purity, when comparisons of the separated bands were made to commercially-available myosin. Addition of tannins to the isolated myosin dissolved in a dilute salt solution resulted in protein precipitation. The precipitate was recovered, dried and confirmed to be a complex of protein and tannin by Hagerman and Butler's colorimetric assay. It was suspected that the myosin-tannin complex so formed might have biological value as an antioxidant. When added to meat systems, which were then thermal processed, cooled and stored under refrigeration conditions for a period, TBARS data indicated that the myosin-tannin complexes imparted protection to the meat against lipid oxidation. Again, the efficacy was concentration dependent as depicted in Figure 2. At a 200-ppm addition level (sample D), the complex exhibited weak inhibition of lipid oxidation; however, when greater addition levels were incorporated in the system (*i.e.*, 500 and 750 ppm; samples E and F, respectively), an antioxidant efficacy equivalent to that of the free tannins added at 50 ppm was observed. As the myosin-tannin complex is free of tannin residues, the antioxidant activity observed in the cooked meat systems is due to either the complex itself or the release of tannin constituents therefrom. Because tannins can have strong covalent bonding interactions with protein, the latter theory seems to be more likely. The fact that protein-tannin complexes can impart a beneficial biological activity to a food system tends to negate the historical view that the protein-tannin precipitation products only reduce the nutritional value of food. This study demonstrates that the complex formed could be of a more significant value, as protein-tannin complexes consumed in food products may provide persistent antioxidant activity in the gastrointestinal tract against free-radical species.

Conclusions

The tannin constituents of the bearberry-leaf extract offered marked antioxidant activity to meat systems. Their interaction with meat proteins, such as myosin, did not result in a loss of the observed antioxidant activity. In fact, spectral data from TBARS analyses of cooked pork systems indicated that the isolated protein-tannin complexes added to meat systems survive thermal processing and give stability to meat lipids against oxidation. Thus, tannins bound to proteins may provide a sink for persistent antioxidant activity.

SUCKLING LAMB FATTY ACIDS AS AFFECTED BY EWES FEEDING SYSTEM

Background

Milk produced by ewes grazing grass has a different fatty acid composition than milk from ewes given concentrates (Banni *et al*. 1996). In particular, milk from grazing ewes has lower levels of saturated fatty acids (SFA) and higher levels of fatty acids thought to be more beneficial to human health such as polyunsaturated fatty acids (PUFA) and conjugated linoleic acid (CLA) (Banni *et al*. 1996). In suckling ruminants, milk bypasses reticulorumen and is digested directly in the abomasum. Therefore, also milk fat escapes ruminal biohydrogenation. The effect of production system, and in particular of grass feeding, on the intramuscular fatty acids of suckling lamb (raised with their dams at pasture) has been studied (Velasco *et al*., 2001; 2004). However, literature lacks reports on the effect of the production system of ewes (pasture *vs*. stall feeding) on the intramuscular fatty acids of lambs fed exclusively maternal milk.

Objectives

The objective of this trial was to study the fatty acid composition of intramuscular fat in lambs fed exclusively milk from ewes consuming pasture or concentrates.

Materials and methods

Twenty pregnant Comisana ewes were selected about 30 days before lambing and divided into two groups of ten animals. One group of ewes was allowed to graze a vetch pasture (grass) from 07:00 to 18:00 every day. The second group of animals was penned and given hay and concentrate (stall). After lambing, all ewes were allowed to stay with the respective lambs between 18:00 and 07:00 of the following day in two different group pens. The lambs were kept in these pens for the whole trial, and fed exclusively maternal milk. Every ewe gave milk to only one lamb. In case of twin lambing, one was removed.

The lambs were slaughtered at 38 days of age. Twenty-four hours after slaughter samples of *longissimus thoracis* muscle were taken at the level of the 13th thoracic rib, minced, vacuum-packed (50 g for each animal), and stored at –25°C until analysed (10 days on average). Intramuscular fat was extracted, from a 4 g ground meat sample, according to Folch *et al*. (1957) as described by French *et al*. (2000). Fatty acids were quantified as fatty acid methyl esters prepared by acid-catalysed methanolysis (French *et al*. 2000). Separation of fatty acid methyl esters was performed with a capillary column SP-2380 in fused silica (60 m x 0.25 mm i.d.; 0.20 µm film thickness) using He as a carrier gas. The gas-chromatograph used was a Thermo Finnigan, TRACE with the software ChromQuest (Thermo Finnigan, San Jose, CA, USA). The conditions were the following: initial temperature 140°C; initial isotherm 1 min; temperature increasing, 1°C per min up to 165°C with an isotherm of 1 min, then increasing 6°C per min to the final temperature of 225°C; final isotherm 8 min; carrier He, injector temperature 230°C; detector (F.I.D.) temperature, 250°C; injector mode split, flow carrier on column constant (1.2 ml/min). The different fatty acids were identified by the retention time with reference to fatty acid standards. The fatty acid standards were purchased from Larodan Fine Chemicals AB (Malmö, Sweden). Standard mix was prepared in our laboratory, and palmitic acid was used as the reference fatty acid (response factor = 1.00). Fatty acids are expressed as percentage (w/w). Data were analysed by t-test to compare the two maternal feeding regimes (grass *vs*. stall).

Results and discussion

Mean carcass weight of the lambs was unaffected by the feeding treatment of the ewes, and was on average 9.3 kg. Intramuscular fatty acid proportions are reported in Table 1. Palmitic acid (16:0) was more abundant ($P < 0.05$) in the fat from lambs raised by ewes consuming concentrates. At the moment of writing this report, total fatty acid composition of ewe milk has not been finished. However, in a recent trial Scinardo

Tenghi (2003) found that ewes allowed to graze a natural pasture exclusively, showed lower ($P < 0.001$) levels of palmitic acid in their milk compared to ewes given hay and concentrate. Our result on the meat is in accordance with the report of Velasco *et al*. (2001). Trans-vaccenic acid (18:1 11trans) was more abundant ($P = 0.01$) in the fat of the grass-fed lambs. It is well known that milk from cows fed pasture has higher levels of this fatty acid compared to milk from animals given concentrates (Jahreis *et al*., 1997). Linoleic acid (18:2 cis *n*-6) was more abundant ($P < 0.0005$) in the intramuscular fat from lambs raised by ewes given concentrates. In milk, Scinardo Tenghi (2003) reports a concentration of linoleic acid in concentrate-fed ewes being thrice the amount of that in milk of grazing ewes. Linolenic acid (18:3 *n*-3), however, was three times more abundant ($P < 0.0005$) in the fat of the lambs of the grazing ewes compared to the offspring of the stall group. It is well known that grass contains high proportions of linolenic acid (Aurousseau *et al*., 2004). However, in the lambs of the grass group, we found a proportion of this fatty acid much higher than that reported so far in the literature for light lambs (Velasco *et al*. 2001, 2004). On the other hand, compared to lambs of the stalled ewes, conjugated linoleic acid (9cis, 11trans isomer; CLA) was present at about double concentration in the fat of the offspring of the grazing ewes ($P < 0.0005$). This isomer of conjugated linoleic acid in the ruminant tissue may be derived mot only from milk CLA but also from trans-vaccenic acid through the action of Δ^9 desaturase (Barber *et al*., 2000). Indeed, in milk from ewes grazing pasture, both CLA and trans-vaccenic seem to be at higher concentration compared to milk from ewes given concentrates (Jahreis *et al*., 1999). Two long chain *n*-3 fatty acids (EPA; 20:5 and DHA; 22:6) were more abundant (respectively $P < 0.0005$ and $P = 0.01$) in the intramuscular fat of lambs from grass group compared to stall group. These fatty acids are derivates of linolenic acid, and diets rich in this fatty acid result in an increased level of EPA and DHA in meat (Raes *et al*., 2004). Since the *n*-3 fatty acids were more abundant ($P < 0.0005$) and the *n*-6 fatty acids less abundant ($P < 0.01$) in lambs of the grass group compared to the stall group, the former produced a lower ($P < 0.0005$), and therefore more favourable (Wood and Enser, 1997) *n*-6/*n*-3 ratio in their meat than the latter. In both groups of lambs, however, this ratio was below 4.0, which is the recommended minimum for a human diet as a whole (Enser *et al*., 1998).

Conclusions

Intramuscular fatty acid composition of lamb fed exclusively maternal milk was highly affected by the feeding regime of the ewes. In particular, meat from lambs fed by ewes grazing grass showed higher levels of trans-vaccenic acid (18:1 *trans*11), CLA, linolenic acid and its derivates (EPA and DHA). Meat of lambs of the concentrate-fed ewes was higher in linoleic as well as other *n*-6 fatty acids. The *n*-6 to *n*-3 ratio was lower, and therefore more favourable in the meat of lambs of the grazing ewes.

Acknowledgments

This trial was founded by Regione Siciliana – Assessorato Agricoltura e Foreste – Progetto 6/F Assistenza Tecnica in zootecnia.

EFFECT OF A LINSEED OIL SUPPLEMENTATION ON TOTAL FATTY ACIDS OF MUSCLES AND ON COLOUR STABILITY AND LIPID OXIDATION OF BOVINE MEAT

Gatellier, P [1], Bauchart, D.[2], Durand,[2] Renerre, M. [1]

[1]Station de Recherches sur la Viande ; INRA Theix ; 63122 St Genès Champanelle ; France

[2] Unité de Recherches sur les Herbivores, INRA Theix, 63122 St Genès-Champanelle, France

Background

Recent decline of beef consumption in European countries is mainly due to problems with food safety (e.g. BSE) and the health aspect of eating red meat. Enhancing the polyunsaturated fatty acid, especially n-3 PUFA, and decreasing the saturated fatty acid (SFA) content of meat improve the nutritional value and increase the attractiveness of meat to consumers. In beef, it has been previously described that the PUFA/SFA and n-6/n-3 ratio can be modulated by dietary manipulation with oil. For ruminants, pasture, grass silage, whole linseed and linseed oil are the most important sources of n-3 fatty acid but the dietary PUFA must escape biohydrogenation in the rumen (Raes et al., 2004). In bovine, increasing PUFA of the diet can also increase the production of conjugated linoleic acid (CLA) (Enser et al; 1999 ; Bauchart et al; 2002) which may have health benefits to man. If nutritional value of meat can be improved by increasing dietary PUFA level, its sensorial quality must remain acceptable to consumers. It has been established that animal diet can affect beef colour stability and lipid oxidation during display life (Gatellier et al., in press)) and after cooking.

Objectives

The aim of this study was to assess the effect of increasing dietary PUFA level, especially n-3 PUFA, with linseed added to the diet or linseed oil directly infused in the duodenum, on intramuscular total fatty acids composition and on oxidative stability of bovine meat.

Materials and methods

Experiment was carried out with 12 crossbred Charolais x Salers 15 months old steers. Three diets were given for 70 days: a *control (C)* diet consisting in hay (45%) and concentrate feed (55%); a *linseed* (*L*) diet consisting of the same control diet supplemented with 4% of lipids provided by extruded linseed; a *linseed oil* (*O*) diet consisting of the control diet supplemented with 4% of lipids provided by linseed oil continuously infused into the proximal duodenum in the aim to bypass rumen hydrogenation. Animals were slaughtered in the INRA abattoir and, at 24 h *p.m*., muscle *Semi tendinosous* was removed. Meat portions were placed on a fibre board tray, overwrapped with an oxygen permeable film and exposed in darkness for a maximum of 13 days at 4°C. Total lipids in muscles have been extracted according to the method of Folch et al. (1957). Their fatty acids were converted into methyl esters by transmethylation using borotrifluorure at 14% in methanol according to the method of Sébédio et al; (1999) for their analysis by gas-liquid chromatography using CP Sil 88 glass capillary column. Colour measurement was determined with a spectrophotometer equipped with an integrating sphere (2°-viewing angle, illuminant D65). Colour coordinates were calculated in the CIELAB (1976) system. The results were expressed as lightness (L*), redness (a*) and yellowness (b*). Meat discoloration was determined by difference R_{630}-R_{580} (Renerre, 2000). Lipid oxidation was measured by the TBA-RS method according to Mercier et al. (1998). All values are reported as the mean +/- standard deviation for each animal group. The unpaired Student *t*-test was used to test differences between each group.

Table1: Effects of diets on total fatty acids % in muscle

As shown in table 1, compared to the control diet (diet C), addition of extruded linseed (diet L) induced a large increase of the content of CLA, especially of the isomer 9c,11t (P<0.0001). No difference was noted in the major SFA (C16:0 and C18: 0) between treatments. However, the impact of the lipid supplement on fatty acids content of muscle was more marked with diet O, leading to a large incorporation of 18:3n-3 (P<0.0001) and to a large increase in the P/S ratio (P<0.0001) up to the recommended value for the health of consumers. Moreover, diet O decreased the ratio of PUFA n-6 /PUFA n-3 (P< 0.0001) but, with diet L compared to diet C, no significant difference was noted in C18:3n-3 such as noted in the literature (Choi et al., 2000) but quantity and nature of extruded linseed are different between experiments.

About colour characteristics measurements, a slight increase of luminosity L* during the 13 days of meat storage was observed (figure not showed) but with no significant differences between treatments. Figure 1 showed a good stability of a* values until 3 days. From 7 to 13 days, the decrease of redness was more important in O group than in C and groups. The decrease of a* was slightly higher in L group compared to C one. At the end of storage, redness was approximatly two fold higher in C and L groups compared to O group with only a significant difference between C and O group. This indicated a greater myoglobin oxidation rate in meat of animals from O group while feeding animals with extruded linseed (L group) gave meat with myoglobin oxidation identical toC group. It was not showed a significant variation of b* during meat storage and no differences were measured between animals groups (not showed). Some authors (Vatansever et al., 2000; Wood et al., 2003) showed that linseed supplementation slightly decreased colour saturation $(a^2 + b^2)^{1/2}$ of bovine meat comparatively to controls.

Variation of meat discoloration (figure 2) during a refrigerated storage, showed that decrease of R_{630}-R_{580} was more important in O group than in two other animal groups. C and L groups showed similar decrease of R_{630}-R_{580} with values slightly higher (NS) in C group. After 9 days of air storage, mean values of R_{630}-R_{580} in O group were below the limit value of 12.5 which corresponds to 50% acceptability for the consumers (Renerre, 2000). This limit was reached after 10 days in L group and only after 13 days in C group. These results showed the highest reduction of retail shelf life of meat from animals receiving PUFA by oil infusion in the duodenum.

Figure 3 showed an important increase of lipid oxidation measured by accumulation of TBA-RS as soon as 3 days storage. This increase was particularly noted in O group. After 7 days, TBARS values were also above 2 mg MDA/Kg meat in C and L groups and largely exceeded this cut off value, at which rancidity may be detected by consumers (Younathan and Watts, 1959). At the end of storage, TBA-RS values in O group were

approximately two fold higher than values measured in the two other groups and were very high (> 8mg MDA/kg meat) After 7, 9 and 10 days storage, *t*-test showed significant differences between O and L groups. Moreover, lipid oxidation was more important in C than in L group but differences were not significant. This paradoxal effect could be attributed to antioxidants present in linseed grain which could offer better protection against lipid oxidation in membranes. In steers, for Vatansever et al. (1998), linseed (+/- fish oil) showed only small increase in TBA-RS when compared with control. In charolais cattle, it was observed lower TBA-RS values in meat from animals fed pasture, even if PUFA content was higher in meat of these animals (Gatellier et al., in press), compared to mixed-diet.

Conclusions

Compared to controls, including extruded linseed in the finishing diet of steers significantly increase the content of CLA, but not the C18:3n-3 content; but extruded linseed don't change significantly colour stability and lipid oxidation in meat after a refrigerated storage. Bypassing rumen hydrogenation by direct infusion of linseed oil in the duodenum had a significant effect on PUFAn-6/PUFAn-3 and P/S ratios; moreover, infusion of linseed oil increase myoglobin and lipid oxidation. Lipid oxidation induced by linseed oil infusion could be decreased by the use of antioxidants. Further investigations on the relation of PUFA increase and nutritional antioxidant status on beef qualities would be of interest as it was done on other animal species such as turkey (Mercier et al., 1998).

Background

The eating quality and fatty acid composition are known to influence nutritional, technological and sensory qualities of both fresh and processed meat products as important factors that affect the consumer's choice.. Although it is generally accepted that an increased level of the intramuscular fat (IMF) has a positive influence on the sensory qualities of pork (Fernandez et al., 1999), the variation in fatty acid composition also affected firmness of fat, shelf life, and flavor. As fatty acid composition was changed for diet, genetics, sex or fatness, the ratio of the certain fatty acids such as C18:0 and C18:2 provided the best prediction of firmness with the highest correlation with firmness measured subjectively or objectively(Wood et al., 1978). Campo et al.(2003) found that C18:3 produces more intense odors in a model system. In this point, manipulating fatty acids in pork will ultimately influence not only the economics of meat processing, but also the acceptance by the consumer. There were clear effect of breed type on the concentrations of total fatty acids in muscle has been reported. Wood et al. (2004) reported that the *longissimus* and *psoas* muscles of Duroc and Berkshire purebred pigs contained higher concentrations of both neutral lipids and phospholipids than those of Large Whites and Tamworth. Meat of Korean Native Black Pigs (KNBP), on the other hand, has been characterized as redder and higher palatability than that from other commercial breeds especially for Korean consumers. This finding, however, for lack of information, was substantiated by conducting this study.

Objectives

The objective of this experiment was to determine the effect of breed on meat quality of loin muscle and fatty acid compositions.

Materials and methods

Animals : A total of thirty male pigs (10 KNBP, 10 Landrace, and 10 Yorkshire) were sampled from the National Livestock Research Institute's (NLRI) breeding program. KNBP weighed an average of 72 kg; Landrace, 118 kg; and Yorkshire, 118 kg; with ages of 192 days, 201days, and 194 days; respectively. All pigs were transported to the National Livestock Research Institute and conventionally slaughtered for two consecutive days with an electronic stunner (230 volts for 2.5 sec). The carcasses were placed in a 1℃ chiller until the following day and submitted to standard processing procedures and divided into retail cuts. Loin muscle and subcutaneous fat layer samples were separated from each carcass and analyzed for meat quality and fatty acid composition.

Analytical methods: Chemical compositions were analyzed by using methods of Association of Official Analytical Chemists (AOAC) (1996). Water-holding capacity(WHC) was measured by using the method of Ryoichi et al.(1993). WB-shear force(WBS) was measured on cooked steaks(25-mm thick) according to the method described by Wheeler et al.(2000). Color values on freshly cut surface of the WBS block were measured by a chroma meter (Minolta Co. CR 301) for lightness (L), redness (a) and yellowness (b) of CIE after a 30-min blooming at 1℃. Cooking loss was calculated as a percent for the weight changes during cooking for WBS measurement. Total lipids were extracted by using chloroform-methanol (2:1, v/v) according to the procedure of Folch et al.(1957). An aliquot of the lipid fraction was methylated as described by Morrison and Smith(1964). Fatty acid methylesters were analyzed by a gas chromatograph (Varian 3400) fitted with a fused silica capillary column, Omegawax (205, 30 m × 0.32 mm I.D., 0.25 film thickness). The injection port was at 250℃ and the detector was maintained at 260℃. Nitrogen was used as the carrier gas. Results were expressed as percentages, based on the total peak area.

Statistical analysis: Data were analyzed by using the SAS program (1996) and means were separated by the Student-Newman-Keuls' test. To determine the breed effect on samples, data were analyzed as one-factor randomized block experiments with treatments. The level of significance was $p<0.05$.

Results and discussion

Objective meat quality KNBP was significantly higher in fat contents and lower in moisture content than those of the other two breeds (Table 1). Protein and ash contents, however, were not significantly different among three breeds. The loin muscle of KNBP had significantly higher *a* values(redness) than those of the other two breeds. The *L* values(lightness) of KNBP were lower than those of Yorkshire, and the *b* values(yellowness) were higher than those of Landrace($p<0.05$). Consumer perference and choice was believed to depend on the interaction of the objective qualities of the product with expectation of consumers and the consumer prefers pork with a high intensity of pink (Brewer et al., 1998). The loin muscle of the Hampshire breed, according to the studies of Lindahl et al.(2001), has been reportd to have redder and yellower color than the loin muscle of the Swedish Landrace and the Swedish Yorkshire breeds. These differences in color were related to the lower pH and higher glycogen level of Hampshire, resulting in higher internal reflectance and higher pigment content. In this study, postmortem pH_{24hr} values were not significantly different for three breeds (data were not shown). Variations in pigment content between pork breeds have been reported (von Lengerken et al., 1985), but no data that compare the pigment content of the pork from KNBP, Landrace, and Yorkshire were found. Among these three breeds, data on WHC and cooking loss were not significantly different($p>0.05$). However, the Warner Bratzler shear force values of KNBP and Landrace were significantly lower than those of Yorkshire ($p<0.05$)

Fatty acid compositions There were significantly higher levels of C18:1n-9, C16:0, C18:0, 18:2n-6, C16:1n-7, and C14:0 in decreasing order for the intramuscular fat and the subcutaneous fat of three breeds. KNBP had significantly higher levels of C18:2n-6, C18:3n-3 in the intramuscular fat, and C18:2n-6, C18:3n-6, C20:4n-6 in the subcutaneous fat than those of the other breeds. The higher concentrations of C18:2n-6 and C18:3n-3 in Duroc were associated with high fat deposition in muscle adipose cells relative to the other breeds such as Berkshire, Large white, and Tamworth(Wood et al., 2004). Significantly higher levels of C16:1n-7, C20:1n-9, C20:4n-6, and C20:5n-3 in the intramuscular fat and C16:1n-7 and C20:5n-3 in the subcutaneous fat were observed in Landrace and Yorkshire than in KNBP($p<0.05$). However, total SFAs and total MUFAs in the intramuscular fat and subcutaneous fat did not significantly differ among the three breeds (Table 2).

On the other hand, total PUFAs were significantly higher in the intramuscular fat as well as in the subcutaneous fat of KNBP than those of the other two breeds (Fig. 1). Higher PUFA level in the backfat of the three breeds possibly led to a softer fat(Warnants et al., 1999). The ratio of C18:0 to C18:2 was found to provide the best firmness(Whittington, 1986). There were no significant differences in the concentrations of C18:0 among the three breeds($p>0.05$). Total contents of PUFA n-3 were not significantly different among three breeds, but the total contents of PUFA n-6 of KNBP were significantly higher than those of the other two breeds. The ratio of PUFA to SFA (P:S) of KNBP was 0.47, and it is significantly higher than that of Landrace(0.32) and Yorkshire(0.33)($p<0.05$) (Fig. 2). The recommended ratio of polyunsaturated fatty acids(PUFA) to saturated fatty acids(P:S) should be increased to above 0.4(Wood et al., 2003). Since health practitioners have correlated meat with an imbalanced fatty acid intake among the consumers of today, there must be ways to improve the P:S ratio during meat production. In addition, researchers have also reported that the ratio of n-6:n-3 PUFA is a risk factor in cancers and coronary heart disease, especially in the formation of blood clots leading to heart attacks (Enser, 2001). The recommendation, therefore, is for a ratio of n-6: n-3 PUFA less than 4, but that in pork is usually higher than this value. In this study, pork from three breeds had significantly higher ratio of n-6 to n-3 due to their relatively low concentration of n-3 PUFA. Therefore, pork can be manipulated towards a more favorable n-6:n-3 ratio as with the.P:S ratio. Saturated and monounsaturated fatty acids are synthesized in vivo and less readily influenced by diet than the polyunsaturated fatty acids, C18:2n-6 and C18:3n-3, which cannot be synthesized, but can be manipulated by dietary change (Enser et al., 2000). Pork of KNBP, which grew slow and deposited more fat in muscle when compared with other breeds, contained significantly higher PUFA n-6 than that of Landrace and Yorkshire under the same feeding program and environmental rearing condition. Therefore, the feeding program needs

to be established to increase the levels of the PUFA n-3 such as C18:3n-3 for a more balanced and potentially beneficial composition of fatty acid for different breeds.

Conclusions

Breed influenced growth rate and affected the fatty acid composition of intramuscular fat and subcutaneous fat. High levels of polyunsaturated fatty acids, especially for C18:2n-6 and C18:3n-3, were found in KNBP. High levels of monounsaturated fatty acids, especially for C16:1n-7, C20:1n-9, C20:4n-6, and C20:5n-3, were observed in Landrace and Yorkshire. Meat is a major source of fat in the human diet and there is interest in modifying the composition of meat by dietary means to improve the nutritional value. Fat and fatty acids are important because of their effects on human health; thus, it is important to select production options which maximize both meat quality and healthiness in meat production. To improve the nutritive value of pork, manipulation of the fatty acid composition by using dietary means is necessary in the light of today's consumer's health. Thus, it is essential that researchers try to increase the proportion of unsaturated fatty acids in the meat. This can be done by establishing a feeding program that can increase levels of the PUFA n-3. Grass feeding or high levels of C18:3n-3 supplementation, in particular, can be done to put in place a more balanced and potentially beneficial fatty acid composition of different breeds. Our findings in this study showed a significantly higher level of polyunsaturated fatty acids in KNBP compared with that of Landrace and Yorkshire. Thus, further studies on fatty acid metabolism for different breeds must be investigated.

EFFECT OF HIGH PRESSURE TREATMENT ON THE ALLERGENICITY OF BOVINE SERUM ALBUMIN EVALUATED BY HISTAMINE RELEASE ASSAY USING SERA FROM ALLERGIC PATIENTS AND HUMAN BASOPHILIC KU812F CELLS

Suzuki, A.[1], Hara, T.[1], Koyama, H.[2], Nogami, N.[2], Han, G.D.[2], Odani, S.[3], Matsuno, M.[4], Joh, T.[1], and Nishiumi, T.[1]

[4]Department of Pediatrics, Yoshida Hospital, Yoshida 959-9213, Japan

Background

In our previous study (Han *et al*., 2000), we indicated bovine serum albumin (BSA) played important role in the allergenicity of beef. Various food-processing techniques have been applied to foods in order to eliminate their allergenic proteins or to reduce levels. The effects of heat treatment on food allergenic proteins have been widely studied by many groups. Heat treatment reduced the sensitization of beef, even if the treatment was less effective on pure BSA under domestic conditions (Werefel *et al*., 1997; Fiocchi *et al*., 1998). On the contrary, in some cases, heat treatment showed negative results. Restani *et al*. (1998) reported that the heat treatment was not able to decrease the BSA capability to bind to immunoglobulin E (IgE).
High pressure treatment has recently been considered a useful food processing techniques and the efficiency of this treatment on meat has been reported by several research groups including that of Suzuki (Suzuki *et al*., 1998). However, to date studies on the effects of high pressure treatment on food allergenicity have not been done, except our previous report (Han *et al*., 2002)

Objectives

Basophils, as well as mast cells, play an important role in the induction of allergic inflammatory responses via release of inflammatory mediators. The purpose of this study is to evaluate the effect of high pressure treatment on the elimination of BSA allergenicity on the basis of histamine release from human basophilic KU812F cells sensitized with sera from allergic patients.

Materials and methods

Sera: Sera from food allergic patients were obtained from Yoshida Hospital (Niigata) for this study.
Heat or pepsin treatment: Heat or pepsin treatment of BSAwas done in captube at 100ºC for 10min and at 37ºC for 60 min, respectively.
High pressure treatment: High pressure treatment of BSA was carried by the procedure of Homma et al. (1994). The sample sealed in a polyethylene bag was pressurized under 100, 200, 300, 400, 500, and 600 MPa at 5~7ºC for 10min using NBIP (Nikkiso Isostatic Processor).
Cells and cell culture: Human basophilic KU812F cells were obtained from the Cell Resource Center for Biomedical Research, Institute of Development, Aging and Cancer, Tohoku University (Sendai, Japan) and were maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS). The cells were cultured at 37ºC in humidified atmosphere with 5% CO_2.
Histamine release: Briefly, in order to bind IgE to high affinity IgE receptor FcεRI on the surface of KU812F cells, the cells (1.0×10^6 cells/ml) were incubated with the sera (diluted 1:100) exhibiting IgE binding activity to BSA in RPMI-1640 medium at 37ºC for 60 min. To evaluate the IgE binding activity of sera, enzyme linked immunosorbent assay (ELISA) was performed according to the method of Han *et al*. (2000). Then the cells were washed twice and resuspended in Tyrode's buffer. Histamine release was measured after stimulation of serum-sensitized cells with BSA with or without pepsin, heat or high pressure treatment at 37ºC for 60 min. After centrifugation, the amount of histamine in the supernatant was measured by means of a fluorometric assay according to the method of Shore *et al*. (1959) with slight modification. Histamine release was expressed as the percentage of the total amount of histamine; spontaneous release, occurring in the absence of any stimulus, was subtracted from all values.

Results and discussion

KU812F cells are known as human basophilic cells, which produce histamine and express high affinity IgE receptor FcεRI. The cells have a potential to release histamine upon stimulation with antigen and its specific IgE. Prior to evaluate the effect of high pressure treatment on the allergenicity of BSA, we established histamine release assay system using KU812F cells in combination with sera from allergic patients. IgE binding activity to BSA of sera used in this study was evaluated by ELISA (Table I). After sensitization of KU812F cells with sera, histamine release from the cells following addition of BSA was investigated. IgE molecules on the cell surface were confirmed by flow cytometric analysis (data not shown). Intact BSA induced histamine release from the cells sensitized with A5 serum exhibiting high IgE binding activity to BSA in a dose dependent manner (Fig, 1).

It seems that cross-linking of IgE specific to BSA on the cell surface followed by aggregation of FcεRI results in histamine release. On the contrary, no significant histamine release by BSA was observed in the cells sensitized with A4 serum exhibiting low IgE binding activity to BSA. Although we cannot eliminate a possibility that IgG specific to BSA may participate in cell activation through IgG receptor FcγRI, our data suggests that this histamine release assay system could be available to detect histamine release by BSA via its specific antibody. Using this histamine release assay system, we evaluated the effects of BSA treated with pepsin, heat and high pressure on the histamine release.

Our previous study revealed that high pressure treatments of beef extract did not show any significant changes in binding with sera from beef allergic patients (Han *et al*., 2002). In addition, SDS-PAGE and immunoblot analysis revealed that BSA treated with high pressure (600 MPa) or heat (100□) is still able to bind serum IgE (unpublished data). Nevertheless, BSA pressurized at ranging from 300 to 600 MPa reduced histamine release from the cells sensitized with A5 serum with significance (Fig.2). The reducing effect of high-pressure treatment gradually increased with the increase of high pressure applied to BSA. In order to show that the result as mentioned above is not a specific case, the histamine release from the KU812F cells sensitized with 6 individual patient sera was examined here. Simultaneously, the effects of heat and pepsin treatments on the histamine release were evaluated. Almost the same results were observed in this study using A5, A17, A45, A77, A125 and P2 serum (Fig. 3). Intact BSA induced about 32 to 42% histamine release, while the BSA pressurized at 600 MPa or heated at 100□ reduced the histamine release to about 6 to 14% and 5 to 19%, respectively. When the BSA treated with pepsin (1000:1 w/w), the histamine release was higher than that of intact BSA. Even though the fragmentation of BSA was confirmed on the SDS-PAGE (data not shown), the structure around the epitope recognized by anti-BSA IgE from sera seems to be retained and facilitate histamine release more easily. It is necessary to pay an attention that there are some cases where the allergenicity is more intensified by the proteolytic enzyme treatment than that of the untreated.

To our knowledge, this is the first study to report that high pressure treatment can decrease allergenicity of food components on the basis of mediator release from basophils or mast cells. Thus, food-processing by high pressure, as well as heat, raises the possibility that the technique might eliminate allergenicity of food components and contribute to attenuation of allergic responses via food allergen specific IgE. Even if high-pressure treatment fails to decrease BSA capability to bind serum IgE, pressurized BSA may undergo some changes to repress the mediator release from mast cells and basophils. Now, we are studying in detail the effect of high pressure treatment on the structure of BSA molecules responsible for this reducing effect on histamine release.

Conclusions

BSA (bovine serum albumin) is the major allergen in beef-allergic patients. SDS-PAGE and immunoblot analysis revealed that high pressure (600 MPa) treatment failed to decrease BSA capability to bind serum IgE. Nevertheless, the pressurized BSA ranging from 300 to 600 MPa lowered the percentage of histamine release from human basophilic KU812F cells sensitized with sera exhibiting high immunoglobulin E (IgE) binding activity to BSA, Under undesirable condition, enzymatic digestion of BSA by pepsin might intensify histamine release more than intact BSA. Besides industrial heat processing but domestic cooking heated nonuniformly, high-pressure treatment could also be effective food-processing technique to reduce the allergenicity of beef.

Table 1. IgE binding activity to BSA of sera from food allergic patients evaluated by ELISA tests.

Allergic Patient's serum	ELISA test (O.D. 405 nm)	IgE binding activity to BSA
A4	0.213	low
A5	1.257	high
A17	1.040	high
A45	1.660	high
A77	1.050	high
A125	1.147	high
P2	1.632	high

ELISA was performed according to the method of Han *et al*. (2000) previously described. Values are expressed as means of two independent experiments.

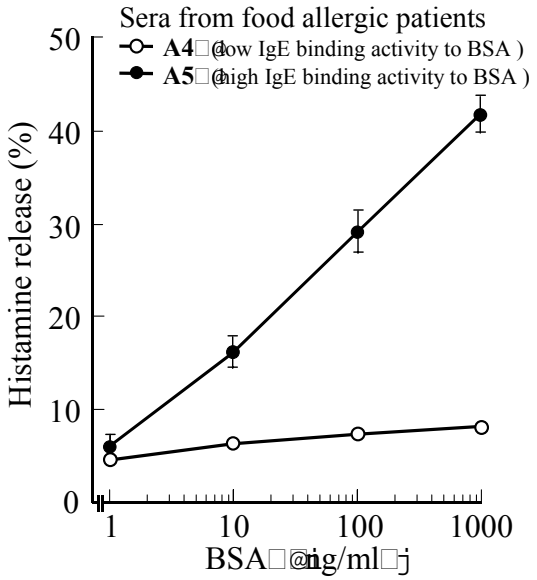

Fig. 1. Effect of BSA on histamine release from KU812F cells sensitized with sera from food allergic patients. Histamine was measured by means of a fluorometric assay. Data are expressed as means ± SE (n = 4).

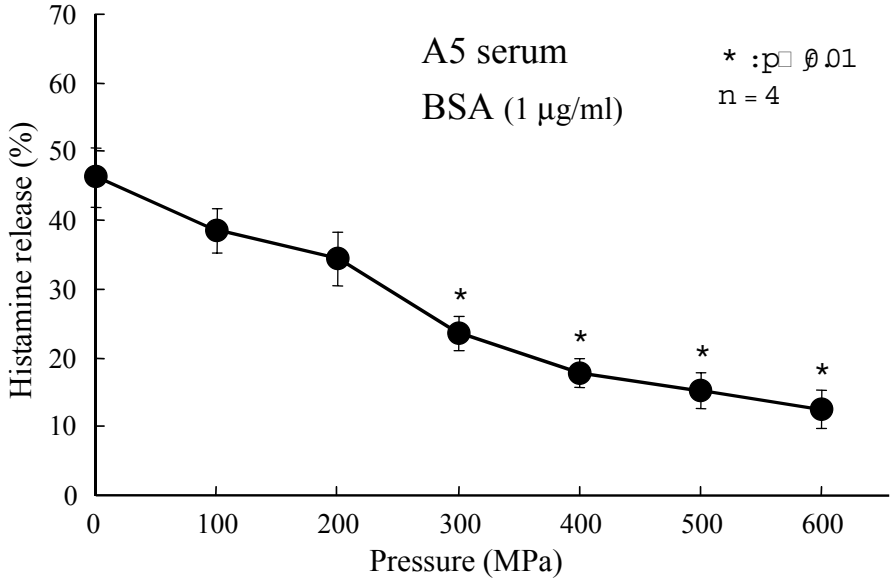

Fig. 2. Effect of BSA treated with high-pressure on histamine release from the KU812F cells sensitized with sera from allergic patients. Cells were sensitized with sera exhibiting high IgE binding activity to BSA (A5), and stimulated by adding 1 μg/ml of BSA pressurized at ranging from 100 to 600 MPa. Histamine released from the cells was measured by means of a fluorometric assay. Data are expressed as means ± SE (n = 4).

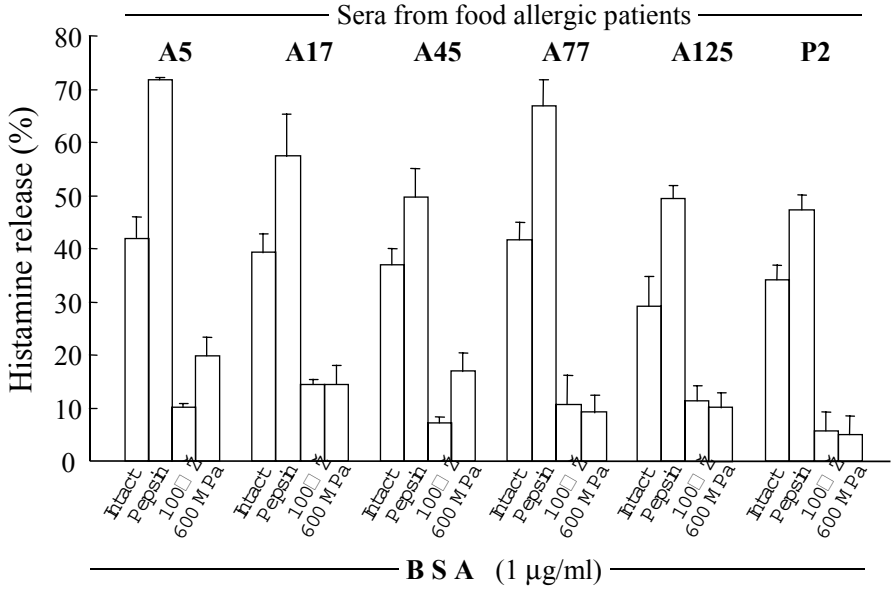

Fig. 3. Effect of digested (pepsin), heated (100 ℃) and pressurized (600 MPa) BSA on histamine release from the KU812F cells sensitized with sera from allergic patients. Cells were sensitized with sera exhibiting high IgE binding activity to BSA (A5, A17, A45, A77, A125, P2), and stimulated by adding 1 μg/ml of processed or intact BSA. Histamine released from the cells was measured by means of a fluorometric assay. Data are expressed as means ± SE (n = 4).

PHYSICO-CHEMICAL CHARACTERISTICS OF RAW AND CANNED OSTRICH MEAT

Torrescano, G., Jiménez, R., Sánchez-Escalante, A., Estrada, M.C., González, N., Valenzuela, M., Cumplido, G. and Dávila, J.L.

Department of Meat and Seafood Products Technology, Centro de Investigación en Alimentación y Desarrollo, A.C., PO Box 1735, 83000 HERMOSILLO, SONORA, MÉXICO

Background

Ostrich meat is a relatively new product in the market, and breeding has gained popularity in recent years in many countries. The consumer wants to be aware of their food nutrient composition, since some components may pose a risk factor in coronary heart diseases. Ostrich meat has a relative high pH (5.9) (Sales, 1996) and low intramuscular fat content (1.6%), this fat content was lower compared with beef (4.5%) and turkey (3.8%) (Paleari *et al*., 1998). This interesting characteristic is of particular interest due to the fatty composition of fat. The ostrich meat is low in mono-unsaturated fatty acid but rich in polyunsaturated fatty acids (PUFA) (Paleari *et al*., 1998), confirming the nutritional characteristics of this meat. However, polyunsaturated oils, including the omega 3 fats, are extremely susceptible to damage from heat, light, and oxygen. When exposed to these elements for too long, the fatty acids in the oil become oxidized.

Objectives

The aim of this work was to: (1) prepare a canned product containing ostrich meat; (2) determine food fatty acid composition in raw meat as well as the canned product; and (3) determine the effects of sterilization temperatures on stability of fatty acids in the canned product.

Materials and methods

Vacuum packaged ostrich meat samples from African Black (*Struthio camelus var. domesticus*) corresponding to *M. iliofibularis* and *M. iliotibialis lateralis* were used. The muscles were obtained from a commercial abattoir. Both muscles were cut into about 2.5 cm^3 pieces, mixed together with salt, and precooked in a kettle for 15 min at 60 °C and then for 5 min at 100 °C., when redness disappeared. After preparation, precooked meat was placed in metal containers. In order to measure the temperature TYPE T (copper-constantan) thermocouple was fastened in the geometric center of the container. A Model 692-000 and Design 5-thermocouple-channel data logger (Barnant) were used to collect and record data. The product was sterilizated at 250°F, Z = 18 until reaching a Fo = 9. Sterilization was repeated three times. Nine samples of raw and processed ostrich meat were analyzed in triplicate to measure the following parameters: pH, moisture, ash, protein and fat (AOAC, 2002). Lipid oxidation was determined by measuring thiobarbaturic acid values (TBA) (Pfalzgraf *et al*., 1995) and conjugated dienes (Sirinivasan *et al*., 1996). After extraction of lipids according to Bligh y Dyer (1959), an aliquot of the lipid fraction was transmethylated as described by Park and Goins (1994) using boron-trifluoride in methanol and the produced fatty acid methyl esters were determined on a Hewlett Packard 6890 gas chromatograph equipped with an automatic sample injector and flame ionization detector. Fatty acids were identified by comparing retention times with those of fatty acid methyl ester standards. Results were statistically analyzed by ANOVA test using SPSS for windows version 10.0.6 (1999).

Results and discussion

Means for pH, proximate chemical analysis, TBA, conjugated dienes, and fatty acid composition are presented in Table 1. The pH and proximate composition showed no significant difference ($P< 0.05$) between raw and canned ostrich meat. Values of moisture, fat, protein, and ash are in agreement with those reported by Paleari *et al*. (1998), and Sales (1996), in raw meat. Lipid oxidation indicators (TBA and conjugated dienes) showed that the canning procedure had a significant effect on their values; an increase ($P< 0.05$) in these parameters was observed due to high temperature process. Many factors affect lipid peroxidation, heat

disrupts muscle cell structure, inactivates enzymes and releases oxygen from oxymyoglobin; the release of oxygen from oxymyoglobin produces H_2O_2 and this reaction is increased at 60 °C (Harel and Kanner, 1985). The effect of sterilization on the fatty acids is shown in table 1. Significant differences ($p< 0.05$) were found for saturated and unsaturated fatty acids between raw and canned process. The profile analyzed of fatty acids in this study was similar to that observed by Sales et al (1996) for cooked ostrich meat. Total saturated fatty acids composition was similar in raw and canned meat in this study (32.13 and 32.28%, respectively). According to Armstrong and Bergan (1992) saturated fatty acids are less susceptible to oxidation than unsaturated fatty acids. Total unsaturated fatty acids in canned ostrich meat were also similar than in raw meat. The tendency of temperature influencing some fatty acids was also observed by some researchers like Anderson et al. (1971) and Smith et al. (1989) on beef meat cooked in conventional heating, observed that excessive heating produced cellular tissue break down and permitted lixiviation of hydro soluble nutrients and fatty acids auto oxidation. Unsaturated fatty acids constituted 67.72% of the total fatty acids in the raw and 67.55% canned meat, respectively. Omega-3 fatty acids, especially eicosapentaenoic acid (EPA, 20:5n-3), docosahexanoic acid (DHA, 22:6n-3) and linolenic (18:3n-3) fatty acids had low values in canned meat, mainly linolenic acid. These particular fatty acids (EPA, DHA and linolenic) are of great interest concerning human cardiovascular health.

Conclusions

It can be concluded from this study that canning procedure caused changes in fatty acid composition, principally linolenic (18:3n-3) fatty acid, while the other parameters studied were relatively constant. However, there is evidence that the variation in percentage fatty acids might differ by the diet and the process used.

PIG HOUSING AFFECTS THE FATTY ACID COMPOSITION OF PORK FAT

Trezona, M.[1,2], Pluske, J.[2], Mullan, BP[1] and D'Souza, DN.[1]

[1]Department of Agriculture, Locked bag no. 4, Bentley Delivery Centre, 6983, Western Australia
[2]Division of Veterinary and Biomedical Sciences, Murdoch University, Murdoch, Western Australia 6150

Background

There has been a rapid uptake of low-cost deep litter housing systems for intensive pig production in Australia over the past decade. This housing system provides a low capital investment alternative to intensive pig housing systems, where pigs are raised in insulated buildings, in small groups of 8 to 15 pigs per pen on fully or partially slatted concrete floors. In deep litter systems, pigs are raised in large groups of 100 or more on bedding, such as straw, in canvas covered, naturally ventilated structures. Studies investigating the impact of rearing pigs outdoors in paddocks versus indoors in conventional housing have shown differences in pig growth, carcass quality and pork quality (Nilzen *et al*. 2001; Gentry *et al.* 2002; Gentry *et al.* 2004). Lambooij *et al*. (2004) investigated the effects of housing conditions on pork quality characteristics, and concluded that the differences in pork quality can be substantial when the differences in housing conditions are large. Hence we would expect that the inherent differences between conventional and deep litter housing systems may similarly affect carcass quality and eating quality.

The fatty acid composition in various depots such as subcutaneous, intermuscular and intramuscular fat affects the technological aspects of meat quality. Differing concentrations of fatty acids have been shown to influence the firmness of the fat which has implications for the appearance and cutting of fresh and processed pork (Tume and D'Souza, 1999). Fatty acid composition can also influence fat colour, with fat of a higher melting point appearing whiter than fat with a lower melting point (Wood *et al.* 2003). The consumption of polyunsaturated fatty acids has been found to benefit human health, but increased levels of polyunsaturated fat in meat have detrimental effects on product shelf life as these fatty acids tend to oxidise rapidly and therefore rancidity and colour deterioration is accelerated (Wood et al 2003).

A number of factors can affect the fatty acid composition of various fat depots in pigs. Generally as the age of the pig increases, the fat becomes more saturated (Cameron *et al.* 1990). The rate of fat deposition can also affect the concentration of polyunsaturated fatty acids within the tissue, where the concentration generally increases when the rate of fat deposition slows (Bee *et al* 2004; Rehfeldt *et al* 1994). Unlike ruminants the fatty acid composition of the tissue of pigs is largely a reflection of the fatty acid pattern of the diet (Wiseman and Augunbiade, 1998), particularly in regards to the essential fatty acids such as linoleic and linolenic acid which are preferentially deposited within tissue and can only be obtained through the diet. Ambient temperature also influences fatty acid composition with pigs raised in cooler environments tending to have higher levels of unsaturated fatty acids and softer fat compared to pigs raised in warm environments (Tume and D'Souza, 1999).

Objectives

The aim of this study was to quantify the effect of housing systems currently used in Australia on the fatty acid composition of subcutaneous backfat in the growing pig.

Materials and methods

The experimental design is a 2 x 2 factorial with two housing types, conventional versus deep litter, and two slaughter ages, 13 weeks (about 50 kg liveweight) and 24 weeks (about 110 kg liveweight).

One hundred and fifty two Large White x Landrace female pigs were obtained at weaning from a high health status commercial piggery at 3 weeks of age. Pigs were stratified by weaning weight into two housing treatments, conventional or deep litter and within each treatment pigs were allocated to a predetermined slaughter date based on age. Eight pigs from each housing treatment were slaughtered at 13 and 24 weeks of

age. In the conventional housing treatment pigs were housed in 8 groups of 9 pigs per pen. Each group was randomly allocated to 8 pens in a conventional weaner facility until 9 weeks of age and then randomly allocated to 8 pens in a conventional grower/finisher facility until slaughter. In the deep litter housing treatment eighty pigs were housed together in one large group. At 9 weeks of age the piglets were moved from the deep litter weaner facility to a deep litter grower finisher facility.

The conventional weaner facility was within an insulated thermostatically controlled building. Pens had a mesh floor in the drinking and dunging area and a solid concrete lying area which was heated. Each pen was 1.2 x 3.1 m and equipped with 4 nipple drinkers and a multiple space feeder. The conventional grower/finisher facility was within an insulated shed and pigs were housed in concrete pens with a solid concrete lying area and a slatted area for dunging. Pens were 2.4 x 3.1 m and equipped with two nipple drinkers and one single spaced feeder per pen.

The weaner deep litter facility was within an open ended canvas covered hoop structure 9 x 14.4 m. The shelter had a concrete feeding and drinking platform with the remainder of the shelter bedded with wheat straw. Extra straw bales were placed with the shelter to provide added protection from the weather. The deep litter housing system was quipped with two multiple spaced feeders and 6 bowl drinkers. The grower finisher deep litter facility was an open ended canvas covered hoop structure that had been divided down the length into two pens. The experimental pigs were housed in one pen (4.5 x 22 m) and at one end of the shelter was a feeding and drinking platform equipped with a multiple spaced feeder and four bowl drinkers.

The pigs were phase fed commercial, cereal based diets *ad libitum* as per industry practice. They had *ad libitum* access to fresh water. Individual liveweights and feed supplied per pen were recorded weekly.

The pigs were transported to a commercial abattoir (one and a half hours travel time) and slaughtered within one hour of arrival. Within 40 minutes post slaughter fat was collected from the hot carcasses. Subcutaneous backfat samples were taken (15g from the dorsal midline in line with the last rib) and stored in two 5 ml polypropylene containers on dry ice. The samples were transported to the lab in dry ice and stored at -80^{o}c until the fatty acid profiles were determined.

Fatty acid profiles were be determined by extracting the lipid from the tissue samples (Bligh and Dyer, 1959). Fatty acid methyl esters prepared and the fatty acid composition was determined via gas chromatography following the AOAC Official Methods of Analysis (1981).

Data were analysed by using Genstat 2002 (Lawes Agricultual Trust, Rothamsted Experimental research Station: Rothamsted, UK) to conduct a two-way analysis of variance.

Results and discussion

There were no significant differences ($P>0.05$) in liveweight, hot standard carcass weight and subcutaneous backfat thickness at the P2 site between housing treatments within slaughter groups (Table 1.)

The fatty acid profiles of pigs slaughtered at 13 and 24 weeks of age are described in Table 2. The profiles indicate that as pigs age, the level of saturated fatty acids within subcutaneous backfat significantly increases ($P<0.001$), whilst the level of polyunsaturated fatty acids, 18:2 and 18:3 was significantly reduced ($P<0.001$). Subsequently the overall proportion of saturated to unsaturated fatty acids increased with age ($P<0.001$). This is in agreement with numerous studies (Cameron *et al.* 1990; review by Tume and D'Souza, 1999) who reported that an increase in weight of the pig was also accompanied by increased fat firmness through an associated increase in saturated fatty acids. Linoleic (18:2) and linolenic acids (18:3) are essential fatty acids and cannot be synthesised by the pig, therefore these fatty acids must be sourced from the diet (Wiseman and Agunbiade, 1998). The percentage of monounsaturates 16:1 and 18:1 did not change over time.

Pigs housed on deep litter had significantly higher percentages of 14:0 (myristic) ($P=0.04$), 16:1 (palmitoleic) ($P=0.01$) and a lower percentage of 18:0 (stearic) ($P=0.05$) in subcutaneous backfat compared to pigs housed in conventional systems. Myristic and palmitoleic acids have been positively associated with firmer fat (Piedrafita et al. 2001). Palmitoleic acid has also been found to be positively correlated to pork

flavour (Cameron *et al*. 1990; Cameron *et al.* 2000; Kimata *et al*. 2001) while stearic acid has been negatively associated with pork flavour attributes (Kimata *et al*. 2001). Hence the higher percentage in myristic and palmitoleic acids in reported in this experiment, may indicate that pork from pigs raised in deep litter housing systems may have firmer fat compared to pork from pigs raised in conventional housing systems. This may also improve the cutability of both fresh and processed pork, and enhance shelf life via a reduced rate of oxidative rancidity. The higher palmitoleic and lower stearic acid percentage in pigs raised in deep litter housing systems may also result in improved flavour, as palmitoleic acid is positively correlated with flavour while stearic acid is negatively correltated with flavour, compared to pigs raised in conventional housing systems. In contrast, Bee *et al*. (2004) reported that pigs raised outdoors only had a lower percentage of stearic acid (18:0) compared to pigs raise indoors. Although there were differences in the levels of individual fatty acids reported in this experiment, there was no significant difference in the total proportion of saturated and unsaturated fatty acids ($P>0.05$) (Table 3).

Conclusions

The results from this experiment indicate that pigs housed on deep litter had significantly higher levels of myristic (associated with improved fat firmness) and palmitoleic acid (associated with improved fat firmness and flavour), and a significantly lower level of stearic acid (associated with reduced flavour) in subcutaneous backfat compared to pigs housed in conventional systems. Therefore raising pigs in deep litter housing systems may have a positive effect on both carcass quality and eating quality compared to pork from pigs raised in conventional housing systems.

Background

Beef is one of the most preferred foods by Venezuelans. Its chemical composition has been well characterized in foreign countries where research (Byers *et al*., 1988) has indicated that intrinsic (gender, species, etc.) and extrinsic factors (plane of nutrition, growth regulation, castration, etc.) are largely responsible for the variation found in beef nutrient composition. Nevertheless, information regarding the proximate and mineral composition of beef produced under tropical conditions is scarce. It is well known that recommended dietary allowances (RDA) are referred to nutrients supplied by the food once it has been processed or cooked. According to Ramos Galvan (1995) this aspect has not been taken into account when designing food composition tables, which express the content of a specific nutrient per 100 g of net weight without indicating the edible portion and/or the refuse of the food. In order to diminish the risk of transmissible diseases by consumption of contaminated meats, thoroughly cooking has been recommended. Over-cooking might produce protein losses, especially from those zones more exposed to heat (Maynard *et al*. 1981). On the other hand, significant losses on mineral content might occur due to leaking or dilution, depending on cooking procedures (Ramos Galván, 1985). Beef cattle producers of Venezuela are constantly searching for new management alternatives to increase cattle productivity and to avoid the traditional need for beef imports (Morón *et al.*, 1999). Bull production offers the advantages of a faster and more efficient growth with a higher yield of lean beef as compared to steers (Huerta and Ríos, 1993). Strategic supplementation has been recommended to complement nutritional deficits of grasses, and to reach elevated production indices and yield from grazing herds (Rowe, 1999). Likewise, the use of anabolic implants allows for accelerating growth rate and improving the production efficiency of grass fed beef (Araujo *et al.* 1991). Efforts to improve beef cattle productivity through better genetics, nutrition and growth regulation must now take into consideration marketplace trends for leaner and more nutritious foods.

Objectives

The purpose of this study was to evaluate the effects of anabolic implant regimes and a supplementation strategy of grass-fed bulls on proximate and mineral composition of cooked beef *longissimus* steaks

Materials and methods

Animals

Seventy-seven bulls representing seven breed-types (Brahman, Angus, Romo Sinuano, Senepol, Simmental, commercial Zebu crossbred and ¾ Bos taurus) were raised in a ranch (Hato Santa Luisa) located at the Western Llanos of Venezuela, under the same pre- and post-weaning conditions including a common antiparasitic treatment at 90 days of age, vaccination program and supplementation with a mineral mixture. The fattening trial was conducted when the dry season started. The zone corresponds to a tropical dry forest with an annual temperature that varies from 22 to 29°C. This savannah area presents a hydric deficit during the rainy season (May-October). The precipitation averages 1,400 mm/year, and most (60%) of it occurs during June to August.

Implant regimes and strategic supplementation

Implant regimes were as follows: 1 = Ralgro™ (72 mg) administered to bulls at 0 d on fattening with reimplantation at d 90 (**RAL-RAL**); 2 = Combined strategy, consisting of Revalor™ administered to animals at 0 d on fattening followed by reimplantation with 72 mg of Ralgro™ on d 90 (**RAL-REV**). Bullocks were

randomly allotted to one of the two following treatments: a) Mineral supplementation *ad libitum* that served as a control diet; and b) Strategic supplementation *ad libitum*, consisting of an adjustment ration of 10% of feather flour, 77.9% of rice flour, 5% of molasses, 7% of minerals and 0.1% de ionophore (Salocin™), during 58 d; followed by a second ration of 49.9% of cotton seed, 28.0% of rice flour, 7.0% of minerals, 10% of feather flour, 5.0% molasses, and 0.1% ionosphere (Salocin™), which was offered during the following 114 d.

Sample collection

Animals were slaughtered ca. 500 kg liveweight. At 48 h *post-mortem* carcasses were reduced to wholesale cuts. One 2.5 cm thick steak (*longissimus dorsii*) was excised from each carcass and individually vacuum-packaged in multi-laminar plastic bags (Cryo-vac™) using a Koch-Ultravac™ packaging machine. Each sample was identified by animal number and kept frozen at -22ºC. To be prepared for chemical analyses, steaks were cooked on an electric broiler (Oster™) to reach an internal endpoint temperature of 70ºC, and trimmed to zero fat cover and other surrounding muscles. Cooked lean samples were ground for homogenization with a Black & Decker food manual processor and packaged by duplicates in hermetically sealed plastic (Zip-lock) bags and immediately stored at -20ºC until chemical analyses.

Chemical analyses

Except for total lipids (by the Folch *et al.* 1957 method), proximate analysis was performed according to the A.O.A.C. (1990). Except for phosphorus (by the A.O.A.C., 1990 method), mineral analyses were conducted by atomic absorption and/or atomic emission with ashing procedure (A.O.A.C, 1990), following the analytical methods described by Perkin-Elmer (1994).

Statistical Analyses

A completely randomized design with an unbalanced number of animals was used. Proximate and mineral composition data were subjected to an analysis of variance (ANOVA) by using the procedure PROC GLM of the Statistical Analysis System (SAS, 1996) to test differences due to supplementation and implant regime. The least squares means (LSMEANS) were separated by Tukey-Kramer´s test (SAS, 1996).

Results and discussion

Effect of implant regime and strategic supplementation on the proximate and mineral content:

ANOVA revealed a significant effect ($P<0.01$) of implant regime on the total intramuscular lipid content (Table 1). Beef derived from animals implanted with RAL-REV showed 0.4g more total lipids than those implanted with RAL-RAL. Lee *et al*. (1990), found that trembolone acetate plus 17β estradiol implanted in the stocking phase did not cause any decrease in the content of muscle lipids. Table 2 shows the effect of RAL-RAL on the content of Cu. The *longissimus* muscle of bulls implanted with RAL-RAL presented 0.01 mg less Cu than that of bulls implanted with the RAL-REV implant combination. Sodium was the only mineral affected by supplementation ($P<0.05$) (Table 3). Cooked samples from the strategic supplemented group had 2.1 mg of sodium than those samples obtained from the control group-

Effects of supplementation x implant regime on proximate and mineral composition

ANOVA revealed that beef derived from supplemented animals which had been implanted with RAL-REV had a higher protein content than those subjected to the other treatments. However, samples from animals fed with the control diet and implanted with RAL-REV showed lesser protein content than counterparts implanted with RAL-RAL. This would explain the synergistic effect of the strategic protein mineral ionophore supplementation and androgenic implant on the activation of protein anabolism and documents that the effectiveness of growth regulation regimes is regulated by the nutrition program provided.

Conclusions

The enhancement of protein accretion depends not only of the use of anabolic growth regulators, but also, it depends of nutrition of the animal, indicating the importance of an integrated nutrition-growth regulation plan in beef production.

FATTY ACID COMPOSITION OF INTRAMUSCULAR LIPIDS IN VARIOUS BEEF BREEDS AND GENOTYPES

Wagenhoffer, Z. S. and Szabo, F.

Department of Animal Husbandry, Georgikon Faculty, University of Veszprém
H-8360 Keszthely, Deák F. U.16., Hungary

Background

Fatty acid composition of dietary fats is of great importance in human nutrition and health. Numerous studies (Sadi et al., 1996; Turek et al., 1996; Zhang et al., 1999) have demonstrated that dietary fatty acids with different degrees of saturation exert various effects on human health. Additionally, the state of saturation of the fatty acids influences the meat flavour (Purchas et al., 1979; Wood and Enser, 1997) and the consistency of adipose tissues (Bozzolo et al., 1990; Martin et al., 1999). Increased unsaturation results in greater flavour changes in ruminants, including beef, than in pork (Melton, 1990). Breed- age- and sex-related differences in the fatty acid composition of beef cattle have been widely demonstrated (Eichhorn et al., 1986; Zembayashi et al., 1995; Huerta-Leidenz et al., 1996; Perry et al., 1998; Malau-Aduli et al., 2000; Laborde et al., 2001).

Objectives

The aim of our study was to evaluate the effects of breed and sex on growth performance, carcass characteristics and fatty acid composition attributes of the longissimus muscle in Limousin, Simmental, Red Angus, Belgian Blue x Simmental, Belgian Blue x Limousin, Simmental x Limousin growing finishing bulls and heifers.

Materials and methods

Fifty-seven (25 bulls and 32 heifers) growing finishing beef cattle were fattened. The animals were housed in free-stall barn with an open corral, fed *ad libitum* a diet consisting of maize silage, alfalfa hay (NEm=6.8; NEg=3.2 MJ/kg) concentrate mixture (NEm=4.0; NEg=2.5 MJ/kg) and corn (NEm=6.2; NEg=9.5 MJ/Kg). The proportion of the concentrate was increased from about 30 to 40 % of the DM during the fattening period. Bulls and heifers were slaughtered at age of 554 to 520 days, and weight of 617 to 543 kg, respectively. The left side of each carcass was sampled approximately 24 hours *post mortem*. Muscle samples were excised from the longissimus dorsi muscle at the 12th rib. Each sample, consisting of approximately 10 g of tissues, was stored at –20°C in a small plastic bag until the fatty acids were analyzed.

Total lipid was extracted by the method of Folch, Leeas and Sloane-Stanley (1957). The fatty acid methyl esters were separated and analysed by gas liquid chromatography according to Husvéth, Karsai and Gaal (1982), using an automated gas liquid chromatograph (Carlo Erba HRGC 5300) equipped with a dual flame ionisation detector and a packed glass column. Fatty acids were identified by comparing their retention times to those of known standard mixtures of fatty acid methyl esters quantified by a Shimadzu C-RGA integrator. The results were expressed as a weight percentage distribution of total fatty acid methyl esters. Data were initially recorded and listed as the percentages of individual fatty acids in the samples. The total saturated fatty acids (SFA) were calculated as the sum of C14:0, C16:0 and C18:0. Monounsaturated fatty acids (MUFA) comprised C16:1n-7, C18:1n-9, C18:1n-7, and C20:1n-9, whereas total polyunsaturated fatty acids (PUFA) was calculated as the sum of C18:2n-6, C18:3n-3, C18:3n-6, C20:4n-6, C20:5n-3, C22:4n-6, C22:5n-3, and C22:6n-3 fatty acids. Statistical analysis of the data was performed using SPSS 9.0 for Windows (Statistical Package for the Social Sciences, 1996).

In the first step the effects of sex and breed were examined with General Linear Model (GLM) procedure applying the following equation:

$$yij = \mu + Ai + Mj + AixMj + eij$$

(yij= being the observed value of the ith age and jth muscle type, μ = mean value common to all observations, Ai = fixed effects of sex, Mj = fixed effects of breed, AixMj = interaction between sex and breed, eij= the error term). Treatment means were compared by least significant differences (LSD).

Significant differences between the treatments are reported at $P < 0.05$. Statistical models and factors fitted for least square analysis are shown in Table 1.

Results and discussion

Intramuscular lipid content and fatty acid composition of the longissimus muscle in growing finishing bulls and heifers are shown in Table 2. Breed and sex had significant effect on MUFA and PUFA content. With respect to SFA, sex and breed effect was significant ($P<0.05$) only in case of stearic acid (C18:0). Belgian Blue x Simmental bulls had the highest, while heifers of this genotype had the lowest, C18:0 percentages. This difference suggests that sex had a high impact on stearic acid content of the muscles. Dietary intake of SFA has been attributed to elevate serum cholesterol level and increased risk of cardiovascular disease in humans (Hegsted et al., 1965). In the MFA group only the oleic acid (C18:1n-9) content of the longissimus muscle differed significantly ($P<0.001$) in all models. Limousin heifers had the highest oleic acid level in their muscles, while Belgian Blue x Limousin crossed bulls had the lowest percentage. Most of the significant differences were found in polyunsaturated fatty acids such as C18:2n-6; C18:3n-3 and C18:3n-6. From a nutritional and dietetic point of view, enhanced PUFA content of beef is advantageous as it increases flavor and decreases cardio-vascular risks, which translate to a more healthful product. Belgian Blue x Limousin bulls had the highest percentage of PUFA the lowest values being detected in Limousin bulls. The opposite results were found in SFA percentages. The longissimus muscles of Belgian Blue x Limousin crossed bulls had the lowest values of SFA the highest proportions being detected in Limousin bulls. SFA and MUFA proportions were higher in heifers, whereas PUFA content of the longissimus muscle was superior in bulls.

Conclusions

Both sex and breed had significant ($P<0.05$) effect on the intramuscular TL content and on fatty acid composition with the exception of saturated fatty acids (SFA). Belgian Blue x Limousin crossed animals had the lowest proportion of SFA and monounsaturated fatty acids (MUFA), and consequently, the highest level of polyunsaturated fatty acids (PUFA). The highest SFA and the lowest PUFA contents were found in Limousin breed.

[3] Department of Bromatology, pl. Nankera 1,50140 Wroclaw, Medical University, Poland

Background

There are 5 strains of meat type ducks that have been produced in the Department of Poultry Breeding in Dworzyska and, that were recognised by Polish Ministry of Agriculture and Country Development as breeding strains. Two of them A44 and A55 have been the sire, and three of them P66, P77 and K11 have been the maternal strains. They, except K11 have been intended to broiler production – Astra K, K1 and K2. The A55 male and P66 female ducks have been the parental combination for broiler production.
The parental combinations of those strains for production of two strain crosses have been characterized by high: laying, fertilisation, and hatching as well as good vitality. However, the two strain crosses have been characterized by: very good musculature, small fatness and big feed efficiency per 1kg gain (Mazanowski 2002).
The ducks from A55 strain have been characterized by more favourable parameters such as: body weight, percentage of skin with subcutaneous fat and abdominal fat content, as well as water holding capacity than from A44 (Mazanowski and Ksiazkiewicz 2004) .
The characteristic of both P66 and P77 ducks has been alike. However, the body weight of K11 has been significantly lower than P66 and P77 (Mazanowski 2002). They are characterized by resistance to hard environment conditions, big ability to crossing and laying.
Such parameters as : body weight at 7 weeks of rearing, slaughter yield, content of breast and leg muscles, skin with fat, bones and fat in carcass, geometrical body measurements, reproductive trait, fall down of ducks during rearing were determined for all above mentioned strains (Mazanowski 2002). Additionally for sire strains chemical composition (protein, fat, moisture and ash), water holding capacity, pH 15 and pH 24 were determined (Mazanowski and Ksiazkiewicz 2004).
There are no adequate data on the chemical composition of maternal strains and composition of fatty acid, amino acid and cholesterol content in muscles of the all above mentioned breeding strains.

Objectives

The objective of the work was to evaluate and compare the chemical composition of the breast (BM) and leg (LM) ducks' muscles from A55 and P66 breeding strains.

Materials and methods

The material consisted of the breast and the leg muscles isolated from 10 male ducks 7 week old selected from population of 60 heads of each strain. The weights of birds being close to arithmetic mean of strains for male (A55-2869g and P66-2617g). Ducks were fed by standard mixture containing 19.6% crude protein and 11.96 MJ metabolizable energy (ME) to 3 weeks of rearing and 18.2% crude protein and 11.73% MJ ME from 4 to 7 weeks.

Each kind of muscle was separately ground and homogenized before analysis, 24 hours after slaughter. The analyses were made in 6 repetitions.
The analyses were carried out using the following methods:
Protein - multiplying nitrogen content with Kjeltec System 1026 by 6.25.
Fat – with Soxtec System HT2 using the petroleum benzine as the extraction solvent.
Moisture – by drying at 105^0 C.

Cholesterol – using enzymatic Human test in the extract prepared by Folch et al. (1957) procedure. The saponification was carried out by the Rhee et al. (1982) method.
Amino acid composition – by the procedure described by Skrabka-Blotnicka et al. (1997).
Fatty acids - with Agilant Techn. 6890N gas chromatograph. The methyl esters of fatty acids were separated on the CP-Sill 88 (Chrompack 100 x 0,25 mm) column, at the temperature from 165 to 200^{0}C. The temperature rose by 2^0 C /min. The helium was used as carrier gas.
The Duncan's multiple range test was used for establishing the differences between means.

Results and discussion

Comparing the chemical composition of breast and leg muscles in both investigated strains, only significant differences in cholesterol content were found. The A55 breast muscles comprised less cholesterol than P66, inversely A55 leg muscles comprised more cholesterol than P66 (table1).
The higher protein content and lower moisture and fat content in both kinds of A55 muscles was found than reported by Mazanowski and Ksiazkiewicz (2004).
The breast muscles from A55 birds comprised more : ILE, LEU, LYS, TRP, and less THR comparing to P66 (table2). However, the leg muscles from A55 comprised more PHE+ TYR, THR and less TRP than from P66.
The limited amino acid index was lower than 84% only for TRP (68-78%). The amino acids limiting the biological values of proteins established by Woloszyn (2002) for Mullard ducks were MET+CYS (22-45%) and TRP that was on the same level as in the muscles of investigated ducks.Taking into consideration the biological values of protein the A55 breast muscles appeared the most favourable, but the A55 leg muscles the least favourable.
The fatty acids from C4 to C22 were detected in all the investigated muscles.
The contents of C4 – C12 acids were lower than 0.1% of total fatty acids content. Among saturated fatty acids C16:0 was dominant (22.3% BM P66 , 19.9% LM P66 and LM A55, 21.9% BM A55), next C18:0 (from 9.1% LM P66 to 10.5% BM A55). The C18:1 fatty acids dominated among the monounsaturated (MUFA) fatty acids. It was in the lower percentage in lipids of A55 (BM 27.41% and LM 34.90%) comparing to P66 (29.41% and 36.32 % respectively). The presence of such fatty acids as C18 :2, C18:3, C20:4, C20:5, and C22:6 that belong to the essential polyunsaturated fatty acids (PUFA) has been very important. Lipids of A55 breast muscles comprised more C18:3 (1.30%), C20:5 (1.12%) and less C20:4 (7.11%) as compared to P66 (1.03%, 0.91% and 7.49% respectively).
The lipids of leg muscles from A55 comprised more C20:4 (6.63%), C20:5 (0.45%) and less C18:2 (13.4%) than P66 (6.10%, 0.38% and 14.06% respectively). The contribution of fatty acids C18:2 (14.2%) and C22:6 (3.4%) did not significantly differ in lipids of breast and leg C18:3 (1.13%), C22:6 (2.6-2.8%) muscles of both strains.
The ratios of n-6/n-3 fatty acids were very favourable (from 3.3 to 4.4) for all investigated muscles, from the human health point of view. They were close to recommended which amounted to 4 (Leskanich and Noble 1997).
Though, it was established the significant differences between contents of fatty acids in lipids influenced by the strains, they were not so large so that they were recognized as significant from the practical point of view. The contribution of saturated fatty acids and PUFA were higher and MUFA were lower in lipids of the breast than of the leg muscles regardless of strains (table3).

Conclusions

It is hard to say which investigated strain is more favourable, because the differences – though statistically significant – were small and some components were in more favourable quantities in the A55 muscles and the others in the P66 muscles.
It is evident that muscles from both examined strains have been characterized by the high nutritional value.

SALIVA INCORPORATION DURING MEAT BOLI FORMATION IN RELATION TO CHEWING EFFICIENCY

Yven C. and Mioche L.

Station de Recherches sur la Viande, INRA, Theix, 63122 Saint Genes Champanelle, France

Background

Meat undergoes important structural changes during chewing (breakdown of fibers as well as saliva incorporation). During this transformation, sensory quality (texture and flavor) of meat is perceived, and determines the acceptability of the meat (Harris, 1972; Mathevon *et al*., 1995; Mathonière *et al*., 2000).

When swallowing, the properties of the boli make an important contribution to the overall acceptability of meat. It is therefore relevant to characterize these properties as well as the changes that occur in meat structure during chewing in relation to the initial properties of meat in order to get consumer-oriented clues in the understanding of meat acceptability. Cooked meat texture prior to chewing has been widely investigated and many mechanical measurements have been validated for its evaluation (Lepetit and Culioli, 1994; Culioli, 1995). Mechanical properties usually correlate with texture assessments performed during sensory analysis sessions (Bouton *et al.*, 1975; Boccard *et al.*, 1981). In contrast, properties of meat boli as affected by saliva incorporation are only sparsely documented. In a previous study (Mioche *et al.*, 2002), saliva incorporation was evaluated by the variation of the weight of the samples before and after chewing. This method does not allow quantification of the meat juice lost under bite force. Therefore, methods to determine total saliva incorporation need to be developed in order to get a better estimation of net saliva incorporation along with the juice lost from the meat.

Objectives

This study aims to investigate 1) the relationship between saliva incorporation and juice release during chewing as well as 2) the relationship between saliva incorporation and the structure of the mat boli when swallowed.

Materials and methods

Subjects

Fifteen healthy elderly subjects with very different chewing efficiencies participated in the study; eight dentate (4 male, 4 female, 66.6 ± 3.1 years) and seven complete denture wearers (3 male, 4 female, 68.7 ± 5.9 years). The subjects were selected after dental examination. All dentate subjects had at least eight pairs of natural post-canines teeth. Denture-wearing subjects had been edentulous for at least five years. They wore full dentures with a correct interocclusal relationship and a satisfying prosthetic stability. Subjects felt comfortable with their dentures, which had been integrate for at least 6 months. All subjects declared to eat meat on a regular basis and all of them were able to chew the samples in the present study. All subjects were thoroughly informed and gave their consent. The protocol was approved by the Regional Ethical Committee.

Sample

Two different textures of beef meat were obtained from the muscles *Semimembranosus* of the same animal by combining different aging times and cooking temperatures ad modem (Mathevon *et al*., 1995). One muscle was aged for 3 days at 4°C and then fully cooked to 80°C (tough meat). The other was aged for 15 days at 4°C and then cooked to 65°C (tender meat). After cooking, meat was vacuum-packed, placed at -20°C (maximal storage 3 month) and then cut into cubes (5.1g ± 0.3). Just before using, the samples were thawed by immersing the packs in a 15°C water-bath for 1h.

Data acquisition:

1) Saliva collection

Subjects' saliva was collected with salivette (Sarstedt, Germany) in stimulated condition. Salivation was stimulated by chewing parafilm (American National Can, Chicago, Il., USA). Afterwards, two salivette were placed at the aperture of parotid ducts and the subjects were asked to chew a third one for 1 min. Salivette

were frozen at –20°C until centrifugation at 1000g for 10 min and analysis. Saliva from three salivettes of each subject was then pooled.

2) Boli collection

Subjects were asked to chew a cold meat sample without swallowing, and to spit out the bolus when they felt that a swallow would normally be triggered. Textures were randomized among subjects and six replicates were analyzed for each texture giving twelve boli per subjects. Every four samples, the subjects were given a tender meat sample to eat in order to reset their natural chewing pattern. After collection, all boli were frozen at –20°C until analysis.

Food bolus analysis

Dry matter measurement

Possible losses of matter due to unexpected swallows were reported (Mishellany, Woda and Peyron, 2003). In order to evaluate the losses in meat, total dry matter of each bolus was controlled and compared to total dry matter of initial samples, calculated from cooked meat dry matter content and initial sample weight. Lower amounts of dry matter in boli than in cooked meat should reflect meat loss. For dry matter determination, samples were weighed before and after being placed in a 110°C oven for 24 hours.

Saliva incorporation measurements

Three methods were tested to evaluate saliva incorporation.

1) Weight increase: increase between the weight of meat samples and the weight of boli was determined weighing meat samples before and after chewing, which allowed saliva impregnation. To determine the losses of food matrix, boli weights were recalculated from losses evaluated by dry matter measurement.
2) Volume increase: increase in the volume of the sample was considered saliva incorporation. Volumes were measured immersing samples in water and measuring water volume increase using a graduated pipette with 0.2 ml accuracy. The volume was determined from five meat samples to obtain original meat density and from four frozen boli for each texture.
3) Marking of saliva: one bolus was collected for human secretory Immunoglobulin A (sIgA) analysis, using sIgA as a salivary marker. Boli were squeezed and the mix of meat juice and saliva was collected. The concentration of saliva in a sample was calculated using a human sIgA radial immuno-diffusion (RID) kit (The Binding Site, United Kingdom). Saliva collected with salivette was used as a reference and compared with values measured from the juice mix of saliva and meat in the boli. The quantity of sIgA in the boli was calculated from the sIgA rate in the boli obtained by RID and the quantity of the boli liquid phase obtained by dry matter measurement. From these values of sIgA in the boli and the rate of sIgA in saliva, the volume of saliva incorporated in boli was calculated.

Mechanical measurement

Samples used in this section were previously used for volume measurements. The mechanical properties of the food boli were measured by applying a shear test using a double-bladed cell with a displacement rate of 60 mm/min (Culioli, 1995). After thawing at room temperature, two boli per texture and per subject were gently placed into a U-shape mould (70 x 10 x 10 mm). Samples then had a section of 10 x 10 mm with a length depending on the bolus size. After removal from the mould, they were sheared. Three to five measurements were performed on the same bolus, 5 mm apart from each other, without any interference from one measure to another one. The maximum shear force was calculated from the force-distance curves and expressed as stress relative to the initial bolus section area. The replicates were performed to get information about structure homogeneity.

Statistical Analysis

Statistical analyses were carried out with SAS Analyst (SAS software, version 8.01, 1999 – SAS Institute Inc., NC, USA). To analyze correlations between variables, Pearson correlation coefficients were calculated. The SAS Mixed Model procedure was used to study the effect of dental status on saliva incorporation and on boli texture analyzed by shear tests.

Results and discussion

Total dry matter was determined in order to identify possible losses due to unexpected partial swallows. The texture of meat affected significantly the material losses, which varied from 5.6% to 12% of the initial sample weight for tender meat and tough meat, respectively. The losses were not significantly different between the two groups of subjects. This method allowed to highlight losses which were not identified in a

previous study (Mioche *et al.*, 2002). In similar experiments performed with brittle foods, the losses could reach an average of 60 % of the initial sample weight (Mishellany, Woda and Peyron, 2003). Losses may be due to food thinning with saliva during mastication. These losses appeared to be out of subject control as the losses occurred for all subjects whatever the food product. Losses appeared to be related to the cohesiveness of the food, and therefore, their determination might be relevant for the acceptability of meat.

The variables describing saliva impregnation correlated with each dental status and each meat texture, except in dentate subjects chewing tough meat, where volume increase values did not correlate with the other variables. These correlations are illustrated in figure 1 showing correlations between values obtained by weight increase measurements and by the levels of sIgA on boli from tough meat. With tender meat, the Pearson coefficients of correlation were 0.796 ($p<0.05$) and 0.933 ($p<0.01$) for dentate subjects and denture wearers respectively. Variations in meat sample weight during chewing did not allow reliable separation of lost meat juice and saliva incorporation. Therefore, saliva intake during boli formation was underestimated. Volume measurements were equally underestimated, since this method did not allow quantifying the loss of meat juice, and the accuracy of the measurement was insufficient in terms of the volumes measured (from 5 to 12 ml). Using sIgA as a salivary marker permitted to determine juice losses but this method took longer and was more expensive to perform than the other two. However, the values obtained from the three methods were not significantly different.

Saliva incorporation does not vary along with food boli properties. No correlation was observed between shear stress and saliva incorporation values. Denture wearers produced boli that was less disorganized than that of the dentate subjects for each meat texture (figure 2) with the same amount of saliva. With tough meat, 5.167 ml (± 1.615ml) and 6.254 ml (± 2.832ml) of saliva was incorporated by dentate subjects and denture wearers, respectively. In this case, denture wearers characterized by reduced mastication efficiency, had their salivary flow stimulated by their denture (Veyrune and Mioche, 2000). Therefore, these values were not significantly different. However, meat texture induces large variations in the amount of saliva incorporated, tougher and dryer meat requiring more saliva than tender and juicy meat to trigger a swallow.

Conclusions

Evaluation of unexpected food matrix losses by controlling dry matter reduces the underestimation of saliva incorporation. Among the three methods tested to evaluate saliva impregnation in boli, the one using a salivary marker gave the highest estimation of saliva incorporation, but the values obtained were not significantly different from those obtained by measuring increases in weight and volume. Furthermore, it was observed that changes in chewing efficiency had a direct effect on the dynamics of meat bolus formation. With respect to the amount of saliva, the denture-wearers swallowed boli that was less disorganized to that of the dentate subjects. Therefore, saliva incorporation was not linked to the level of meat disorganization. This may suggest that a certain level of loose moisture is required to trigger a swallow.

CONJUGATED LINOLEIC ACID AND THE RATIO OF ω6:ω3 FATTY ACIDS ON THE LIPID METABOLISM OF BROILER CHICKENS

Zanini, S.F.[1], Colnago, G.L., [2] Pessotti, B.M.S.[1], Bastos, M.R.[1], Casagrande, F.P.[1], and VR Lima[1]

Background

From the point of view of food safety it has been a growing concern of the poultry industry to improve not only the yield but also the composition of the poultry products, maximizing the deposition of protein and reducing the fat content. Quality and quantity of fat present in the food of animal origin has been an important criteria of nutritional evaluation. Conjugated linoleic acid (CLA) is a functional metabolite that has the potential of reducing carcass fat deposition (Akahoshi et al., 2003). This effect is related to the modification of gene expression of lipogenic enzymes (Bauman, 2001) showing that the hepatic lipogenisis and fat deposition may be reduced by the supplementation of CLA in the feed. CLA may reduce adipose tissue mass by minimizing accumulation of triglycerides in adipocytes. t10c12-CLA inibits activity of lipoprotein lipase in vivo (Park & Pariza, 2001). Also, there are reports of the effects of CLA in the increase of carnitine palmitoil transferase activity, a key enzyme on the β-oxidation (Akahoshi et al., 2003). Supplementation with CLA also reduced significantly the level of liver fat in broilers (Badinga et al., 2003) and total triglycerides and cholesterol in the plasma of rabbits (Corino et al., 2002). The use of CLA in association with oils rich in ω3 fatty acids or in diets that have a balanced ratio of ω6:ω3 has optimized the CLA effect (Aydin et al., 2001) showing that the CLA effect depend upon the amount of fatty acids ω6 and ω3 in the diet. Therefore, since CLA has the potential of alter the genetic expression of the lipogenic enzymes, it is believed that the use of CLA in association with different sources of fat in the diet may improve the productive efficiency as well as the carcass yield.

Objectives

The aim of these studies were to evaluate the dietary supplementation of CLA and the ratio of ω6:ω3 on the lipid metabolism of broiler chickens.

Materials and methods

Two studies were conducted simultaneously using 100 male or female Ross broiler chickens with 21 days of age at the start of the experiment. Birds were selected from a population of 300 animals so that, male or female birds used in the studies were within of 10% of the mean body weight of the population. The experimental design was a completely randomized in a factorial arrangement 2 x 5 (two oil source, i.e. soybean or canola oil and five levels of CLA supplementation, i.e. 0.0, 0.25, 0.50, 0.75 and 1.00). Oils used were supplied by Bunge Alimentos and CLA (Lucta – CLA 60) by BASF. The control diet had 4% of soybean or canola oil. CLA levels were obtained by isometrically replacing soybean or canola oil in the control diet. The ratio of ω6:ω3 fatty acids in the soybean and canola oil was 12:1 and 3.5:1 respectively. From 1 to 21 days of age chicks were raised in a corn-soy starter diet with 21% protein and 2,950 Kcal of metabolizable energy per Kg of diet. From 22 to 45 days of age the experimental diets were corn-soy diets formulated to at least reach nutrient levels recommended by the NRC (1994). The final body weight was determined individually at 45 days of age, when birds were killed by cutting the jugular vein. Blood samples were collected from all 10 birds. Abdominal fat pads and livers were collect from the five birds with body weight closest to the mean body weight of the treatment. Total serum cholesterol was measured using spectrometry (LABTEST – cholesterol liquiform). ANOVA and the F test (5% level) were used to compared results of the effect of oil sources and regression analysis for CLA levels.

Results and discussion

The effect of oil source on final body weight of males and females chickens is shown in Table 1. For both sexes, supplementation with canola oil resulted in heavier birds ($P < 0.05$) when compared to soybean oil.

The effect of CLA supplementation on final body weight of female birds was significant and better explained by a cubic response. It decreased until the level of 0.20% of CLA and increased to a maximum between 0.75 and 0.80% of CLA (Figure 1). Research with growing swine have also shown that CLA supplementation improved feed efficiency, growth and carcass composition (Thiel-Cooper et al., 2001). On the other hand, Badinga et al. (2003) showed a reduction on the body weight of broilers receiving CLA supplementation. Abdominal fat pad content of females have shown a significant interaction between oil sources versus levels of CLA. A linear reduction in abdominal fat pad content was observed on females receiving canola oil and CLA (Figure 2). Probably, this effect of the CLA was due to a higher body fat content in the heavier females fed canola oil. The effect of CLA supplementation on reduction in body fat of heavier animals was also reported by Corino et al. (2003). Table 2 shows the effect of oil source on liver weight ($P < 0.05$). Canola oil fed male and female birds had a reduction in liver weight ($P < 0.05$) when compared to soybean oil fed birds. An interaction effect between canola oil and CLA was also verified on the liver weight of females ($P < 0.05$). The results follows a cubic response where liver weights were reduced to a minimum at 0.25% CLA supplementation and increased to a maximum at 0.80% of CLA (Table 2). There was effect of the oil source on the serum cholesterol levels of females ($P < 0.05$). Total serum cholesterol was lower (115,1 mg/dl) in females fed canola oil when compared to that of females fed soybean oil (131.8 mg/dl). In both sexes, the supplementation with CLA in association with two sources of oil influenced ($P < 0.05$) the lipid metabolism of birds (Figures 3, 4 and 5). Badinga et al. (2003) reported a significant reduction in liver lipids due to CLA supplementation of birds diets. Fatty acids production in birds occur mainly in the liver, therefore the lighter livers of male and female birds fed canola oil found in this study may be due to a reduction in the endogenous production of lipids as also shown by the reduced serum cholesterol levels in the females. The significant interaction effect between oil sources and levels of CLA on liver weight and serum cholesterol levels suggested that the CLA effect may be related to the ratio of omega 6 to omega 3 fatty acids in the diet. Brown et al., (2001) reported that culture of pre-adipocytes supplemented with CLA and sunflower oil (rich in omega 6 fatty acids) resulted in higher content of triglycerides when compared to the cultured treated with only CLA, showing that the anti-adipogenic effect of CLA on the pre-adipocytes can be reversed. Therefore, it is reasonable to think that in studying the CLA effect on the lipid metabolism is important to take in consideration the fatty acid composition of the diet as well as the ratio of omega 6 to omega 3 fatty acids. Zanini et al. (2003) reported a reduction in total fat, cholesterol and saturated fatty acids in the carcass of roosters fed canola oil. The ratio of omega 6 to omega 3 in theirs study was 6,6:1 that is within the range of 4:1 to 10:1 recommended to humans (British Nutrition Foundation, 1991). The results of this study suggest that effects of oil source and CLA levels on abdominal fat pad, liver weight and serum cholesterol of females may be related to a reduction in the hepatic lipogenesis.

Conclusions

The results of this study have shown that:

1. Canola oil fed birds were heavier than soybean oil fed birds.
2. The CLA response on abdominal fat deposition depend upon body weight, sex and the source of fat added to the diet.
3. The effect of CLA in reducing total serum cholesterol was dependent of oil source.
4. Liver weight in both sexes and serum cholesterol in the females were reduced in the canola oil diet.

Background

Studies to change the composition and the quality of lipids present in the carcass of meat producing animals have increased lately. Products high in lipids, as meats, have call the attention of the meat scientists due to the high probability to suffer auto-oxidative reactions. The intake of rancid products may cause a great deal of health problems to the population due to its toxic effect on the cells (Ferrari, 1999). Adding conjugated linoleic acid (CLA) to the animal feed it is a reasonable way to improve meat lipid quality, therefore, its nutritional value. Dietary supplementation with CLA may change the composition of lipids produced by the liver (Belury & Kempa-Steczko, 1997) as well as reduce the total lipid concentration in rats (West et al., 1998). These alterations on the lipid profile by CLA supplementation may also result in changing on the oxidative stability of tissues. Joo et al (2002) supplemented finishing swine diets with CLA and observed that thiobarbituric acid-reactive substances (TBARS) values in the meat were higher for animals fed the control diet. Similar results were reported by Corino et al. (2002) in the meat of rabbits fed diets with 0,5% CLA. Previously, Du et al. (2000) reported that the oxidative stability of broiler meat is improved by using CLA supplemented diets. No information were found in the literature about the oxidative stability of broiler meat fed diets supplemented with different oil sources and enriched with CLA. It is believed that this association may improve carcass lipid composition as well as carcass quality.

Objectives

The purpose of this study was to evaluate the dietary supplementation of broiler diets with CLA and oil sources to produce different ratios of ω6:ω3 fatty acids on the oxidative stability of broiler meat submitted to refrigeration or freezing storage temperatures.

Materials and methods

One study was conducted using 100 male Ross broiler chickens with 21 days of age at the start of the experiment. Birds were selected from a population of 300 animals so that males birds used in the study were within of 10% of the mean body weight of the population. The experimental design was a completely randomized in a factorial arrangement 2 x 5 (two oil sources, i.e. soybean or canola oil and five levels of CLA supplementation, i.e. 0.0, 0.25, 0.50, 0.75 and 1.00%). Oils used were supplied by Bünge Alimentos and CLA (Lucta CLA 60) by BASF. The control diets had 4% of soybean or canola oil. CLA supplementation levels were obtained by isometrically replacing soybean or canola oil in the control diets. From 1 to 21 days of age chicks were raised in a corn-soy diet with 21% protein and 2.950 Kcal of metabolizable energy per Kg of diet. From 22 to 45 days of age the experimental diets were corn-soy diets formulated to at least reach nutrient levels recommended by the NRC (1994). At 45 days of age birds were killed by a cut in the jugular vein. Samples of breast and thigh meat were collected and part kept under refrigeration at 5˚C and the other part kept under freezing conditions at -20˚C. Oxidative stability was measured on meats kept under refrigeration after the third day of storage and on the frozen meat on days 25, 50, 75 e 100 of storage. Oxidative stability was measured using the procedure described by Tarladgis et al (1960) for the TBARS values. The F test at 5% of significance was used to compare results between sources of oils when interactions were not detected. When there was an interaction ($P<0.05$), it was used the SNK test to compare results between sources of oils. Regression analysis was used to report the effects of CLA levels.

Results and discussion

Under storage conditions fats and the fat content foods may undergo oxidation. The rate of oxidation depends upon the type of food and the storage conditions. The malonaldehyde is formed primarily by the oxidation of insaturated fatty acids, being the reaction more intense as the level of insaturation of the fat increases (Janero, 1990). Under freezing conditions our results (table 1) show that oxidation of the both breast and thigh meat occurred slowly and followed a linear pattern as storage time increased. Gava (1984) reported that in frozen food the enzymatic reactions occur at a slow but continuing rate. Lipids oxidation in highly insaturated fats particularly in red meat is a matter of concern due to the high levels of iron and phospholipids. On the thigh meat, during the first 50 days of storage was observed a significant interaction (oil sources x levels of CLA) on TBARS values. These results were better explained by a quadratic function (table 1 and figure 1, 2 and 3, $P < 0.05$). However on days 75 and 100 of storage this effect was not observed ($P > 0.05$). A significant interaction (oil sources and CLA levels) was also observed on TBARS values of breast meat (table 1). At day 25 of storage, independently of the oil source, was observed a significant reduction on TBARS values on thigh meat that plateau between 0.50 and 0.75% of CLA supplementation (Figure 1 and 3). At 25 days of storage, supplementation with 0.50% in association with soybean oil resulted in lower TBARS values for both breast and thigh meat when compared to that of canola oil supplemented birds. On breast meat of birds fed the soybean oil there was a linear reduction ($P<0.05$) of TBARS values with increasing CLA levels at 25 days of storage. However, as storage time increased the interactive effect of oil source and levels of CLA on TBARS values of breast meat was better explained by a quadratic function. On days 50 and 100 of storage, a reduction on oxidation of the breast meat was observed with soybean oil and supplementation of CLA, stabilizing at the level of 0.50% and increasing again with higher levels. At 50 days of storage, levels of 0.75% of CLA in association with canola oil resulted in lower oxidation on both breast and thigh meat when compared to soybean oil. At this storage time, even without CLA supplementation the oxidation of breast meat was lower in birds fed canola oil. At 75 days of storage, again 0.75% of CLA in association with canola oil resulted in lower breast meat oxidation. Also, there was a linear reduction on TBARS values with growing levels of CLA on breast meat of canola fed birds. These overall results showed a synergic effect between CLA and oil source improving oxidative stability on breast and thigh meat during storage. Shantha et al.(1995) reported that CLA is a stable fat and its deposition on carcass fat may reduce the oxidative potential. Previously Shantha et al. (1994) have suggested that the stability of the levels of CLA on the meat during storage were probably related to its higher stability when compared with fats higher in polyunsaturated fatty acids. On the other hand, Du et al. (2000) suggested that the effect of CLA on meat stability quality is related to its effect on the increase in saturated fat content. Fresh food can be stored under refrigeration for a limited period of time, which reduce the rate of microbiological and enzymatic deterioration. The results of oxidative stability of breast and thigh meat stored under refrigeration are shown in table 2. Significant interaction (oil sources and levels of CLA) on refrigerated meat was observed (Figure 4 and 5). On the breast meat a linear reduction on TBARS values was observed with increased levels of CLA in association with canola oil (figure 4). Variations on TBARS values of breast meat of birds fed soybean oil was best explained by a quadratic function with reductions up to 0.50 % levels. However, the 0.25% level of CLA in association with soybean oil produced the lowest TBARS value on breast meat when compared with canola oil. On the thigh meat of broilers fed canola oil, variations on TBARS values followed a cubic function (figure 5). Therefore, under refrigeration supplementation of 1% of CLA in association with canola oil produced the lowest oxidation levels on the thigh meat when compared to that of birds fed soybean oil.

Conclusions

Considering the conditions under which this experiment was carried out, it can be concluded that:

1. The improve in the oxidation stability by CLA and dietary fat allows the use of diets with highly unsaturated fatty acids with no impairment of chicken meat quality

2. Oxidation stability of broiler breast and thigh meat was improved by CLA and oil supplementation.

3. On the frozen thigh meat CLA supplementation in association with canola or soybean oils resulted in higher oxidative stability during the first 50 days of storage. For breast meat the maintenance of meat quality was even longer up to 100 days.

4. Under refrigeration, breast and thigh meat quality was improved by the synergic effect of CLA and dietary oil. CLA in association with canola oil resulted in lower TBARS values for both breast and thigh meat, when compared with soybean oil.

5. The effect of levels of CLA on TBARS values depend upon the oil source used in the diet, the storage condition as well as the duration of storage.

LIPID COMPOSITION OF LAMB MEAT, AFFECTED BY GENOTYPE AND SEX

Žlender, B.[1], Rajar, A.[1], Polak, T.[1], Gašperlin, L.[1], Čepin, S.[2]

Background

In the last two decades the breeding of sheep in Slovenia has grown up. According to Zagožen (1984), humid climate allows production of meat and milk, but not very high quality wool. Sheep breeding has, therefore, been directed to more meaty crossbreeds, which has enabled the consumption of lamb meat to increase. For the consumers, this trend creates refreshment to nutrition as well as gastronomy.

Lamb meat is a category of red meats, which nutritionally is not highly appreciated because of high fat content and fairly high proportion of saturated fatty acids (SFA). In comparison to other red meats, lamb contains the highest proportion of SFA (52.1%) (beef (44.9%); pork (42.5%)), the lowest proportion of monounsaturated fatty acids (MUFA) (40.5%) (pork (47.9%); beef (49.3%)), and an intermediate proportion of polyunsaturated faty acids (PUFA) (5.0%) (beef (4.3%); pork (8.3%)) (Southgate, 1993). Lipid content and composition of lamb meat are affected by different factors: genotype, animal fattening, animal live weight, age and sex. Breeds for meat production contain less fat than those for milk production (Wood *et al*., 1980, Croston *et al.*,1987, Fisher *et al.,*2000) and there are significant differences in FA composition between different milky breeds (Arsenos *et al.,* 2000). Animal age significantly affects intramuscular fat content (IMF), which is lower in meat of younger animals (Failla *et al*, 1996, Čepin & Žgur, 2003) as well as FA composition (higher degree of SFA, and lower degree of MUFA and PUFA as an animal gets older) (Cifuni *et al.,*2001). The data on the influence of animal sex on IMF content are: female animals contain more fat (Hammel and Laforest, 2000; Mc Clinton and Carson, 2000), but in other experiments no difference was found between sexes (Vergara *et al., 1999)*. There are no data concerning the influence of sex on the FA composition of lamb meat. Cholesterol content of lamb meat varies from about 60 mg/100g to 140 mg/100g (Sevi *et al.,* 1997, Arsenos *et al.,* 2000), and is dependent on the genotype, fatness, age and sex of the animal, as well as analytical method applied.

Objectives

The aim of this research was to investigate the effect of genotype and sex of lambs on the intramuscular fat (IMF) content, cholesterol content and fatty acid composition of meat.

Materials and methods

The experiment was conducted on 24 lambs of two genotypes: improved autochthon Jezersko-Solcavska breed (JSR) and crossbreed between Jezersko-Solcavska and Texel breed (JSR×T). 12 animals (6 male and 6 female) represented each genotype. Lambs were raised by the same farmer under the same feeding system, and were slaughtered at 33–52 kg live weight, at the age range from 91 to 159 days. Left *Longissimis dorsi* muscle from the 7th to the last thoracic vertebra was removed from each carcass 24 h *post mortem,* and the subcutaneous fat was trimmed off. The loins were homogenized with a blender, packed into polyethylene bags and frozen at –21 ºC±1°C until analysed.

Intramuscular fat (IMF) content was determined using the method described in AOAC Official Methods 991.36 Fat (Crude) in Meat and Meat Products (A.O.A.C. 991.36., 1997). The fatty acid composition was determined using the modified *in situ* transesterification method after Park and Goins (1994), as well as the capillary Gas-Liquid Chromatography. The cholesterol content was determined by the modified method adapted from Naeemi *et al.* (1995), as well as with HPLC. All analyses were made in duplicate.

The data were statistically analysed by the least squares method using the GLM procedure (SAS Software. Version 8.01, 1999). The statistical model for IMF content, fatty acid composition and cholesterol content of

lamb included the effects of genotype (G_i; i=JSR, JSR×T), sex (S_j; j=male, female) and repetition (R_k; k=1-6): $y_{ijkl} = \mu + G_i + S_j + R_k + e_{ijkl}$.

Results and discussion

Results of studied effects (genotype and sex) on the quality parameters of lamb meat are presented in table 1.

Lamb meat of two genotypes (JSR + JSR×T) and both sexes contained 2.2 g of intramuscular fat (IMF) and 67.5 mg of cholesterol per 100 g. The IMF content was not influenced by genotype, but was significantly lower in male animals (1.90% vs. 2.45%), which is in accordance with statements of Hammel and Laforest (2000) and McClinton and Carson (2000). The cholesterol content was not affected by genotype or sex, and the relatively low concentrations found correspond with literature (Arsenos *et al.,*2000).

Table 1. Influence of genotype and sex on IMF (g/100g) and cholesterol (mg/100g) content and fatty acid composition (expressed as relative proportion) of the lamb meat (mean values)

Parameter		Breed			Sex

Sign. - Level of significance: *** – $P \leq 0.001$ highly statistically significant; ** – $P \leq 0.01$ statistically significant;
* - $P \leq 0.05$ statistically significant; Ns – $P \geq 0.05$ statistically not significant;
N=Number of observations;
P/S=PUFA/SFA;
AI=atherogenic index = (C12 + 4 C14 + C16 + trans FA) / (PUFA + C18:1 + MUFA) (Ulbricht *et all*., 1991);
HH=(C18:1 n-9 + C18:2 n-6 + C20:4 n-6 + C18:3 n-3 + 20:5 n-3 + C22:5 n-3 + 22:6 n-3) / (C14:0 + C16:0) (Santos-Silva *et all.,* 2002).

Fatty acid (FA) composition was affected by genotype and sex. The meat of JSR breed vs. JSR×T breed contain significantly higher proportion of α-linolenic (C18:3, n-3), arahidonic (C20:4, n-6) FA, higher MUFA and n-6/n-3 ratio and lower P/S ratio.

The meat of female lambs shows significantly higher total IMF content (2.45% vs. 1.90%) and higher proportion of lauric (C 12:0); proportion of oleic (C 18:1, n-9t), linoleic (C 18:2, n-6) and eicosadienoic acid (C 20:2, n-6c), but proportion of PUFA, n-6 FA and P/S index were significantly lower than in meat of male lambs.

The lambs tested in our experiment showed higher P/S indexes (0.3 – 0.4) than previously reported in literature (0.10 – 0.15) (Rowe *et al.,* 1999; Cifuni *et al*., 2001), reaching the minimum value recommended by Food Advisory Committee (Enser *et al.,* 1998).

Conclusions

Lamb meat of two genotypes (JSR + JSR×T) and both sexes contain 2.2 g/100g IMF and 67.5 mg/100g cholesterol. Neither parameter was affected by genotype or sex.

Fatty acid (FA) composition of meat lipids was affected by genotype and sex when expressed by the P/S ratio. JSR breed and female lambs had lower P/S ratio than the JSR×T breed and male lambs, respectively.

Introduction

Traditionally, the term 'meat quality' covers inherent properties of meat decisive for the suitability of the meat for eating, further processing and storage including retail display. The main attributes of interest are safety, nutritional value, flavour, texture, water-holding capacity, colour, lipid content, lipid composition, oxidative stability and uniformity. However, the dramatic changes at the international market over the past decade also require high standards of quality assurance regarding diversity and of aspects related to environmental, ethical and animal welfare problems in the production of meat. Consequently, quality is now to be considered a complex and multivariate property of meat, which is influenced by multiple interacting factors including the conditions under which the meat is produced. Production conditions include management system, breed, genotype, feeding, pre-slaughter handling and stunning, slaughter method, chilling and storage conditions.

Feeding strategy is the management factor, which is most actively used as a quality control tool in the production of meat and in relation to improvement and/or control of performance, animal welfare, safety, nutritional value, and eating and technological quality. Most feeding strategies tested and implemented in meat production have until recently been based on 'passive' effects, i.e. the uptake and incorporation of specific feeding components or chemical/structural behaviour in the intestinal tract, e.g. contribution to lipid content and composition in relation to nutritional value (Wood, Richardson, Nute, Fisher et al., 2004), technological quality (Allen & Foegeding, 1981; Sheard, Enser, Wood, Nute, Gill & Richardson, 2000) and/or anti-oxidative status (vitamin E) in relation to storage life and technological quality (Faustman & Cassens, 1989; Morrissey, Buckley & Galvin, 2000; Granit, Angel, Akiri, Holzer et al., 2001) and also to minimize pathogen growth in the intestinal tract (Engberg, Hedemann & Jensen, 2002; Hansen, Bach Knudsen, Jensen & Kjærsgaard, 2001a,b) and off-flavour formation by regulation of microbial fermentation in the intestinal tract (Jensen, Cox & Jensen, 1995). However, the use of feeding to optimise livestock performance and lean meat percentage has also produced a considerable biological understanding of the influence of diet composition on muscle deposition.

In view of our present knowledge of the effect of feeding on meat quality, it might be relevant to ask whether additional focus on individual feedstuffs in relation to meat quality is an area where we can expect significant breakthroughs in the years to come? The answer might be ***no***, if the traditional thinking of feed *versus* meat quality continues to dominate. On the other side, if the focus changes towards an understanding of how feeding influences biological mechanisms and the outcome of these in relation to specific meat quality parameters, a picture begins to emerge of a huge potential for future production of diverse and specific meat qualities.

The present paper will pinpoint a few critical areas where a strengthened emphasis on a basic understanding of the influence of specific feeding strategies on biological responses may help to revolutionise future management practices aiming at the production of meat of the required quality. A fundamental understanding of muscle physiological and physical processes, and their interactions in relation to gene expression and environmental stressors, will be fundamental to exploiting future meat science and production through a systems biology[1] line of thought. Considering the already extensive knowledge of feed and meat quality, feeding seems the optimal tool in the further elucidation of physiological and physical events of importance for demanded meat qualities. Feeding can hereby become a key parameter together with the impending presence of genomes of most of the significant livestock in establishing a systems biology line of thought in the future quality assurance of meat. Simultaneously, the understanding obtained in employment of the discrete feeding strategies necessary for data accumulation to a systems biology approach will ensure temporary short-term solutions for specific meat quality problems.

In the following a few examples of feeding-dependent meat quality aspects of high priority from both an economic and/or socioeconomic point of view will be highlighted in relation to their potential as quality assurance tools. Furthermore, their contribution to the knowledge of importance for a coming systems biology line of thought in meat science will be discussed.

Feeding-regulated muscle protein turnover

Basic principles of muscle growth

Muscle growth is the major determinant of the performance of meat-producing animals. The amount of meat produced is related to the number of muscle fibres and the growth of the individual muscle fibre. Muscle fibres are formed during the embryonic and foetal stages, and the number is fixed around birth in most mammals. Thus postnatal growth is related to growth in the cross-sectional area (hypertrophy) and length in the fibres by adding additional sarcomeres. Postnatal growth is determined by the difference between two dynamic processes; i) the rate of protein synthesis and ii) the rate of protein degradation, referred to as the protein turnover. Thus, during postnatal muscle growth the rate of synthesis exceeds the rate of degradation. With increasing age both the rate of synthesis and degradation decrease and become equal in adult animals (for review see Oksbjerg, Gondret & Vestergaard, 2004). The rate of protein turnover is also related to the fibre type frequency, being higher in slow-twitch fibres than in slow-twitch fibres (Garlick, Maltin, Baillie et al., 1989, Goldspink, 1996).

Influence of feeding-regulated muscle protein turnover on specific meat quality parameters

The growth rate of farm animals is related to muscle protein turnover. Thus the more positive the muscle protein balance becomes the better is the growth performance of farm animals, hereby making this parameter economically essential in meat production. Moreover, maintenance of maximal positive muscle protein balance throughout the life of farm animals with minimal feed intake (superior feed conversion rate) is decisive for the environmental load during production. The proteolytic potential in the muscle at the time of slaughter has long been regarded as an important factor in the tenderisation process in meat, which claims

[1] Systems biology is an emerging field that aims at system-level understanding of biological systems. What is meant by a "system level"? In contrast to molecular biology, which has its focal point on molecules, systems biology focuses on systems that are composed of molecular components. Although systems are composed of matters including diversities and functionalities of components, the core of systems lies in dynamics and it cannot be described merely by enumerating components of the system. Moreover, both structure and components of the system play indispensable roles in forming the symbiotic state of the system. Within this context, *i*) understanding of structure of the system, such as gene regulatory and biochemical networks, as well as physical structures, *ii*) understanding of quantitative and qualitative dynamics of the system, and construction of theory/models with powerful prediction capability, *iii*) understanding of control methods of the system, and *iv*) understanding of design methods of the system, are the landmarks to assess to exploit how much we understand the system. For a further definition of systems biology, see Ideker, Galitski & Hood (2001) and Kitano (2002).

high muscle protein turnover in healthy animals at the time of slaughter. Consequently, management of muscle protein turnover may enable control of the three important meat quality attributes - *price*, *tenderness* and *sustainability*.

Relationship between muscle protein degradation in vivo and tenderisation post mortem

Several reports suggest that a relationship between the rate of muscle protein degradation and the rate and extent of tenderness in meat exists (Table 1). Thus, in situations where the rate of protein degradation is decreased, this may lead to increased muscle growth but decreased tenderness, e.g. *i*) treatment with β-adrenergic agonists (for review see Beermann, 1993), *ii*) restrictive feeding (Kristensen, Therkildsen, Riis, Sørensen, et al., 2002), *iii*) bulls versus steers (Morgan, Wheeler, Koohmaraie, Crouse & Sawell, 1993) and *iv*) animals possessing the callipyge gene (Lorenzen, Koohmaraie, Shackelford, Jahoor et al., 2000). In contrast, treatment with porcine growth hormone results in increased muscle growth by stimulating both the rates of synthesis and degradation without change in tenderness, which most probably can be explained by simultaneous increase in lean tissue (Sevé, Ballèvre, Ganier, Noblet et al., 1993; Oksbjerg, Petersen, Sørensen, Henckel et al., 1995). Finally, short term fasting for 5 days leads to increased rate of muscle protein degradation resulting in increased tenderness in lambs (McDonagh, Fernandez & Oddy, 1999). The link between the rate of muscle protein degradation and tenderness development may be coupled to the calpain system, which is known to be the rate-limiting proteolytic system disassembling the myofibrillar proteins to their individual constitutive proteins (Goll, Thompson, Taylor & Ouali, 1992; Koohmaraie, Kent, Shackleford, Veiseth & Wheeler, 2002). Having established a link between the rate of protein degradation and postmortem tenderisation, the challenge becomes to implement this into a feeding strategy.

Table 1. Factors affecting protein degradation parameters and shear force in muscle and meat, respectively, of meat producing mammals.

[a]Fractional Degradation Rate; [b]porcine Growth Hormone

For decades it has been recognised that compensatory growth may occur after a period of feed restriction in most farm animals, and the phenomenon has continuously been supported to take place in pigs (McMeekan, 1940; Critser, Miller & Lewis, 1995), cattle (Abdalla, Fox & Thonney, 1988; Rossi, Loerch, Keller & Willett, 2001), broilers (Washburn & Bondari, 1978; Acar, Petterson & Barbato, 2001) and sheep (McManus, Reid & Donaldson, 1972; Kabbali, Johnson, Johnson, Goodrich & Allen, 1992). The degree of compensatory growth or the index is calculated as: Index = (A-B)/A, where A is the difference in weight between feed-restricted animals and *ad libitum* fed animals following the restriction period and B is the difference between *ad libitum* fed animals and compensatory animals at the end (at slaughter) of the period (Hornick, Van Eenaeme, Gerard, Dufrasne, & Istasse, 2000). The degree of compensatory index may dependent on;

- Degree of restriction
- Length of the restriction period
- Length of the period of compensatory growth
- Sex
- Genotype.

During compensatory growth both the rate of protein synthesis and degradation are elevated according to findings in rat (Milward, Garlick, Stewart & Nnanyelugo, 1975) and cattle (Jones, Starkey, Calkins & Crouse, 1990). Consequently, implementation of a compensatory growth strategy in production of meat-producing animals could be a means to improve tenderness of meat.

However, the increase in protein turnover during compensatory growth is dynamic. Thus, initially during compensatory growth increased protein synthesis is evident while protein degradation remains low as a consequence of the former restricted feeding regime. Later on also the rate of protein degradation increases gradually and eventually exceeds the rate of protein degradation of control *ad libitum* fed animals. Thus, one of the goals to successfully implement a compensatory feeding approach in the production of meat of high quality is to establish the length of the compensatory period which results in highest muscle protein degradation potential at the time of slaughter. Recently, Therkildsen, Riis, Karlsson et al. (2002) showed that the optimal length of the compensatory period in pigs was between 42 to 50 days with regard to elevated protein degradation rate at slaughter. This was verified by measuring the activity of μ-calpain, m-calpain and their inhibitor calpastatin as indicators of protein degradation and total RNA and elongation factor-2 (eEF-2) as indicators of protein synthesis.

Having established the optimal length of the compensatory period of pigs in relation to elevated protein degradation rate at slaughter we have continued studies on the effect of compensatory growth response on muscle protein turnover and tenderness (Therkildsen, Vestergaard, Busk, Jensen et al., 2004; Kristensen et al., 2002; Kristensen, Therkildsen, Aaslyng et al., 2004). In general these studies showed that both castrated male pigs and female pigs exerted compensatory growth, while tenderness was only improved in meat from female pigs, see Figure 1 (Page 15). The reason for this is unknown at present; however, the compensatory growth response resulted in decreased intra-muscular lipid in castrated male, which may counteract the increase in tenderness by elevated protein degradation. In female pigs no effect of compensatory growth response on intra muscular-lipid was observed (Kristensen et al., 2004).

Use of a compensatory growth approach has also been verified to increase tenderness in meat from cattle (Allingham et al., 1998), and studies including young bull calves are now in progress in our laboratory, where the compensatory growth response may prove to be of even larger significance regarding the tenderness of beef compared to pork. The preliminary data show that both muscle protein degradation and synthesis reach a maximum level in bull calves exhibiting compensatory growth that exceeds the level found in continuously *ad libitum* fed calves. Thus there may be a time during compensatory growth, which would be the optimal time of slaughter with respect to tenderness development *post mortem* (Therkildsen, 2004).

Relationship between feed regulated muscle protein turnover and sustainability
The compensatory growth model used by Oksbjerg, Sørensen & Vestergaard (2002) and Therkildsen et al. (2004) resulted in a more efficient production in terms of feed, as the feed conversion ratio was improved by 5% in pigs exerting compensatory growth over the total period of growth. This will result in a lower environmental load with nitrogen and phosphorus. Similar results have been found in ruminants with

improved feed conversion ratio in periods involving compensatory growth, whereas the overall feed conversion ratio of both the restrictive period and the realimentation period is likely to be the same as in ruminants fed *ad libitum* throughout the experimental period (Abdalla et al., 1988; Carstens, Johnson, Ellenberger & Tatum, 1991; Sainz, De la Torre & Oltjen, 1995; Rossi et al., 2001).

Feed-induced manipulation of muscle energy levels

Basic principles of post mortem muscle metabolism

Glycogen plays the leading role as substrate for energy metabolism of living muscle as well as in the *post mortem* metabolism during which muscle converts to meat. The *post mortem* conversion of muscle to meat is an energy-demanding process, which requires ATP. After exsanguination, the energy needed for the *post mortem* process is mainly obtained from ATP produced by anaerobic metabolism and partly from phosphorylation of ADP by creatine phosphate (Henckel, Karlsson, Jensen, Oksbjerg & Petersen, 2002). The anaerobic metabolism of glycogen results in formation of lactate and a simultaneous decline in pH. Both the degree (Hamm, 1960; Bendall, 1973) and rate (Offer, 1991; Offer & Cousins, 1992) of *post mortem* metabolism are known to influence critical meat quality attributes, which is why control of glycogen and creatine phosphate levels at the time of slaughter may enable control of the vital technological quality parameters, e.g. water-holding capacity and sensory characteristics including colour and juiciness.

Influence of feeding-regulated glycogen levels on specific meat quality parameters

Sugar feeding, e.g. supplementation of high levels of sucrose or other digestible carbohydrate sources, a few days prior to slaughter or during overnight lairage has for decades been known to increase muscle glycogen stores and thus reduce $pH_{24\ h}$ (Briskey, Bray, Hoekstra, Phillips & Grummer, 1959; Fernandes, Smith & Armstrong, 1979). This is a short-term effect (Fernandez, Tornberg, Mågård & Göransson, 1992), where glucose is transported from the gastrointestinal tract via the circulation to the liver and the muscle, and subsequently incorporated into the glycogen stores. Such an increase in glycogen stores does not call for changes in the expression of any of the key enzymes of glycogenesis, as the increase is solely of a regulatory nature.

In contrast, other diet-induced regulations of the glycogen pools in monogastrial animals require changes in metabolic pathways and the glycogen synthesis apparatus. In this context muscle glycogen stores are reduced in rats (Lapachet, Miller & Arnall, 1996) and rabbits (Gierus & Rocha, 1997) using diets with a high fat content and digestible carbohydrate content. Similar results have been obtained after feeding standard diets with increased fat content to pigs from 25 kg live weight to slaughter (Lauridsen, Nielsen, Henckel & Sørensen, 1999). Recently, feeding diets high in fat (approx. 17-18%) and protein (22-24%) in combination with a low content of digestible carbohydrate (< 5%) to pigs during the last three weeks of finishing has been shown to reduce muscle glycogen stores in *M. longissimus dorsi* without influencing the overall growth performance (Rosenvold, Lærke, Jensen, Karlsson et al., 2001a; Rosenvold, Petersen, Lærke, Jensen et al., 2001b; Rosenvold, Lærke, Jensen, Karlsson et al., 2002). The combination of low digestible carbohydrate and high fat content in the diet causes a muscle glycogen-reducing effect (Figure 2, Page 16). The reduction in muscle glycogen content improved the WHC of *M. longissimus dorsi*, *M. biceps femoris* and *M. semimembranosus* (Rosenvold et al., 2001a; 2002). This reduction in muscle glycogen level did not result in higher $pH_{24\ h}$, but a higher $pH_{45\ min}$, suggesting a diet-induced delayed *post mortem* conversion of glycogen to lactate.

Bee (2001) has shown that only a minor reduction in digestible carbohydrate content (~20%) with a simultaneous iso-energetic supplement in fat has no influence on *post mortem* glycogen stores in porcine *M. longissimus dorsi* and the red part of *M. semitendinosus*. Hence, feed-induced reduction in muscle glycogen content, which affects pH_{45} and WHC in the porcine muscle, as observed by

Rosenvold et al. (2001a; 2001b; 2002b) seems to claim a critical ratio between fat and digestible carbohydrate. In support of this theory, Leheska, Wulf, Clapper, Thaler, and Maddock (2002) found no effect on *post mortem* glycolytic potential or pork quality attributes upon feeding a low digestible carbohydrate/high protein diet during the last two weeks prior to slaughter.

In ruminants several studies too indicate that muscle glycogen levels are at least to a certain extent responsive to finishing composition (for review see Immonen, 2000), despite the general belief that muscle glycogen stores are hardly affected by diet composition, as the ruminal fermentation is expected to dominate the availability of gluconeogenic precursors for hepatic glucose production. In an experiment with intensive (concentrate) or extensive (pasture) feeding with or without finishing feeding with concentrate of Friesian bulls, Vestergaard, Oksbjerg & Henckel (2000) found a decreased concentration of glycogen in *M. longissimus* and *M. semitendinosus* from bulls fed with pasture (E) compared with bulls fed on concentrate (I). However, when the E-bulls were finished on a concentrate ration for 10 weeks and had a compensatory feed intake compared with the I-bulls, the glycogen concentration increased and exceeded the level seen in the I-bulls.

Although muscle glycogen stores at the time of slaughter have long been recognised to be decisive for meat quality (Briskey, 1964), the physiological nature of the regulation of muscle glycogen stores is poorly understood (Graham & Adamo, 1999; Roach, 2002). This applies especially in *post mortem* muscle as existing knowledge is mainly based on findings in *in vivo* muscle. However, the recent identification of a key enzyme, glycogenin, and renewed interest in the existence of the two forms of glycogen, proglycogen and macroglycogen, may remedy this fact.

Proglycogen and macroglycogen are distinguished on the basis of size and protein content. The existence of two pools of glycogen was first studied extensively forty years ago (Stetten & Stetten, 1960). However, Lomako, Lomako, Whelan, Dombro, Neary & Norenberg (1993) were the first to describe the two forms in detail. The pool with a high ratio of carbohydrate to protein (maximum M_w ~10^4 kDa) is termed macroglycogen. The pool with relatively high protein content to carbohydrate (M_w<400 kDa) is termed proglycogen. It is known that the macroglycogen pool increases with high muscle glycogen concentrations (Jansson, 1981; Adamo & Graham, 1998; Hansen, Derave, Jensen & Richter, 2000; Graham, Adamo, Shearer, Marchand & Saltin, 2001). Moreover, dietary energy favours the *post* exercise synthesis of proglycogen over that of macroglycogen (Adamo, Tarnopolsky & Graham, 1998; Derave, Gao & Richter, 2000) and the metabolism of the two pools appears to depend on the type of exercise (Asp, Daugaard, Rohde, Adamo & Graham, 1999; Graham et al., 2001).

Proglycogen is degraded in favour of macroglycogen during the first 45-60 min *post mortem* in porcine muscle (Charpentier, 1966; Rosenvold, Essén-Gustavsson & Andersen, 2003). Moreover, total glycogen and the concentration of proglycogen have been found to be higher in pigs showing a rapid pH decline *post mortem* and subsequent development of inferior meat quality (pale, soft and exudative meat) (Wismer-Pedersen & Briskey, 1961). Reduced muscle glycogen stores as a result of a 3-week strategic finishing period are reflected in a reduction in the macroglycogen pool (Rosenvold et al., 2003). Interestingly, the subsequent reduction in the rate of *post mortem* glycolysis observed in muscle from these animals was due to reduced metabolism of the proglycogen pool. Recently, it was found that the increased glycogen level in pigs carrying the RN^- gene is reflected in larger macroglycogen stores (B. Essén-Gustavsson, unpublished observations), which might explain why early *post mortem* glycolysis is not enhanced in pigs carrying the RN^- gene compared with that of non-carriers. These preliminary data clearly show that a complete understanding of how feeding influences glycogen pools might be critical in setting up quality assurance schemes for the production of high quality meat.

Significance of vitamin E supplementation on muscle glycogen level

Vitamin E stripped diets have been reported to reduce liver glycogen stores in rats (Schroeder, 1974) and muscle glycogen stores in pigs (Lauridsen et al., 1999). Recently, we found that supra-nutritional vitamin E supplementation on the day prior to slaughter in both a strategic finishing diet known to reduce muscle glycogen stores and control diets gave rise to significantly higher muscle glycogen levels and tended to decrease WHC of meat from supplemented pigs (Rosenvold et al., 2002). Schroeder (1974) suggested that metabolic changes caused by vitamin E depletion were controlled by cyclic AMP, which is central in the co-ordinated control of glycogen synthesis and breakdown (Stryer, 1988). The hypothesis was rationalised on the fact that the result of vitamin E deficiency (e.g. increased catabolic activity) can be mimicked by the administration of glucagon, which stimulates glycogenolysis, lipolysis and the activity of certain catabolic enzymes through an increase in the cellular concentrations of cyclic AMP (Jost & Rickenberg, 1971 in Schroeder, 1974). It has also been noted that adenylate cyclase, the enzyme responsible for the synthesis of cyclic AMP, is localised mainly in the cellular membranes where vitamin E could play a major role (Srivastava, Robin, & Thakur, 1992). Moreover, vitamin E possibly inhibits protein kinase C (Mahoney & Azzi, 1988), which catalyses the phosphorylation and inactivation of glycogen synthase - the rate-limiting enzyme for glycogen synthesis (Ahmad, Lee, DePaoli-Roach, & Roach, 1984). However, the mechanism behind this effect of vitamin E on protein kinase C is still debated (Azzi et al., 2001). Thus, a vitamin E-induced inhibition of protein kinase C would increase the activity of glycogen synthase and stimulate glycogen synthesis, as found in the studies by Schroeder (1974), Lauridsen et al. (1999) and Rosenvold et al. (2002). Even though none of these studies can identify the mechanism for the significance of vitamin E supplementation on muscle glycogen levels, they do indicate that vitamin E has a direct effect on the mechanisms controlling glycogen metabolism. Considering the positive effect of vitamin E supplementation of farm animals on other meat quality parameters, e.g. colour and oxidative stability (Jensen, Lauridsen, & Bertelsen, 1998) and the negative effect on WHC in the study of Rosenvold et al. (2002), one could speculate whether an optimal level of vitamin E supplementation exists, where improved colour and oxidative stability are obtained before the possible elevation of muscle glycogen stores and increased drip formation overrides these positive effects. However, this calls for a better understanding of the influence of vitamin E supplementation on muscle glycogen stores.

Creatine

In contrast to many years of general belief, dietary supplementation with creatine monohydrate in humans, has been found to increase intramuscular creatine load by 20% (Balsom, Söderlund, Sjödin & Ekblom, 1995; Greenhaff, 1996). Moreover, it has been suggested that creatine supplementation increases the muscle energy stores as phosphocreatine (Balsom, Söderlund & Ekblom, 1994; Casey Constantin-Teodosiu, Howell, Hultman & Greenhaff, 1996). Supplementation with creatine monohydrate is known to increase weight gain (Maddock, Bidner, Carr, McKeith, Berg & Savell, 2000; Berg & Allee, 2001; Stahl, Allee & Berg, 2001; Young, Bertram & Oksbjerg, 2004a), probably by increased water retention in lean tissue (Balsom et al., 1995; Juhn, 1999). Moreover, muscle protein may also increase as the synthesis of myosin heavy-chain probably increases upon creatine supplementation in chicken skeletal muscle cells (Ingwall, Morales & Stockdale, 1972). A feed-induced increase in energy stores, as a consequence of elevated muscle phosphocreatine level should according to the generally accepted theory delay the glycogen metabolism in *post mortem* muscle and thus slow down the pH decline in the muscle, which minimize potential protein denaturation during the conversion of muscle to meat. A reduction in protein denaturation will consequently increase water-holding properties of the meat (Offer, 1991; Bertram, Dønstrup, Karlsson et al., 2001). Creatine monohydrate supplementation for five days has been shown to reduce the rate of the early *post mortem* pH decline and decrease cooking loss (Maddock et al., 2000; Berg & Allee, 2001; Stahl et al., 2001). Moreover, the incidence of PSE was significantly reduced in supplemented pigs (Maddock et al., 2000). However, extending the supplementation

period to 10 or 15 days had no (O'Quinn et al., 2000) or negative (Stahl et al., 2001) effect on technological pork quality, and high concentrations of creatine had even adverse effects on chicken meat quality (Young, Karlsson & Henckel, 2004b). The PSE-reducing effect of creatine monohydrate supplementation observed by Maddock et al. (2000) could be explained by the fact that half the pigs were carriers of the Halothane gene, and that the effect of creatine monohydrate supplementation was most pronounced in meat from pigs carrying the gene. However, in a consecutive study Maddock et al. (2002) found no significant effects of creatine monohydrate supplementation on technological pork quality. Effects of dietary creatine on meat quality traits are thus very diverse, and recent results by Young et al. (2004a) also demonstrate how differently two breeds of pigs are affected by creatine supplementation. Young et al. (2004a) showed that pure Duroc pigs had an increased pH both early *post mortem* and after 24 h, as well as reduced drip loss after dietary creatine treatment. Similar dietary creatine addition, however, had no systematic affect on *post mortem* pH in pure Landrace pigs, and drip loss was not significantly affected, although two independent drip loss methods indicated increased drip loss upon creatine supplementation (Figure 3, Page 17). These opposing results indicate that genetics play a major role for meat quality attributes related to dietary creatine treatment of pigs, and could be used in the elucidation of underlying mechanisms.

Genomics versus feeding - Nutrigenomics

The genetic influence on meat quality comprises differences among breeds as well as differences among animals within the same breed. With the exception of a few monogenic effects (major genes) in the different farm animals, e.g. the calipyge gene in sheep, the myostatin gene in cattle, the halothane, RN^-, 'intramuscular fat' and 'androstenone' genes in pigs, the heritability of most attributes relating to the quality of meat is low to moderate (0.15–0.30) (Sellier & Monin, 1994; Sosnicki, Wilson, Sheiss, & Vries, 1998). These differences in quality attributes are caused by a large number of genes with small effects, polygenic effects. The best approach to genetically improve meat quality is to identify relevant DNA-markers directly in populations under selection (de Vries, Faucitano, Sosnicki & Plastow, 2000). This calls for continuous meat quality measurements on the nucleus population of breeding organisations. However, this is a very long-term approach, which is extremely expensive, and as full assessment of meat quality can only be done after slaughter, the data have to be collected on culled animals and cannot be obtained on potential breeding animals. Another way to utilize the genetic potential of farm animals, considering the emerging development of molecular biological techniques, is the introduction of a molecular approach, e.g. DNA therapies, for altering biological processes of importance for meat quality (Grant & Gerrard, 1998). However, such an approach will hardly become ethically acceptable for conventional exploitation.

Alternatively, a fundamental understanding of the biological processes, which are directly linked to meat quality attributes, will rationalise a marker-assisted DNA approach, as this allows sampling on live breeding animals. Considering that most traits of interest for meat quality have a multifactorial background, i.e. meat quality attributes are due to interaction between the genetic potential and the environment, with feeding being the most decisive factor in meat production renders that a nutrigenomic approach seems most optimal in the exploitation of biological processes of direct importance for vital meat quality attributes. A nutrigenomic approach in relation to meat quality will in this way kill two birds with one stone, as it will support both a marker-assisted DNA approach and include a basic understanding of the most pronounced interaction of importance for meat quality, namely the interaction between the genome and the feed.

Nutrigenomics – an emerging strategy in modern meat science?

As illustrated in the above paragraphs, feeding has a regulatory effect on biological processes in muscle, which is directly reflected in the quality of the meat from the fed animals. This is in accordance with the fact that specific diet components *inter alia* are known to regulate gene expression within the cells. The knowledge of the complex interaction between the individual nutrients and their interaction on the genome of farm animals, which represent 30-40,000 genes within each species, is practically an unexplored area. The major reason for this is that the technical resources for such an understanding have only become accessible within the past few years. The ongoing mapping of the genomes of the principal farm animals together with the progress within information technology and molecular biological techniques will undoubtedly accelerate this process in the future.

The key element that distinguishes nutrigenomic from nutrition research is that the observable response to diet, or phenotype, is analysed or compared in different genotypes (or individuals). Classical nutrition research essentially treats all test individuals as genetically identical, and hereby misses a considerable part of the potential differentiation, which is essential in the future production of meat. Likewise, molecular biology and biochemical approaches show the same limitations as classical nutrition. Consequently, to include the environments, here represented by feeding, in relation to the expression or activity of variant forms (within groups or individuals defined by Single Nucleotide Polymorphisms (SNPs), haplotypes, and other polymorphism) of normal genes will allow a new essential understanding, which will have significant implications on future strategies to control meat qualities.

Conclusions

Considering a pro-active quality control system in the future production of high quality meat, the traditional way of using feeding as a quality control tool has outlived its usefulness. However, as emphasized by above results regarding fed induced control of muscle protein turnover and muscle energy levels and subsequent influences on important meat quality attributes of importance for the industry and/or consumers, feeding seems the optimal tool to explore biological processes of importance for meat quality development. Via a nutrigenomic approach feeding could be the base to initiate a systems biology line of thought in meat science, which subsequently could change from the present qualitative strategy to a quantitative strategy enabling development of optimal decision support systems for future meat quality control.

THE FUTURE OF BSE FROM THE GLOBAL PERSPECTIVE

D. Heim*, L.Mumford

*Corresponding author: Swiss Federal Veterinary Office, e-mail: Dagmar.Heim@bvet.admin.ch

Abstract

Although the BSE risk of most countries in Europe has been assessed and they have implemented both measures to control BSE and extensive surveillance systems, complete and valid data is still not consistently available. Globally, data is largely unavailable. Assessments based on incomplete or invalid information could lead to false conclusions. The BSE risk of countries throughout the world must continue to be assessed, and improvements in collection of surveillance data must be made, both in countries already reporting BSE cases and worldwide, in order to evaluate the global BSE picture and assure that cattle and products can be safely traded.

*Keywords**:** BSE, surveillance, risk assessment, GBR*

BSE in the world: what we know today

After bovine spongiform encephalopathy (BSE) was first diagnosed in cattle in the United Kingdom (UK) in 1986 (Wells et al., 1987), it became clear that the disease had been spread throughout Europe through trade in live animals, meat and bone meal (MBM) contaminated with the BSE agent, and feeds containing this MBM. Now, it is evident that the disease agent has continued to spread throughout the world through global trade in these products (Figure 1).

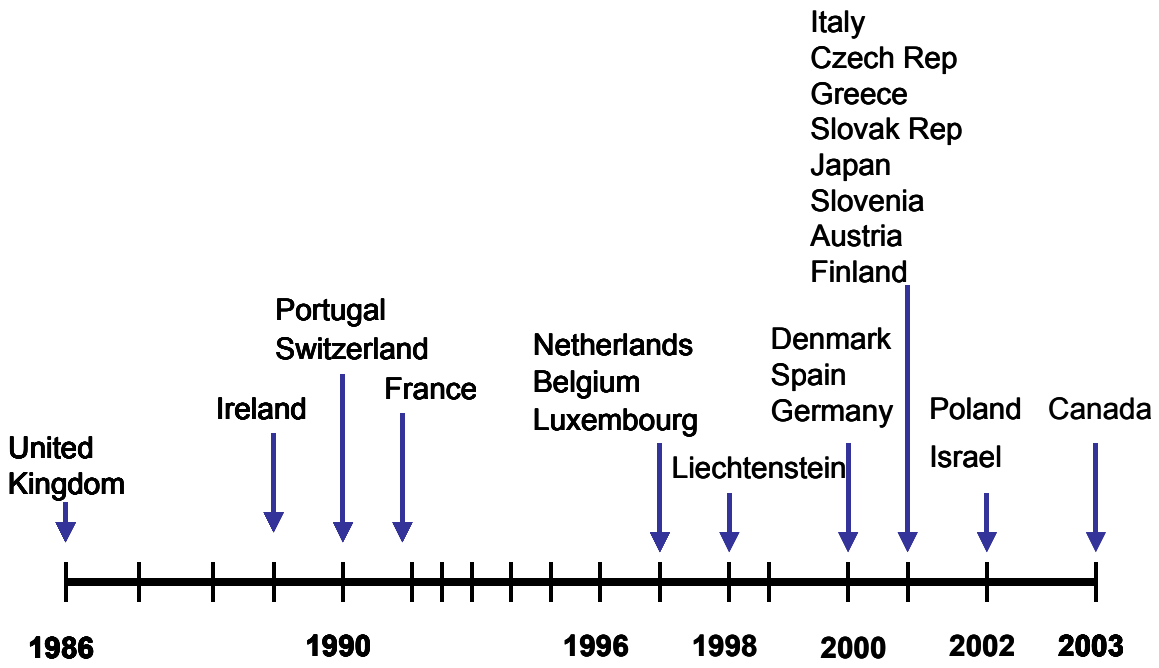

Figure 1: Year of first reporting of indigenous BSE cases

Extensive epidemiological studies have traced the cause of BSE to animal feed containing inadequately treated ruminant MBM (Wilesmith, Wells, Cranwell & Ryan, 1988), which was then recycled through the rendering/animal feed chain and amplified over time. It is possible that this amplification cycle began in the UK as early as the 1970s (Wilesmith, Ryan & Atkinson, 1991). The appearance of indigenous BSE cases throughout the world (e.g. Japan in 2001, Israel in 2002, North America in 2003) (Office International des Epizooties, 2004c) shows that, once the BSE agent is introduced, this cycle can be propagated outside Europe.

However, it was only after implementation of active surveillance programs targeted to BSE risk populations that many countries (in Europe and elsewhere) finally detected BSE, and year after year more countries detect their first BSE cases. Most of these countries had previously considered themselves to be “BSE-free” and many had exported BSE risk products. Trade in these products still continues among some countries that are considered “BSE-free” but possibly could have undetected cases. Therefore it is essential to be able to determine if an exporting country could have BSE before the first case is detected.

Risk Assessment & the GBR

This determination of the BSE status of a country can only be made on the basis of the outcome of a BSE risk assessment, which evaluates imports, surveillance data, and internal factors. This recommendation is codified in the BSE chapter of the Terrestrial Animal Health Code of the World Organisation for Animal Health (Office International des Epizooties, 2004a).

On the basis of the recommendation of the OIE, the Scientific Steering Committee (SSC) of the European Commission initiated the "Geographical BSE Risk Assessment" (GBR) for several countries. The GBR is defined as a qualitative indicator of the likelihood of the presence of one or more cattle being infected with BSE, pre-clinically or clinically, within the native cattle population of a country at any given point in time. In countries already reporting BSE, the GBR gives an indication of the level of infection (Scientific Steering Committee, 2000a, Scientific Steering Committee, 2000b, Scientific Steering Committee, 2002a, Scientific Steering Committee, 2002b, Scientific Steering Committee, 2002c).

The GBR qualitatively assesses risk factors that contribute either to the potential for introduction of BSE into the country or to the ability to cope with an introduction by asking the following questions:

- Had the agent been introduced to the country by import of potentially infected cattle or by feed with MBM, and if so to what extent ("external challenge")?

  In the assessment it is assumed that the BSE agent can only be introduced into a country by imports of cattle and MBM.

- What would happen if the agent were introduced into the animal production system, i.e. would it be amplified or eliminated ("stability of the system")?

  When risky imports are found to have occurred, the system's ability to minimize the exposure of cattle is evaluated in terms of the use made of MBM, the use made of SRM, the rendering conditions, and the feeding systems.

Currently 63 countries have been assessed (Table 1). These countries have been categorized into the following four levels defined by the SSC:

GBR I: highly unlikely that any BSE infected cattle are present.

GBR II: the presence of any BSE infected cattle is still unlikely, but it cannot be excluded.

GBR III: the presence of BSE infected cattle is likely or, if cases already were discovered, the number of BSE cases identified during the last 12 months is below 100 per million adult cattle.

GBR IV: more than 100 BSE cases per million adult cattle were discovered in the last 12 months.

The GBR has proven to be a useful tool in assessing countries in terms of their potential BSE risk. Before the detection of the first cases in many "BSE free" countries, the GBR showed that a risk could be present by categorizing them as GBR III. For example, Germany, Italy, Spain, the Czech Republic, the Slovak Republic and Poland, none of which had reported indigenous cases of BSE at the time of the original assessment, were included in GBR III and subsequently reported BSE in their national herds. Israel detected their first BSE case before the assessment was finalized, but the draft report already indicated GBR III. Thus, the results of the GBR (or any objective, comprehensive risk assessment) can be practically and reliably used to estimate the likelihood of a BSE problem in countries and categorize countries according to their risk.

However, as with all risk assessments, valid data is required to give a valid outcome. Until 2002, the GBR only considered imports of live cattle and MBM from countries with confirmed BSE cases as an external challenge. The subsequent detection of BSE cases in some GBR II countries (e.g. Austria, Finland, Slovenia and Canada) indicated that the approach underestimated the risk. In 2002 the method was changed to consider imports from all GBR III countries as an external challenge, even in the absence of reported cases.

Table 1: GBR level of countries assessed through June 2004

GBR I	Argentina*, Australia, Botswana, Brazil*, Chile*, El Salvador, Iceland, Namibia, New Caledonia*, New Zealand*, Nicaragua, Norway, Panama, Paraguay*, Singapore*, Swaziland, Uruguay*, Vanuatu*
GBR II	Colombia, Costa Rica, India, Kenya, Mauritius, Nigeria, Pakistan, Sweden, USA
GBR III	Albania, Andorra, Austria, Belarus, Belgium, Bulgaria, Croatia, Denmark, Canada, Cyprus, Czech Republic, Estonia, Finland, Former Yugoslav Republic of Macedonia, France, Germany, Greece, Hungary, Ireland, Israel, Italy, Latvia, Lithuania, Luxembourg, Malta, Poland, The Netherlands, Romania, San Marino, Slovak Republic, Slovenia, Spain, Switzerland, Turkey
GBR IV	United Kingdom, Portugal

* Newly assessed in 2002/2003

Therefore, all GBR I and II countries have had to be re-assessed under these criteria. Re-assessments of some countries are complete and some are still ongoing. However, these re-assessments were initiated before the BSE cases in North America were reported and so, again, some re-assessments are necessary to account for this increased risk. This emphasizes the fact that, as the BSE situation changes worldwide, national risk assessments should be updated continuously using the most current data in order to remain valid and useful. As well, the fact that assessments should be carried out for all countries is clearly shown.

Risk assessments can also be used to ask additional questions, such as what are the BSE risk populations within the country, in order to guide development of a surveillance system. Although initial assessments of BSE risk can be performed using challenge data and internal stability data, further assessment requires additional information, such as surveillance data, from within the country, making risk assessment an iterative process.

Surveillance

Surveillance programs for BSE should be determined by, and commensurate with, the outcome of a national BSE risk assessment, as recommended by the Terrestrial Animal Health Code of the OIE (Office International des Epizooties, 2004b). The two major objectives for BSE surveillance are to determine whether BSE is present in the country, and, if present, to monitor the extent and evolution of the prevalence over time, thus monitoring the effectiveness of measures in place. It is important to remember that the number of BSE cases reported by a country can only be evaluated within the context of the quality of the national surveillance system. However, although OIE provides general guidelines, it does not currently provide specific guidelines for an appropriate level of surveillance for the different BSE risk categories. This makes the comparison and evaluation of national surveillance systems even more difficult.

Passive surveillance

Until 1999, BSE surveillance was limited to the notification of clinically suspected cases (passive surveillance). Mandatory reporting is certainly a basic requirement for a surveillance system, and in many countries it was assumed that this level of surveillance would allow early detection of a BSE outbreak.

However, passive surveillance relies solely on the identification and reporting of clinical suspects by farmers, veterinarians and others involved in handling animals to the veterinary authorities. For this system to function effectively, several factors must be considered (Doherr, Heim, Fatzer, Cohen, Vandevelde & Zurbriggen, 2001):

- Disease awareness at every level and in every sector is essential. Cases are often overlooked because the more dramatic clinical signs are normally only observed at the end-stage of the disease. Farmers, veterinarians, slaughterhouse personnel and others handling cattle play a crucial role and should be trained to recognize even the subtle, early signs of BSE. This requires an extended, long-term education program.

- The willingness to report suspected BSE cases is also essential. There must be minimal negative consequences to the identification of a positive case at the farm level, i.e. measures must be "reasonable". The motivation is low for a farmer to notify a suspect case if their whole "life-work" could be destroyed, therefore all consequences should be understood and accepted by the farmers and a reasonable compensation paid. Moreover, the stigma associated with BSE – especially with the first cases of BSE detected – should not be underestimated. These issues can be improved through proactive communication of information.

- Adequate laboratory competence must be available to ensure appropriate handling and examination of brain or other tissues collected through the surveillance system.

Because these factors vary greatly, both among countries and within countries over time, the results of passive BSE surveillance systems are subjective and evaluation and comparison of reported case numbers should be made carefully.

For example, the legal framework for passive surveillance within all EU member countries states that cattle of all age with clinical signs consistent with BSE should be examined for BSE. However, even within this stringent EU framework, variability exists, and some EU countries with a known BSE problem do not test the minimum number of animals set forth in the OIE code (Office International des Epizooties, 2004b). In the OIE code section, the minimum number of animals exhibiting one or more clinical signs of BSE (clinical suspects) that should be tested (based on the total cattle population over 30 months of age) is indicated, and suggestions are that the number is even too low. However, analysis of the number of tests performed in the EU between 2001 and 2003 showed that the number of suspect cattle examined varied between 2 and 408 per million adult cattle. (European Commission, 2002, European Commission, 2003, European Commission, 2004). Therefore, despite the OIE code recommendations, much less the stringent EU regulations, in some member states passive surveillance seems to be nonexistent and, with a few exceptions, it may be actually declining (Table 2).

Given this variability in the factors involved and the difficulty in effectively implementing a passive system, it has become obvious that passive surveillance alone is not sufficient to establish the real BSE status of a country, therefore, other solutions were sought.

Active surveillance

Other groups of cattle that are at increased risk of having BSE have been identified and can be actively targeted within a national surveillance system to improve the chances of identifying positive animals in the overall population and improve the validity of the data. These risk groups include cattle with signs of disease non specific to BSE (e.g. weight loss, loss of production) and cattle that died or were killed for unknown reasons. In different countries these animals may be defined as sick slaughter, emergency slaughter, fallen stock, or downer cows. It is known from the pathogenesis of the disease that cattle younger than 30 months rarely test positive, so the age of the population tested also is important.

Table 2: Number of clinically suspected cases of BSE per million adult cattle in the European Union, 2001-2003

Country	Clinical suspects per million cattle		
	2001	**2002**	**2003**
Austria	2	4	2
Italy	3	29	19
Finland	8	15	13
Greece	10	0	3
Germany	32	55	136
Sweden	36	37	23
France	43	18	39
Netherlands	54	23	15
Denmark	81	42	42
Spain	136	20	21
Luxembourg	140	140	40
Ireland	142	142	92
Belgium	161	186	111
UK	228	174	91
Portugal	408	188	128

For example, in January 1999 Switzerland initiated an active, targeted surveillance scheme to enhance the detection of BSE cases in the adult cattle population (Doherr, Oesch, Moser, Vandevelde & Heim, 1999). In addition to the mandatory reporting of all suspect clinical cases, all cattle that are in the above groups and that have at least four permanent incisors are tested. Additionally, a random sample of apparently healthy cattle is examined during regular slaughter to minimise diversion of questionable animals to slaughter (i.e. to improve compliance with passive surveillance and reporting). The development of rapid BSE tests (Scientific Steering Committee, 1999, Scientific Steering Committee, 2002d) facilitated testing of the increased number of samples collected through this system.

n the spring of 2000, a similar surveillance approach was introduced in Western France (Calavas et al., 2001). In January 2001, the EU introduced a standard system for the active screening of cattle for BSE (Heim & Kihm, 2003), in which all animals in the entire risk population (i.e. all cattle that have died or been killed on farm or during transport, fallen stock, and cattle sent to emergency/sick slaughter) over 24 months of age are tested. Additionally, all cattle subject to regular slaughter over 30 months of age are tested. Through this program, many more positive cases were detected and the number of reported cases in the EU increased in 2001 and 2002. In the 15 original countries of the EU (EU 15) in 2003 1,364 cattle were positive of more than 10 million tested. This suggests an overall downward trend in the number of cases. Interestingly, Spain and Portugal were the only countries in the EU 15 with increased cases in 2003 (figure 2). The basis for this reported increase is unclear.

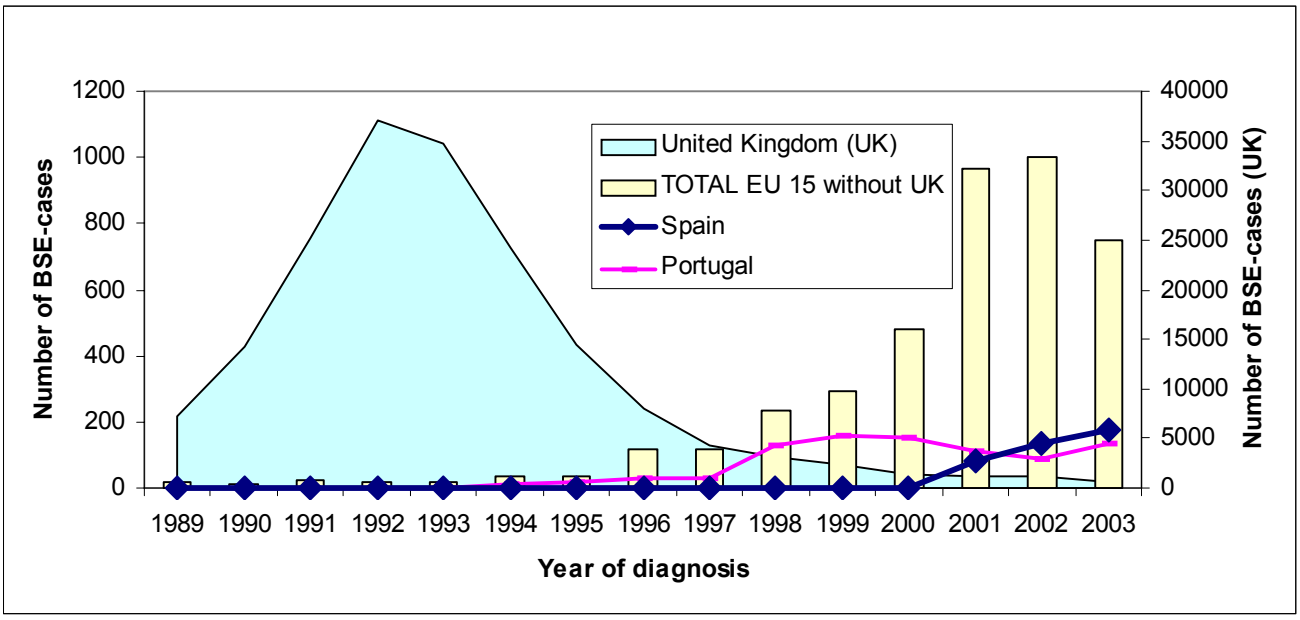

Figure 2: Number of BSE cases in the 15 original member states of the European Union from 1989 to 2003

Despite the fact that all EU member countries have the same legal requirements for surveillance (except UK and Sweden which have special regulations), other variability and inconsistencies can also be identified.

One evaluation of the data from 2001 and 2002 concluded that active BSE surveillance was operating reasonably in most member states although anomalies persisted (Bird, 2003). However, it is clear that some of the countries with a very low number of cases also tested fewer animals (Figure 3 and 4) and that the number of cattle tested varies substantially among member states. For example, the risk population tested has ranged between 0.62% and 5.86%, and the population of cattle at regular slaughter has ranged between 7.5% and 37.9% (excluding UK and Sweden) of the total adult live cattle population. Although some variations in the number of tests performed could be explained by different production and detection systems, the deviation is that significant that it can only be explained with an imperfect implementation of surveillance. This emphasizes that legal requirements alone are not sufficient and enforcement of implementation is crucial.

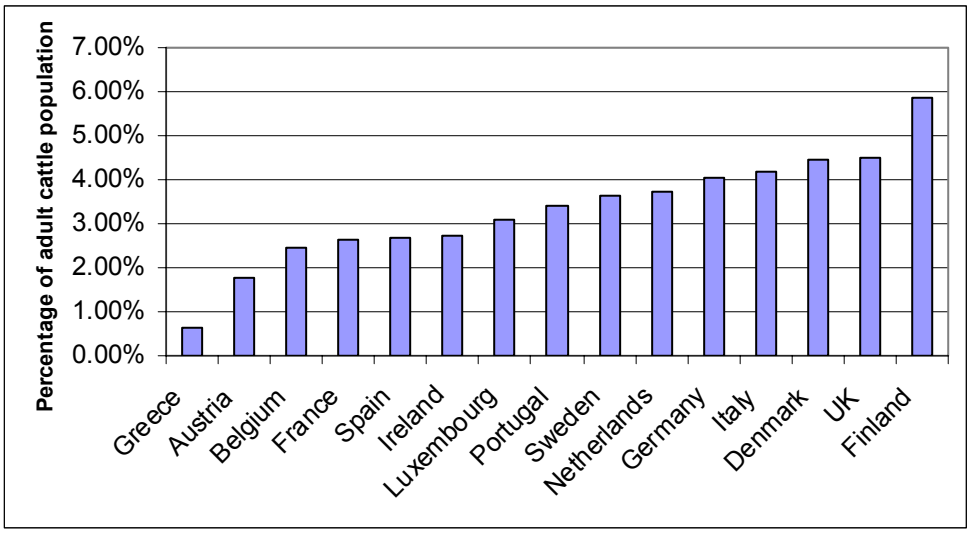

Figure 3. Cattle tested from the risk population, shown as a percentage of the adult live cattle population

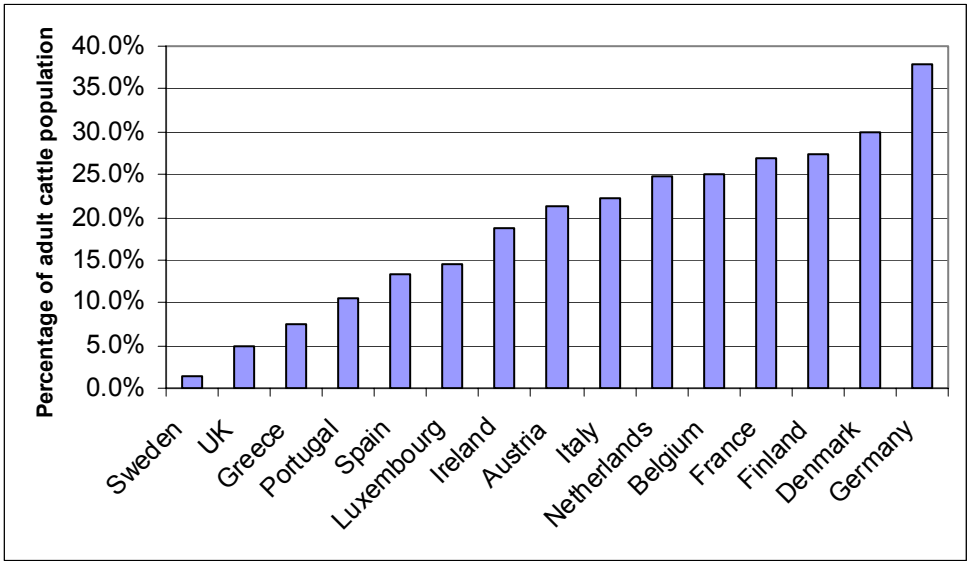

Figure 4. Cattle tested from the regular slaughter population, shown as a percentage of the adult live cattle population

The variability in the cattle population tested also affects the interpretation of the results. If risk populations, as described above, are tested, the efficiency of testing (i.e. the number of tests performed to find one positive) increases. If testing focuses on regular slaughter cattle, especially cattle younger than 30 months (or even younger than 24 months), a country may report a very high number of tests performed and low number of cases, but these numbers only give part of the picture. Most reports of tests performed and cases reported are not age adjusted, making country-to-country comparisons difficult. In addition, testing large numbers of low risk animals greatly increases the cost of a surveillance program, which may be especially important for countries with limited resources (Table 3).

Table 3: Number of cattle tested and BSE positive cases in the risk and the regular slaughter populations in the European Union

	Regular slaughter population		**Risk population**	
Year	2002	2003	2002	2003
number of cattle tested	7’511’862	8’716’481	1’030’484	1’295’770
number of BSE positives	237	265	938	783
rate of positives: 1 of	31’696	32’892	1099	1655
Costs to find one positive BSE case (assuming €70/ sample)	**€ 2,2 million**	**€ 2,3 million**	**€ 76901**	**€ 115’841**

Taken together, the different aspects of the variability in implementation make it extremely difficult to judge and compare the data even among member states of the EU. When systems in other countries are then compared, differences in basic system structures complicate interpretation of the variability in implementation even further. Therefore, as stated above, reported case numbers from the EU and worldwide must only be evaluated in the context of the quality of the surveillance program implemented in the individual countries, and trends must be looked at critically.

Outlook: the rest of the world

There remain many countries with an unknown BSE risk, as materials potentially infected with BSE have been distributed throughout the world (Office International des Epizooties, 2001). In a joint WHO/FAO/OIE Technical Consultation on BSE in June 2001, it was therefore concluded that all countries should evaluate their potential exposure through systematic assessment. As well, it is important for other countries to know the real BSE distribution worldwide in order to minimize import risks. Historically, however, few countries have undertaken a national risk assessment before detection of their first BSE case. In the same joint meeting it was concluded that countries should strongly consider, on the basis of these risk assessments, the use of appropriate BSE tests on target populations and on a sufficient number of animals, i.e. the development of targeted surveillance systems.

In North America, both Canada and the USA have undertaken quantitative risk assessments. The assessment of Canada (Morley, Chen & Rheault, 2003), published just before the first case was detected, concluded that the likelihood of BSE in Canada was extremely low to negligible. The Harvard risk assessment of the USA (Cohen et al., 2001) also concluded that the nation was highly resistant to any introduction of BSE and that BSE was extremely unlikely to become established in the USA. However, the many uncertainties over export data from Europe and lack of internal data (such as the effectiveness of enforcement of measures), combined with general problems in data validity as previously described, make it difficult to make reliable quantitative assessments of BSE risk. The quantitative and mathematically sophisticated nature of these assessments can lend an air of accuracy and validity to the conclusions that, in truth, they do not possess (Gravenor & Kao, 2003). Without good data, reliance on quantitative predictions is potentially dangerous and current quantitative risk assessments need to be interpreted carefully. Although in Canada and the USA some surveillance has been in place for several years, experience shows that it is likely not sufficient, either in population tested or in number of animals tested, to estimate the extent of the problem. Therefore, in June 2004, the USA began a one-year program to test the whole cattle risk population for one year (Anonymous, 2004).

In South America, several countries have been assessed in the GBR. Most of these are GBR I, one is GBR II. Argentina made their first risk assessment in 1991, and has already updated it several times. In the countries not assessed in the GBR, no risk assessment has been undertaken, often BSE is not notifiable, and the implementation of surveillance is in the initial stages (van Gelderen, Gimeno & Schudel, 2003).

In Asia, one survey on BSE concluded that the majority of Asian countries did not perform a risk assessment (Ozawa, 2003). According to Eurostat data, however, many Asian countries did receive significant amounts of MBM, implying that the BSE agent could have reached them. This was confirmed when Japan reported its first case in 2001. In Asia there are still countries in which notification of BSE is not mandatory. In other countries it is notifiable, but few have a compensation scheme for BSE suspects. This is reflected in the negligible number of suspects in most of these countries. In Japan, a quantitative risk assessment was published after the first case was detected (Sugiura, Ito, Yokoyama, Kumagai, & Onodera, 2003), and only in Japan has an intensive surveillance program been introduced.

Australia and New Zealand have been assessed in the GBR process and are currently categorized as GBR I. Both countries have implemented some surveillance.

From most other regions of the world, there is no information available regarding risk assessment and surveillance systems in place. As well, in most countries, only minimal measures are in place and may not be effectively enforced. Control of the amplification cycle, primarily through control of cattle feed, can significantly decrease the risk of BSE spreading within countries.

Conclusions

The evidence accumulated to date indicates that the control measures put in place since 1988, and especially since 1996 in the United Kingdom, have brought the epidemic under control, and there is no logical reason why the consistent decline seen over the past decade should not continue. Also in most of the other EU member states and many countries with reported BSE cases, measures including a targeted surveillance system, have been implemented.

However, differences in the structure and implementation of surveillance systems lead to variability in the amount and quality of the data available from almost all countries, including some countries of the EU. The variability complicates the ability to interpret and compare results.

Many countries have neither a risk assessment nor a surveillance system for BSE in place. These countries might be exporters of potential risk material to other countries, even though they have not been identified as countries affected with BSE. Because, minimal information exists regarding the BSE situation in these countries, their trading partners are subsequently limited in their ability to assess their own risks.

These uncertainties emphasize the need for all countries throughout the world to assess their risk. Implementation of a targeted surveillance system can at least provide basic information on the BSE status of these countries. As well, implementation and enforcement of some economically feasible proactive measures can act to control, or at least suppress amplification, of BSE at whatever level it is present.

PRELIMINARY RAMAN SPECTROSCOPIC INVESTIGATION OF THE CHANGES IN BEEF STERNOMANDIBULARIS MUSCLE DURING THE THAWING OF MUSCLE STRIPS FROZEN PRE-RIGOR.

Background

The potential of Raman spectroscopy in the analysis of foods has long been known, mainly due to the high information content (which can be understood in terms of chemical and physical parameters) which can be obtained without sample destruction and on any physical state, even in the presence of water. Very few investigations have been carried out on the application of Raman spectroscopy to the study or analysis of meat since Asher *et al* (Asher, et al 1976) first published a short account of the Raman spectrum of whole muscle. A number of studies in the mid 1980s investigated contraction of single fibres and various purified myofibrillar protein (Pézolet et al 1988). However, much of the work has concentrated on simplified systems and only recently has any work been attempted on bulk meat tissue (Beattie et al, 2004;Brondum et al 2000;Pedersen et al 2003).

The background understanding of the factors governing the Raman spectrum of meat is very limited so that it is important to extend the investigations of intact samples to conditions which are somewhat distant from conventionally processed consumer beef but where the data are easier to interpret. During the rigor process there are biochemical changes due to post mortem glycolysis (eg ATP depletion, lactate accumulation) and also changes in protein conformation due to the formation of actomyosin. Muscles frozen pre rigor when thawed go into rigor at a much faster rate and with a greater degree of contraction than normal rigor (Lawrie 1998). Davey & Graafhuis (1981) used thaw rigor as a technique for the early prediction of ultimate pH, since this was achieved within 10 to 20 minutes of thawing the samples. Thaw rigor provides a potential technique for studying boith the biochemical changes and contraction together by allowing samples to contract whilst thawing and the biochemical changes independent of contraction by securing the muscle to prevent contraction during thawing. The latter procedure should be similar to the normal rigor process where little contraction is observed aas the muscle goes into rigor.

Objectives

To study the changes in Raman spectra as strips of beef *sternomandibularis* muscles frozen pre rigor go into rigor on thawing in conditions which allow and prevent physical contraction occurring.

Materials and methods

Experimental

Samples of *m. sternomandibularis* were dissected from the neck at 30 min *post mortem* from 6 animals. From each muscle sample a number of strips 5 mm thick, 10 mm wide and 60 mm long were cut, wrapped in aluminium foil and placed in liquid nitrogen within 10 minutes of dissection.

Raman Spectroscopy

Raman spectra were recorded using the 785 nm excitation wavelength Raman spectrometer previously described (Beattie et al., 2004). Removal of the 'fluorescence' background was effected in SpectraCalc ™ where the multiple point baseline correction program was modified to allow the positions used for baseline points to be fixed. The initial and final spectra were averaged then subtracted to elucidate the variation between spectra recorded pre-thaw *rigor* and post thaw *rigor*.

The samples rapidly dissected upon removal from the freezer to give a fresh cut surface. Typically recording commenced *ca.* 8-10 min after removing from the freezer, while defrosting was complete *ca.* 12-15 min after

removal. Spectra were recorded for 1 min with a 20 second delay before recording the subsequent spectrum. The precise start time of each spectrum was recorded and every three spectra the length of the muscle was measured. For the thaw *rigor* studies the sample was not moved from its location. Half of the sample strips were loosely clipped on the rotating stage to allow contraction to occur, while half of the strips were firmly clamped at each end to prevent significant amounts of contraction.

The presence of collagen in the beef samples was determined by the band intensities at positions which are known to correspond to various modes of proline and hydroxyproline (Beattie 2002). Any samples showing exceptionally large changes in collagen within the spectra upon contraction were eliminated, to allow clearer interpretation of the changes affecting the myofibrillar proteins. Subtracted Raman spectra were generated to elucidate the changes in the Raman spectrum during thaw *rigor*. For the unclamped sample set this subtracted spectrum was produced by averaging all the samples prior to the onset of contraction, those after contraction had completed and performing a spectral subtraction normalised on the phenylalanine band at 1003 cm^{-1}, which is widely recognised as being insensitive to environmental factors. A residual band was evident at a slightly higher wavenumber positions, but was sufficiently weak to not interfere with the normalisation. For the clamped data set, the spectra recorded at the same times when contraction started and had completed in the unclamped samples were selected for averaging and subtracted as before.

A sample of silverside aged for 21 days (Beattie,et al., 2004) was used to compare the effects of sample orientation relative to the incident beam by mounting the sample with the myofibrillar long axis parallel and perpendicular to the incident beam.

Results and discussion

Figure 1 shows the average Raman spectrum of the pre-thaw *rigor* samples, with some bands of interest marked with a number referring the table of band assignments (Table 1).

The subtracted Raman spectrum from the unclamped data set is shown in Figure 2a. There are large changes in the regions known to be sensitive to the secondary and tertiary structure of proteins, the amide I (1640-1685 cm^{-1}), amide III (1225-1305 cm^{-1}) and ν(C-C) region (880-1020 cm^{-1}). One possible explanation of changes in these regions is typically that there is widespread conformational change within the proteins of the sample. However, there is another explanation which might apply in this particular case due the very high degree of orientation involved in the myofibrillar proteins and that is that the Raman spectra might have changed due to reorientation. It is well known that the Raman spectrum of highly oriented molecules can look different depending on their orientation relative to the incident radiation. Figure 2b shows the subtraction Raman spectrum obtained by subtracting the Raman spectrum of aged beef acquired with the myofibrillar long axis parallel to the beam away from the Raman spectrum acquired with a perpendicular orientation. Comparing Figure 2 a and b shows that there is a striking similarity in many areas, which would suggest that much of the changes occurring in the three regions highlighted above may be arising from reorientation of the myofibrillar proteins.

The average contraction observed was 60 % of the original muscle length, the level of contraction at which the myosin pushes against the Z-disk that hold the actin in place. Since both major proteins (actin and myosin) overlap fully and the anchor proteins are being perturbed, it is reasonable to assume much of the protein will be distorted, causing widespread reorientation with respect to the myofibrillar long axis. Thus it seems reasonable to assign the changes in the amide and ν(C-C) regions to reorientation of the myofibrillar proteins rather than large scale conformational changes.

Figure 2c shows the subtracted Raman spectrum of the clamped samples, and it is readily noticeable that the effect of thaw *rigor* on the amide and ν(C-C) regions is significantly different from the unclamped samples. The amide I and ν(C-C) regions are noticeably weaker for the clamped samples, suggesting a much slighter change in orientation. This is not surprising as only a small amount of overlap occurs between the actin and myosin so only a few myosin S2 heads are reorienting, along with the various other minor proteins involved in the binding of myosin to actin. If the predominant effect had been conformational change, rather than orientation, it would be expected that the spectra of the clamped and unclamped data set would be much more similar. The fit between the orientation subtraction spectrum and the unclamped thaw rigor is expected since the effect of extreme contraction would be that the myofibrillar axes would be buckled and instead of recording the Raman spectrum using a beam which truly perpendicular to the fibre axis we are recording some of the fibres at an angle to that axis.

While there are clear differences between the amide and ν(C-C) regions of the Raman spectra of the clamped and unclamped data sets, there are also some bands which show similar changes between the two data sets. These bands are marked in Figure 2 by the dashed vertical lines. These bands are all ones that are known to be affected the polarity of the environment of the protein. In the clamped data set the $CH_{2\ sc}$ band at 1450 cm^{-1}, which is negatively correlated with hydrophilicity, shows a strong decrease, which indicates a strong increase in the polarity of the protein environment. This result is expected as the massive contraction observed in thaw *rigor* is caused the release of large amounts of calcium salts, which will significantly increase the ionic strength of the myofibrillar matrix, thus the polarity of the proteins' environment. The same band at 1450 cm^{-1} is observed to increase, contrary to the expectation of the environmental changes, but in line with the changes to the orientation of the myofibrils, showing that the reorientation has a stronger effect on that band than the environmental effects.

Conclusions

We have demonstrated that the Raman spectrum of meat is affected by the process of thaw *rigor*. When the sample is unrestrained and able to contract freely, these changes can primarily be attributed to the reorientation of the myofibrillar proteins. When the sample is restrained so that significant amounts of contraction are not possible, it was found that the effect of reorientation was reduced and that the increase in ionic strength during thaw *rigor* affected the environmentally sensitive bands.

EFFECT OF OUTDOOR REARING SYSTEM ON FAT DEPOSITION AND EATING QUALITY IN ORGANIC HEAVY PIGS

Bondesan, V.[1], Sartori, A.[2] and Danesi P.[1]

Agriculture Veneto, Via dell'Università 14, 35020 Legnaro-Padova, Italy
Department of Animal Science, University of Padua, Via dell'Università 12, 35020 Legnaro-Padova, Italy

Background

Over the last years, the interest in organic production has increased considerably in Italy. However, only a small percentage of pigs today are organically produced (about 0,2 % of total slaughtered pigs in 2003). Nevertheless, the organic sector, both fresh meat (loin) and traditional processed products (dry cured ham, salami, etc.), is growing. The possibility of fattening pigs through outdoor system using pasturage field, seems to meet the organic regulation requirements for animal welfare and farmer demand for low cost investments (housing and manure utilisation). Over the last ten years, several studies were published on the effects of outdoor rearing system on growth performance, carcass composition and meat quality traits of fattened pigs. However, almost all research has considered the slaughter animal live weight approximately between 80 to 110 kg. Effects of grazing, physical activity (exploring, rooting, etc), fattening season (cold or hot weather, raining days), soil conditions (type of cover crops, watery mud), on fresh meat quality traits are still not well known. Investigations on eating quality, mainly performed on loins (*M. Longissimus dorsi*), have produced contradictory results, as far as pigs from different rearing (outdoor *vs* indoor) or finishing systems (conventional *vs* organic) have been compared.

Objectives

In the Italian production, more than 80 % of pigs are slaughtered at an average live weight of 165-170 kg (heavy pig, with minimum age of 9 months) for traditional dry cured ham production. The quality traits of fresh ham intended for curing have obviously been considered more important than those of other cuts. However, eating quality profile of fresh loin is also a concern for organic driven consumers.

This study investigates the main eating quality traits of pork loin (*M. Longissimus dorsi*) from outdoor and indoor organically produced heavy pigs.

Materials and methods

Investigation was carried out using a total of 96 samples of pork loin from heavy pigs –castrated male only-, produced in 3 different organic farms, and slaughtered at the same abattoir during 4 trials.

Animals

The pigs were from three-way cross-bred slaughter pigs, where the terminal sire was pure-bred traditional Italian Large White and the dams were crosses between Landrance and Duroc. All piglets came from one herd, organic farm with reproductive outdoor system; after 45 days of farrowing and 55 days of post-weaning, pigs were delivered to the three finishing farms (average live weight 37.7 ± 3.8 kg). Some pigs was stalled in a conventional piggery according to organic specification (indoor rest area with deep straw and outdoor concrete paddock) in groups of 8. The pigs reared outdoors were kept in grass fields (2/3 grass 1/3 wood bush, about 3000 m^2 each group of 8 animals). All pigs were fed restrictedly twice a day with the same commercial organic feed (15.5% crude protein, 0.65% lysine, 1.8% linoleic acid, 12.2 MJ of ME/kg of dry matter) receiving 2.0-2.5-3.0 and 3.5 kg/d of feed approximately at 40-80-110-140 kg of live weight (the study started in May and ended in November 2003). After 3 h of transport and 2h of rest in the lairage, pigs were electrically stunned and slaughtered.

Meat

At the end of slaughter line, the estimation of carcass meat percentage was performed using FOM (Fat o Meter equipment) by measuring subcutaneous fat (twice) and LD muscle depth. Subcutaneous fat thickness of fresh ham was also manually measured in the lateral side at level of *M. Biceps Femoris*. Carcasses were immediately hot boned (approximately 40-45 minutes after slaughter), and the primal cuts were cooled

separately (loins-rib in, shoulders, hams, bellies, back fat, and neck cuts) at 0-2 °C for 24 h (air speed 0.5 m/s), as usual in Italian pig slaughterhouses. pH was measured at 45 min and 24 h by inserting the electrode in the *M. Longissimus dorsi* at the last rib. A 10-12 cm section of LD sample was dissected from each loin (right side), after 24 h cooling (above the last rib), vacuum packed and transported to the lab for analysis. From each sample a slice of 2.5 cm thick was used for cooking loss and shear force measurement, using a Instron equipment with Warner Bratzler device on boiled meat (cooking was complete when central temperature reached 75 °C). Two chops of 2.5 cm thickness were assigned to panel test (8 trained panellists) for sensory analysis on roosted meat, cooked in oven (cooking was complete when central temperature reached 75 °C). The panellists used an 8-point category scale to score the tenderness, juiciness, pork flavour and overall palatability. Both shear force and sensory analysis were performed on fresh meat after 3 days of ageing. A slice of fresh meat was used for chemical determination of intramuscular fat (IMF) and fatty acid composition (Riley et al., 2000).

Statistical analysis

Lean meat percentage, fat thickness, ph, IMF, fatty acid composition and sensory data were analysed by general linear model procedures (SAS procedure GLM). Rearing system, batch and finishing farm were considered as fixed effects. The two-way interaction between rearing system and farm were also tested. Differences between pair-wise combinations of the least square means were tested for significance ($P<0.05$).

Results and discussion

Main results of carcass quality traits are shown in Table 1. Organic pigs finished outdoors had lighter carcass weights, leaner carcasses and less subcutaneous fat deposits (P <0.005). Difference in daily gain and carcass weight between indoor and outdoor rearing system in finishing pigs may be explained with the different amount of energy needed for physical activities (exploring, rooting, etc.) of free ranging pigs, as reported in similar studies (Enfalt et al., 1997; Sather et al. 1997). However, other studies (Beattie et al., 2000; Gentry et al., 2002) found a positive or no effect of rearing system on average daily gain and carcass weight, in outdoor finished pigs. It is clear that the level of physical activity depends on e.g., soil characteristics, presence of mud, raining days and climate conditions (temperature, day light etc).

Table 1. Least square means for carcass and main LD quality traits

	rearing system (RS)			significance	
Trait	indoor	outdoor	SE	farm	farm x (RS)

LSM estimates with different superscript, within a row (rearing system) differ, $P < 0.05$; n.s. not significant

All these environmental, management and climate variables may play a critical role in increasing or decreasing of the activities of free range pigs, making the comparison between different studies difficult. During this experiment (from May to November, 2003) high summer-autumn temperatures and a long rainless period, may have reduced the environmental effect on energy consumption.

Significant reduction of backfat in carcasses from outdoor finished pigs was observed, with consequent increasing of estimated lean meat percentage. Lean meat percentage values found in this experiment are not comparable with other findings from similar studies, because of the great difference on carcass weight and specific estimating equation used.

An unexpected significant reduction of subcutaneous fat was found in the ham of the outdoor finished pigs. This may be considered a negative aspect, since the required level (Regulation for typical Italian cured ham, EC origin protected product) is fixed at 20 mm minimum of thickness. However, more data should be recorded to clarify if the intense physical activity of free range could affect the development of thighs (bone length and ham thickness etc.).

Intramuscular fat of outdoor finished pigs was significantly higher than that of the indoor finished. The result is in agreement with Gentry et al. (2002), but conflicts with the findings of Enfalt et al., (1997) and Danielsen et al. (2000). Nevertheless, the high carcass weight and the age of pigs in this experiment, call for great attention on comparative findings from different studies. It is possible that in long fattening period with restricted feed, the age (9-10 months), physical activity and muscles maturity, may play an important role on shifting fat deposition from subcutaneous to intramuscular depots. No significant differences were found concerning pH1 and pH24, Warner Bratzler shear force on cooked meat, or cooking loss between the two rearing system.

Table 2. Fatty acid composition (% least square mean and standard error) in intramuscular fat from LD

	rearing system

LSM estimates with different superscript, within a row (rearing system) differ, $P < 0.05$; Identified fatty acids below 0.15% -trace- are not shown

Eating quality can usually be well described by a sensory panel. Juiciness and pork flavour are probably the most important meat quality traits for consumers eating pork. In this experiment, no differences were found for tenderness and pork flavour. However, the panellists found the meat of outdoor finished pigs juicier and more acceptable (overall liking). Several researchers have found no differences in the eating quality of pork when comparing pork from indoor and outdoor rearing (Van der Wall et al., 1993; Jonsall et al., 2000), nor a negative effect on tenderness or juiciness (Enfalt et al., 1997). Jensen and Jakobsen (1996) did, however, report a clear difference in meat quality and sensory quality between loins from organic pigs reared indoors and outdoors. Also Gentry et al. (2002), reported that meat from outdoor finished pigs has higher flavour intensity. In this experiment, better juiciness scores of loins from outdoor finished pigs compared to indoor finished, may be linked with the higher level of intramuscular fat found. No easy comparison is possible from the sensory quality results of this experiment and other similar studies, since slaughter procedure applied in Italy (hot boning and loin dissection from bones, with high risk of cold shortening before rigor mortis) may play a critical role on influencing tenderness and juiciness.

Fatty acid composition in the intramuscular fat of the loins (*M. Longissimus dorsi*) are show in Table 2.

Only small differences in fatty acid composition (%) between the loins of outdoor and indoor finished pigs were found. A slight increase in unsaturated fatty acids was observed for 18:2 n-6, 18:3 n-3 and 20:4 n-6, from outdoor finished pigs, and consequently, SAFA and PUFA were significantly affected. The fatty acid composition of the pork intramuscular fat has been reported to be affected by feed composition (Kouba et al., 2003), breed or genotype, sex as well as carcass fatness (Wood et al., 2003). Furthermore, it has been suggested that the rearing system may affect the lipid composition of pig muscles (Hogberg et al., 2001) when interacting with sex and genotype.

The differences found in this experiment in polyunsaturated fatty acid (18:2 n-6, 18:3 n-3 and 20:4 n-6) composition may due to the intense physical activity of outdoor finishing pigs compared to the indoor groups, with consequent change on lipid classes (neutral and polar lipid) with their respective roles in living animal (Clarke, 2000). However, because outdoor pigs were reared in a large grazing area, the amount and quality of grass daily ingested may have affected the total amount of unsaturated fatty acids in the feed. No significant effect of the type of organic finishing farm was found on the fatty acid composition of IMF.

Conclusions

Overall, results comparing indoor and outdoor pig finishing systems have been variable. Some reasons for this variation include differences in seasonal effects, ground type, grazing area, genotype and final slaughter weight. Organic production system with its specific managing and feeding requirements, may also affect the performance and meat quality of outdoor finished pigs. Changes in carcass composition (leaner of fatter) and fat distribution, in outdoor finished pigs compared to the indoor-finished, may represent a positive or negative aspect depending on final product destination (fresh meat or traditional cured salami).

Manipulation of fatty acid composition, by changing feed composition and feeding regime in outdoor organic pig finishing system, using grass or silages, will have to be carefully tested on large scale experiments. For processed products with long curing, such as dry cured ham (14-16 months of seasoning), increasing of PUFA should be carefully monitored, for increasing risk of fatty acids oxidation and off-flavour development.

QUANTITATIVE EVALUATION OF CHLORAMPHENICOL CONTENT IN CHICKEN MEAT PRODUCED BY DOMESTIC PRODUCERS WITH ELISA - TEST

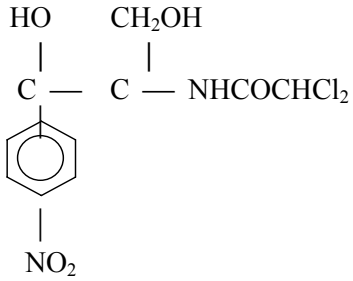
Brdarić Nedim, Zahirović Lejla, Hajrić Džemil, Bećar Elzana

Kantonalna veterinarska stanica Sarajevo
Mikrobiološko-kemijski laboratorij
Azize Šačirbegović 16, Sarajevo, BiH

Background

Chloramphenicol is an antibiotic of wide specter. It affects Gram-positive and gram-negative bacteria, rickettsia, spirochete and Chlamydia. Because of its fantastic antibacterial effects and pharmacokinetics it has been used very often in animal treatment.
According to its chemical composition it is a derivate of nitro-phenol, molecular formula is C11H12Cl2N2O5 molecular weight M =323, 13 g/mol. Its full name is D-[-]-threo-2-dichloroacetamido-1-[p-nitro-phenyl]-1, 3-propaniol.

Structural formula:



This compound is very stable up to temperature of 100°C and it is in the wide range specter of pH (2-9). Pure substance is very liposoluble; poorly soluble in water (0, 25%) because of that it is used therapeutically in the form of palminate, stearate and sucinate. Chloramphenicol is metabolized in liver and excreted from body through urine.
Treatment of human beings by chloramphenicol is only recommended in life threatening infections. Misuse of chloramphenicol can lead to: leucopenia, trombocitopenia, irreversible plastic anemia etc. It is fully cumulative toxin because of its structure or toxic metabolites (mainly the ones that contain nitro group).
Due to chloramphenicol negative impact on human's health, treatment of animals whose products meat, milk and eggs are used for human's consumption, is strictly prohibited in EU since 1994. According to regulations, the presence of residues of this antibiotic in food must be monitored continuously in all products of animal origin.
Conventional method (radioimmunology) for quantitative evaluation of chloramphenicol has been switched by new more precise methods as: gas chromatography/MS, liquid chromatography/MS and ELISA-test. These methods are more specific and more sensible with detection level (10^{-12}g/g), or (ng/kg).

Objectives:

During March 2004 the authors of this paper were investigating presence of chloramphenicol content in samples of chicken meat from market of Canton Sarajevo. We expect higher level of self control at our producers and importers**.**

Materials and methods:

Elisa-test is analytical method which can be used for quantitative evaluation of: antibiotics, hormones, pesticides, vitamins etc; in products of animal origin. Authors of this paper were quantitatively evaluating the content of chloramphenicol residues in chicken meat during March 2004 from market of Canton Sarajevo.

Principle of the assay

Assay is based on the antigen-antibody reaction, which is being done in vitro on micro titer plate. Micro titer plate is precoated by fixed antibodies of sheep to rabbit IgG. Chloramphenicol standards or diluted chicken meat samples, chloramphenicol enzyme conjugates and antichloramphenicol antibody is added. Free chloramphenicol and chloramphenicol enzyme conjugate compete for chloramphenicole antibody binding sites (competitive enzyme immunoassay). After incubation time the non-bound (enzyme labeled) reagents are removed in a washing step. The amount of chloramphenicol enzyme conjugate is visualized by the addition of a chromogen substrate. Bound enzyme conjugate transforms the colorless chromogen into a colored product. Reaction of substrate is stopped by addition of stop solution. The color intensity is measured photometrically, where optical density is inversely proportional to the concentration of chloramphenicol in sample**.**

Preparation of sample(chicken meat)

a) Homogenize 10g of chicken meat weight 3g of the homogenized tissue sample and transfer into a glass tube.
b) Add 6ml of ethyl acetate and mix (head over head) for 10 min.
c) After centrifugation (10 min, 2000g)
d) 4ml of the ethyl acetate and evaporated at 50°C
e) The fatty residue is dissolved in 1ml iso-octane/ thrichloromethane (2:3;v/v) and 1ml of dilution buffer is added.
f) Mix with vortex 1min and centrifuged 10 min with 2000g.
g) 50µl portions of the upper layer are pipetted into the test.

Assay procedure

a) Into wells of microtitar plate, parallel have been filed with 50µl of negative probe two wells (B1 ,B2) and standard dilutient from 0,025ng/ml to 2ng/ml(well C1and C2 to well H1 and H2). In the rest of wells fill in duplicate 50µl of prepared sample.
b) In the same order every well (except A1,A2) was filed with 25µl of enzyme conjugate and 25µl of diluted antibodies
c) After a mixing plate was incubated for 1 hour on 4°C.
d) Content of the wells have been washed three times with diluents.
e) Into each well was added 100µl of substrate and incubated 30min on room temperature.

Then 100µl of stop solution was filled in every well and content roughly mixed.

Spectrophotometeric reading

Optical density of generated color was read immediately by "IDEX" spectrophotometer; on wavelength λ=450nm. Blank probe was done against air.

Calculation

a) After we measured values of absorbance for each well and calculated medium value of two parallels, the calculation of parameters has been done %A (absorbance percentage) by following formulae:

$$\%A = \frac{\text{Average value of absorbance (standard or sample)}}{\text{Average value of absorbance of zero standards}} \times 100$$

b) Calibration curve was drawn for standard dilutions of chloramphenicol with known concentration.
c) Values of chloramphenicol concentration in samples (chicken meat) were read from the curve by appropriate values of %A.

Compared results

To compare these results authors have analyzed same samples by diffuse microbiological test using test species bacteria: Bacillus cereus ATCC 11778, Bacillus subtilis ATCC 6633, Staphylococcus epidermidis ATCC12228, Sarcina lutea ATCC9341 and Sarcina lutea ATCC 15957.

Results and discussion

In 25 examined samples of chicken meat from territory of Canton Sarajevo were not detected quantities of chloramphenicol greater than the limits of detection by this method, the Elisa-test (detection limit is 0,02ng/g) Samples (chicken meat) were from domestic producers and also from different foreign producers. The assay results are summarized and presented in table No: 1. Samples are grouped into next order.

a) A1- domestic chicken meat, locality 1
b) A2- domestic chicken meat, locality 2
c) B1- imported chicken meat, locality 1
d) B2- imported chicken meat, locality 2

NOTICE: Because of are professional relations with clients we did not notify producers names.

Table1. Chloramphenicol content in the samples of chicken meat

Group	Location	Number of samples	Chloramphenicol content (ng/g)
A1	1	7	< 0,02
A2	2	6	< 0,02
B1	1	6	< 0,02
B2	2	6	< 0,02

Conclusions

1. Elisa-test through assay has shown as very sensible, reliable and simple analytical method for quantitative analysis of chloramphenicol residues in chicken meat.
2. In 25 examined samples of chicken meat were not detected quantities of chloramphenicol greater than the limits of detection by this method, the Elisa-test (detection limit is 0,02ng/g)
3. Critical moment of Elisa-test for screening chloramphenicol in chicken meat is procedure of preparing sample for assay which is relatively complicated and long lasting.

FLAVOUR PERCEPTION OF OXIDATION IN BEEF

Campo, M.M.[1,*], Nute, G.R.[1], Hughes, S.I. [1], Enser, M.[1], Wood, J.D.[1] and Richardson, R.I.[1]

[1] Division of Farm Animal Science, University of Bristol, Langford, Bristol BS40 5DU, United Kingdom

Background

Lipid oxidation limits the storage life of meat (Rhee, 1988; Gray *et al*., 1996) through the production of rancid/off flavours but is also important in cooking-induced production of flavour volatiles, both directly and as precursors for the synthesis of other components of meat flavour.

Methods for measuring the effect of oxidation on meat flavour are either direct, ie. taste panel, or indirect by determining the degree of lipid oxidation by measuring oxidation products. The former is expensive, baseline perceptions may vary and they depend on prior experience/conditioning. The latter is usually quicker, cheaper and more reproducible within and between laboratories, but on the other hand, only determines chemical compounds which may or may not be directly involved in the oxidised flavour. Furthermore, widely used assays for rancidity, such as the determination of 2-thiobarbituric acid reacting substances (TBARS) measure a range of compounds. Although the chemical determinations are generally related to the deterioration in meat flavour there are few specific investigations of this relationship.

Ruminant meat is relatively stable in terms of lipid oxidation because of its high proportion of saturated fatty acids relative to polyunsaturated fatty acids (PUFA). However, by feeding cattle with lipids protected against rumen biohydrogenation it is possible to obtain meat with an increased content of n-3 PUFA (Scollan *et al*., 2003) making it more desirable in terms of human nutrition. Protected PUFA with different degrees of unsaturation, such as lipid supplement (C18:2 *n*-6 + C18:3 *n*-3 ratio 1:1) or fish oil (C20:5 *n*-3 and C22:6 *n*-3) can produce meat with a range in oxidative stability, so that knowledge of the shelf-life and flavour of the modified meat becomes important (Richardson *et al*., 2003). This meat with a wide range in oxidative potential can be used to assess the relationship between chemically determined oxidation and the organoleptic assessment of flavour as evaluated by a trained taste panel.

Objectives

The objective of this work was to relate human perceptions of lipid oxidation, as determined by a trained taste panel, to a chemical measurement of oxidation, using meat from animals with a wide range of potential oxidation because of the diet-induced changes in their PUFA composition, and further enhancement by displaying the meat in high oxygen modified atmosphere packages for various lengths of time.

Materials and methods

Meat was obtained from 73 Angus- and Charolais-cross steers raise for different on-going trials on 10 different diets: grass silage (high in C18:3 *n*-3), cereal concentrate (high in C18:2 *n*-6), three diets with 3% added fat consisting of three levels of protected lipid (high in C18:2 *n*-6 and C18:3 *n*-3, ratio 1:1)(PLS) and a control with Megalac ® (relatively saturated)(contPLS) and three diets with three levels of inclusion of protected fish oil (high in C20:5 *n*-3 and C22:6 *n*-3) and a constant amount of unprotected fish oil (PFO), as well as an unprotected fish oil control (contPFO).

48 hours after slaughter, the left loin of each carcass was removed, vacuum packaged, and kept at +1 ^{o}C. Loins of the grass and concentrate fed animals were kept vacuum packaged for an extra 8 days until reaching 10 days of ageing, whereas loins from the rest of the diets were kept for 11 days until reaching 13 days of ageing according to the protocols of their respective projects. After aging, each loin was cut into 2-cm thick steaks, vacuum packaged, frozen, and kept at -18 ^{o}C until analysed.

TBARS and sensory analyses were performed on steaks displayed for 0, 4 or 9 days under simulated retail conditions in modified atmosphere packages (MAP). After frozen storage, samples were thawed at +1 ^{o}C for

24 hours. They were transferred onto a polystyrene tray, covered with a permeable film and enclosed in a plastic transparent bag impermeable to oxygen. The atmosphere in the bag was modified to contain CO_2:O_2 in the ratio of 25:75. Samples were displayed for 4 or 9 days at 4 ^oC under illumination (700 lux 16 h on) until analysed. Samples of day 0 of display were not displayed in MAP, but instead were analysed immediately after the vacuum was broken after thawing to avoid oxidation. These were considered as non-oxidised control samples. TBARS (thiobarbituric acid reactive substances) were analysed by the steam distillation method of Tarladgis *et al*. (1960) and expressed as mg of malonaldehyde per kg of lean muscle. Steaks for sensory analysis were grilled and turned every three minutes for homogeneous cooking until the internal centre temperature reached 74 ^oC measured by a hand-held digital thermometer. Uniform cuboids were cut, wrapped in coded aluminium foil, and kept at 60 ^oC until the sensory evaluation was performed. Sensory assessments were performed by trained taste panel of nine members under controlled conditions, which included booths with red lights to mask colour differences. Panellists received three samples at a time to compare the meat within each animal that had been displayed for 0, 4 and 9 days. Panellists rated typical beef flavour, abnormal and rancid flavours as well as the overall palatability on an unstructured line scale where 0 meant no flavour or 'dislike extremely', and 100 meant very intense flavour or 'like extremely'.

Statistical analysis of panel data was performed by analysis of variance (Genstat 5 Release 3.1) within diet with conditioning time and panellist as factors and panel treated as a block structure. Differences between mean values were assessed post hoc using the least significant difference procedure. TBARS were analysed using the Kruskall-Wallis rank sum test. Spearman's rank correlation coefficients (rho) were calculated on the animal by display means for TBARS and sensory data using Minitab Release 11.

Results and discussion

Table 1 shows the values for TBARS and sensory attributes. Meat oxidation increased throughout the time at display for each of the diets, as shown by the rising TBARS values. The increments were not linear, however, being smaller between days 0 and 4 of display than between days 4 and 9 of display, as lipid oxidation is a free-radical chain reaction (Rhee, 1988). The lowest values and lowest increment in oxidation was produced by meat from the two control diets and the silage-fed animals probably due to the higher proportion of saturated fat in the meat from animals fed the contPLS and contPFO diets, as well as a higher content of vitamin E (Richardson *et al*., 2004) that acts as a powerful antioxidant. Accordingly, meat from animals fed concentrate diet had a low vitamin E concentration and the highest TBARS values. The greater the inclusion of protected PUFA in the diet of the animals, the higher TBARS values were obtained. This was especially observed in PFO diets, where an extra level of inclusion of protected lipid gave a higher oxidation value. In PLS diets, the oxidation of the meat did not increase from PLS2 to PLS3, because the attempt to increase C18:3 deposition in the muscle above PLS2 failed even with a 25% increase in protected lipid in the feed.

Sensory attributes were also influenced by length of display. Positive attributes, such as typical beef flavour or overall palatability, decreased throughout display, whereas negative attributes, such as abnormal or rancid flavours, increased. Although all diets started with similar values, the biggest reduction in beef flavour occurred in the diets producing meat with the most PUFA, especially in PLS2, PLS3, PFO3 and concentrate fed animals, with the lowest beef flavour intensities at day 9 of display. In general, the decrease in strength of beef flavour was more pronounced between days 4 and 9 of display than between days 0 and 4. Byrne *et al*. (2001) suggested that the disappearance of 'meaty' flavour was related to both the 'meaty' compounds degrading and becoming masked by flavour-affecting compounds derived from lipid oxidation. Concentrate, PLS2, PLS3 and PFO3 fed-groups showed also the highest mean ratings for abnormal and rancid flavours, closely related to their higher values of TBARS. Consequently, they received much lower values for overall palatability than the other diets.

Panellists could barely detect rancidity in unconditioned meat (0 days of display) with mean ratings all being less than 2. The lack of oxygen and the use of intact meat during frozen storage avoided the initiation of lipid oxidation (Spanier and Miller, 1996). However, abnormal flavour was perceived from this early stage onwards. Its value was always higher than those of rancidity, implying that rancid was considered an abnormal flavour, but not the only one of such. Negative flavours such as painty, cardboardy, bitter and sour have been described to increase with post-mortem ageing (Spanier *et al*., 1997).

The correlations between these attributes were very high (Table 2). TBARS was a good predictor of the perception of rancidity (rho = 0.84). Panellist preferences were related to the presence of the typical beef flavour (rho = 0.93) and to the absence of abnormal (rho = -0.89) and rancid flavours (rho = -0.84). The development of rancid flavour in relation to TBARS value followed a sigmoidal curve: $y = 0.0553x^3 - 1.122x^2 + 7.3962x + 2.3204$ ($R^2 = 0.62$). The third grade of the curve implied that rancidity is perceived strongly once it reaches the threshold but then, either the perception of the panellists becomes numbed, or the analytical technique fails to discriminate TBARS accurately at high levels of oxidation. The development of beef flavour in relation to TBARS also followed a sigmoidal curve but with a different direction than the previous one: $y = -0.0359x^3 + 0.8276x^2 - 6.2937x + 24.475$ ($R^2 = 0.68$). This means that typical beef flavour gets weaker but there is always a residual beef flavour in the meat throughout display, even if the development of other off-flavours becomes more perceivable. The two curves cross at a corresponding TBARS value of 2.3. From this point onwards, the perception of rancid flavour overpowers the perception of beef flavour. This could be considered as the oxidation limit at which meat could be rejected. Tarladgis *et al*. (1960) and Turner *et al*. (1954) suggested a TBARS of 0.5-1.0 as the threshold value for the detection of off-odour in pork. However, pork has a milder flavour than beef, and therefore, rancid flavours are probably noted at a lower concentration than in beef. Nevertheless, Melton (1985) suggested that oxidised flavours were detectable in beef at TBA numbers of 1.

Conclusions

Oxidation produces a decrease in beef flavour and overall palatability, as well as an increase in abnormal and rancid flavours during retail display of beef. Under the experimental conditions used, a TBARS value of around 2 could be considered the limiting threshold for the acceptability of oxidation-altered flavour in beef. This threshold was clearly higher than that of 0.5-1.0 suggested for pork.

Background

Blood contains 18-19 g/dl of proteins, of which 7-8% is plasma and 10-12% is globin. Those are very useful and valuable materials. Plasma contains fibrinogen, thrombin and factor XIII which are blood coagulant factors. It has been found there are many valuable biomedical materials. If they can be utilized, it can increase blood value and decrease environmental pollution. In 2003, we extracted fibrinogen and thrombin from porcine blood as a haemostat solution and investigated its effectiveness of clotting. We found it had very effective haemostatic action (Chen et al., 2003), thus, we try to develop other forms of haemostats.

Objectives

This study is to use fibrinogen and thrombin to prepare freeze-dried powder and haemostat film, and investigate the properties of the products.

Materials and methods

Fibrinogen and thrombin are extracted by the methods described by Futami et al. (1984) and Divakaran (1982), respectively. The two extracts are dried by freeze-drying to make powder. Haemostatic films are prepared with the combination of original extract solutions of fibrinogen and thrombin by the ratio of 20:1 and added with 12% of 0.25M $CaCl_2$ and coagulated on the surface of petri dish. The films are dried using freeze-drying, and 40□ oven drying for overnight and for five hours, respectively. The solubility and turbidity of the powder products are analyzed. Thickness, water absorption and swelling rate of films are also measured.

Results and discussion

The activity of thrombin, properties and haemostatic function of thrombin and fibrinogen have been studied before (Chen et al., 2003). Figure 1 shows fibrinogen and thrombin powder dried by freeze-drying. The solubility and turbidity for the freeze-dried fibrinogen are 51.2% and 21.5, and for thrombin are 14.35% and 10.1, respectively (Table 1). Figure 2 shows moisten film, oven dried film and freeze-dried film. It is found the thickness and swelling rate of the moisten
film is higher than the others. The moisten film is also more elastic. The water absorption of freeze-dried film is higher than the others and absorbed more water. The picture of freeze-dried film is more porous(Figure 2c). When it is used to arrest the bleeding it may absorbed more blood. In other words, it is more effective on haemostatic action.

Table 1. Solubility and turbidity of freeze-dried powders of fibrinogen and thrombin

Iterms	**Fibrinogen**	**Thrombin**
Solubility(%)1	51.2	14.35
Turbidity(T)2	21.5	10.1

1. Solubility(%)=(protein in supernatant)/total proteinx100.
2. Turbidity=transmittance at 540nm

Table 2.Thickness, water-absorption and swelling rate of haemostatic films

Iterms	Moisten film	Oven-dried film	Freeze-dried film
Thickness(mm)	2.62	1.72	2.29
Water-absorption(%)	6.13	27.14	180
Swelling rate(%)	21	1.16	-30

Water absorption(%)=((Wa-Wb)/Wb)x100 Wa=weight after soaking in water
Wb=weight before soaking
Swelling rate(%)=((Ta-Tb)/Tb)x100 Ta=thickness after soaking
Tb=thickness before soaking

Conclusions

This study is to use fibrinogen and thrombin separated from porcine blood to prepare haemostatic powder and film. The result of film thickness is different due to the methods of preparation. It was found water-absorption of freeze-dried film is higher than the others, and the swelling rate was found higher in moisten film

EFFECTS OF KID FEEDING WITH A DE-STONED OLIVE POMACE ON THE QUALITY OF RAW AND COOKED MEAT

Background

Olive oil by-products have been widely employed for animal feeding in many species (Sansoucy, 1985; Molina Alcaide and Nefzaoui, 1996). In Southern Italy, the semi-arid ecosystems hamper the availability of pastures and forages during the year, therefore, the possibility of using agricultural by-products may be quite interesting, both under a zootechnical and economic point of view, on the condition that the products used are of good quality and safe for animal feeding and welfare. The olive oil industry plays an important role in Southern Italy; furthermore, the exploitation of olive oil by-products is even more feasible in a region like Apulia, where olive oil is produced for about 12% of the total world output and small ruminant breeding is particularly practised. Previous reports carried out on lambs have shown that feeding olive cakes positively affects growth performances and meat quality (Lanza *et al.,* 2000; Zumbo *et al.*, 2001; Foti *et al.*, 2003). In this trial we investigated the use of a new type of by-product, i.e. a virgin olive pulp produced by the removal of stones from the olives (Amirante *et al.*, 2002), which has already provided satisfactory results in lamb feeding, as we have described elsewhere (Ragni *et al.*, 2003; Vicenti *et al.*, 2003).

Objectives

The aim of the study was to evaluate the effect of using a de-stoned olive pomace as a feed for kids' diet on meat colour and on the chemical composition, fatty acid profile and tenderness of raw and cooked meat.

Materials and methods

The experiment was carried out at the University farm located in Bari (Apulia, Southern Italy, 41 °N) on sixteen male Garganica kids, weaned at about 50 days of age, divided into 2 groups of 8 subjects each, homogeneous for age and body weight. Kids were fed *ad libitum* for 6 weeks on either a concentrate pelleted diet (control group) or on a diet containing 20% olive pomace (olive pomace group). Diets were planned in order to contain approximately the same amount of protein (16.5%), fat (5.0%) and crude fiber (10.5%). Kids were slaughtered following 12 hours fasting. After 24 hours of refrigeration at 4 °C, the Longissimus lumborum (Ll) muscle was dissected from the right half carcass and split into two pieces, one of which was used raw while the other was cooked in an electric ventilated oven at 180 °C until the internal temperature of 75 °C was reached in the core of the meat sample, recorded by a thermocouple (ASPA, 1996). Meat samples were weighed before and immediately after cooking to determine cooking loss percentages. Colour (L = Lightness; a = redness; b = yellowness) was evaluated only on raw samples using the Hunter Lab system (colourmeter Miniscan XE; D65/10° illuminant). Tenderness was assessed by the Warner Bratzler Shear device system on raw (cylindrical, half an inch of diameter) and cooked (rectangular, 1x1 cm section) meat cores using a universal test machine (Instron 5544). Peak force was expressed as kg/cm^2 and represents the cutting force required to shear perpendicularly to the direction of the fibres. Raw and cooked meat samples were analysed for chemical and fatty acid composition (ASPA, 1996). Lipids were extracted using a chloroform/methanol 2:1 v/v solution (Folch *et al.*, 1957). Fatty acids were methylated using a BF_3/methanol solution (12% v/v) and analysed by gas chromatography (Chromopack CP 9000) using a 60 m silicated glass column with a 0.25 mm internal diameter and 0.2 μm film thickness. The atherogenicity (AI) and thrombogenicity (TI) indexes (Ulbricht and Southgate, 1991) and the PCL/PCE (plasma cholesterol lowering/plasma cholesterol elevating) ratio (Reiser and Shorland, 1990) were also calculated.

Data were processed by analysis of variance using the GLM procedure of SAS (1999/2000). The model adopted took into consideration as main effects the diet and the cooking method and their interaction. Means were compared by Student's t test.

Results and discussion

Meat colour was not affected by the integration of the olive pomace in the diet (Figure 1). Previous studies have documented that olive cakes are rich in unsaturated fatty acids (Sansoucy, 1985), which in meat may increase its susceptibility to lipid oxidation, with consequences on colour, texture, flavour as well as its nutritional value (Ponnampalam *et al.*, 2002). For this reason, olive cake feeding has been accompanied with the administration of antioxidants such as vitamin E to stabilize meat lipid deterioration (Lanza *et al.*, 2000; Zumbo *et al.*, 2001).

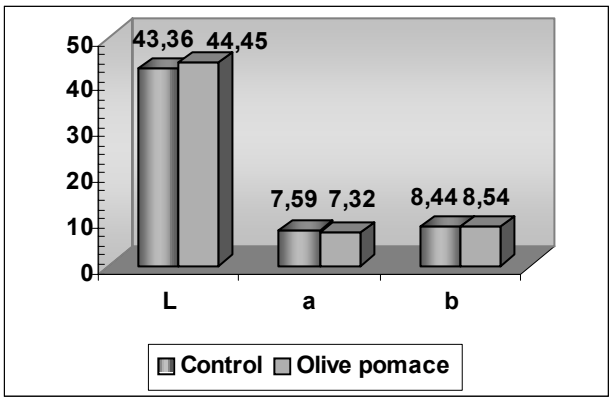

Figure 1. Meat colour of the *Longissimus lumborum* muscle in kids

In this study, similarly to what we (Vicenti *et al.*, 2003) and other Authors (Foti *et al.*, 2003) previously found in lambs, the values of meat colour were not changed by the integration of the olive pomace in the diet.

As for the chemical composition of meat (Table 1), no significant differences between diets were found for raw meat, whereas cooked samples of the olive pomace group displayed a greater moisture content (P<0.05) and significantly (P<0.01) less fat and N-free extract in comparison with cooked control samples. For both the diets administered, cooking determined a decrease of meat moisture in turn of a concentrating effect on fat (P<0.01) and protein (P<0.01) and, although only in the olive pomace group, also on ashes (P<0.01). The olive pomace diet resulted in a significantly (P<0.05) greater cooking loss (16.19%) in comparison with the control group (13.30%). The chemical composition of kid meat obtained in this study was comparable to that reported by Dhanda *et al.* (1999), who studied meat quality characteristics in different goat genotypes.

Table 1. Chemical composition of raw and cooked meat samples and cooking loss (%)

	Control			Olive pomace			Significance of main effects		SED
	Raw		Cooked	Raw		Cooked	Diet	Cooking	
N (samples)	8		8	8		8	32	32	*DF = 28*
Moisture	75.43	**	66.28^{B}	75.05	**	67.18a	ns	**	0.652
Protein	18.97	**	26.12	19.26	**	26.25	ns	**	0.481
Fat	3.29	**	5.20^{A}	3.55	**	4.54^{B}	ns	**	0.327
Ash	1.08	ns	1.12	1.01	**	1.15	ns	**	0.079
N-free extract	1.21	ns	1.27^{A}	1.13	ns	0.87^{B}	*	ns	0.289
									DF = 14
Cooking loss		13.30^{B}			16.19^{A}		*	/	2.227

Differences between diets within raw or cooked meat samples: A, B: P<0,01; a, b: P<0.05. Differences between raw and cooked samples within each diet and significance of main effects: **: P<0.01; *: P<0.05; ns = not significant.

Raw control meat samples showed significantly (P<0.01) more SFA and PUFA in comparison with the olive pomace group, whereas less (P<0.01) MUFA and UFA. In the corresponding cooked samples, the fatty acid class distribution was somewhat reversed. Cooked meat samples of the olive pomace group contained a greater amount of SFA (P<0.01) and a lower proportion of MUFA (P<0.05) as well as UFA (P<0.01) as compared to the control diet.

Within the polyunsaturated fatty acids present in meat, raw samples of the control group, showed a higher (P<0.01) amount of ω6 fatty acids with no difference in the ω3 fatty acid fraction, so that the ω6/ω3 ratio was comparable between the diets for both raw and cooked samples. The PUFA/SFA ratio was markedly better in raw control samples than in the olive pomace ones (P<0.05), while cooking cancelled this difference. However, other studies conducted on goats have reported higher PUFA/SFA values respect to those found by us in this study (Banskalieva *et al.*, 2000), although the differences may be ascribable to the diet, to the slaughtering age and to the goat breed.

With regards to the dietetic properties of meat (Table 3), the atherogenicity index did not differ among diets as far as raw meat samples are concerned, while cooking resulted in a significant increase of the AI in the olive pomace group with respect to the controls, both in the raw (0.62 vs 0.54; P<0.01) as well as cooked ones (0.62 vs 0.52; P<0.01). Within raw samples, the thrombogenicity index was significantly higher in the control group with respect to the olive pomace diet (1.32 vs 1.09, P<0.01), while in cooked samples the trend was completely reversed, with olive pomace samples displaying a thrombogenicity index value of 1.20 against 1.11 obtained for the control group (P<0.05). Moreover, a significant (P<0.01) reduction of the TI value was recorded in control samples after cooking, on the contrary of the olive pomace diet, where cooking markedly increased meat thrombogenicity index (P<0.01).

The control diet improved the PCL/PCE ratio in comparison with the olive pomace feeding treatment, at a level of P<0.05 for raw meat while at P<0.01 for cooked samples. In both feeding treatments the PCL/PCE ratio did not change following cooking.

Table 2. Fatty acid classes in raw and cooked meat samples (%)

	Control			Olive pomace			Significance of main effects		SED
	Raw		Cooked	Raw		Cooked	Diet	Cooking	
Samples (n.)	8		8	8		8	32	32	DF = 28

Differences between diets within raw or cooked meat samples: A, B: P<0,01; a, b: P<0.05. Differences between raw and cooked samples within each diet and significance of main effects: **: P<0.01; *: P<0.05.
ns = not significant.

Table 3. Atherogenicity (AI) and thrombogenicity (TI) indexes and PCL/PCE ratio in raw and cooked meat

	Control			Olive pomace			Significance of main effects		SED
	Raw		Cooked	Raw		Cooked	Diet	Cooking	
Samples (n.)	8		8	8		8	32	32	DF = 28
AI	0.55	ns	0.52B	0.54	**	0.62A	**	ns	0.033
TI	1.32A	**	1.11b	1.09B	**	1.20a	**	*	0.067
PCL/PCE	1.34a	ns	1.31A	1.24b	ns	1.19B	**	ns	0.081

Differences between diets within raw or cooked meat samples: A, B: P<0,01; a, b: P<0.05. Differences between raw and cooked samples within each diet and significance of main effects: **: P<0.01.
ns = not significant.

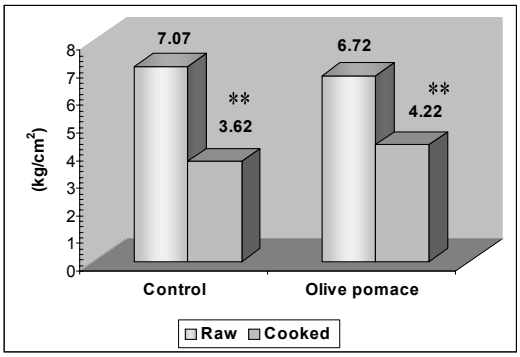

Figure 2. Peak force (kg/cm^2) in raw and cooked *Longissimus lumborum* meat samples
Differences between raw and cooked samples within each diet: ** p<0.01.

Meat tenderness did not seem to be influenced by the diet (Figure 2), neither for raw samples nor for cooked ones. However, cooking improved meat tenderisation, as showed by the significant (P<0.01) decrease of the peak force required to shear meat, both in the control group (7.07 vs 3.62) than in olive pomace meat samples (6.72 vs 4.22).

Conclusions

Based on the findings of this study, we may conclude that the integration of a de-stoned virgin olive pomace at 20% level in the diet of growing goat kids did not influence meat chemical composition, colour and texture. It did, however, provide controversial results in terms of meat dietetic properties, especially following cooking.

USING DENSITY TO MEASURE MYOFIBRILLAR DENATURATION

P. M. Dobbie, S. J. Falconer, N. J. Simmons, C. C. Daly
AgResearch, Ruakura Agricultural Research Centre, Private Bag 3123, Hamilton, New Zealand

Background

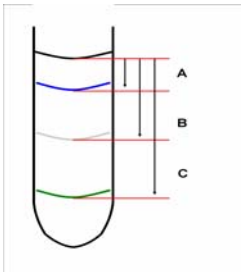
Excessive denaturation of myofibrillar proteins during the post mortem period can have important implications for meat quality. Denaturation of myofibrillar proteins by conditions of high temperature and low pH during, particularly during the pre-rigor period, causes exaggerated shrinkage of the myofibrillar lattice due to reduced electrostatic repulsions between the thick filaments (Offer, et al, 1983. Offer & Knight, 1988). Lattice shrinkage contributes to a paler meat colour, due to increased reflectance, and increased drip loss due to expulsion of fluid from the intra-lattice space. Although the implications of myofibrillar denaturation are well recognised in pork as the PSE condition (Offer & Knight, 1989), similar consequences are reported in beef (Simmons et al, 2000).
Current methods for quantifying myofibrillar denaturation have limitations: direct measurement of the myofibrillar lattice is complex and slow (Offer, et al 1989; Smulders et al., 1990.); reduced myofibrillar solubility is, in our experience, relatively insensitive inconsistent; and myosin ATPase activity is indirect and influenced by unrelated events such as proteolysis (Ouali, 1990). We describe here a simple method to measure denaturation through changes in myofibrillar density.

Objectives

Current methods for measuring directly the changes in myofibrils post mortem are slow and difficult. We set out to develop a simple method of measuring myofibrillar denaturation through changes in myofibrillar density.

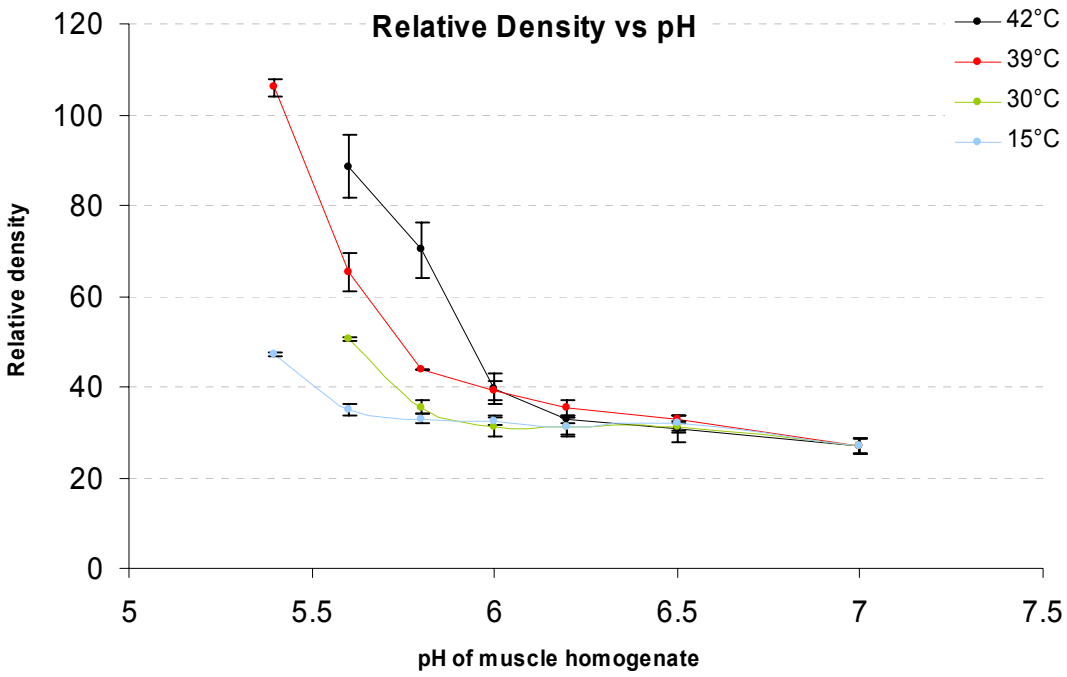
Materials and methods

Beef longissimus samples were held at constant pre-rigor temperatures of 15, 30, 39 and 42°C.
When the pH of the meat reached 7.0, 6.8, 6.5, 6.2, 6.0, 5.8, 5.6 and 5.4; 5 gram samples were taken. These 5 gram samples were Ultra-Turrax homogenised for 20 second at 13500rpm in 30ml of pH 5.3 homogenisation solution, (250mM.Sucrose; 10mM.KCl; 1mM.EDTA, pHed to 5.3 with KOH).
0.5 ml of the homogenate was centrifuged @ 6000g for 2 min and the supernatant discarded. The remaining pellet was washed with 1.0 ml of homogenisation solution, centrifuged and the resulting washed pellet re-suspended in 0.5 ml homogenisation solution.
15 µl of washed, re-suspended homogenate was then thoroughly mixed with 1.5 ml of a 30% Percoll:Sucrose:KCl:Triton (Ratio 29:23:47:1) gradient solution containing 10 µl of Amersham Biosciences density marker beads (mixture of blue (1.042 g/ml) and green (1.063 g/ml)) in the same tube. This mixture was centrifuged at 18,000g for 30 min.
The tube was then carefully removed from the centrifuge and distance from the bottom of the meniscus to "A" Blue marker bead, "B" myofibrils and "C" Green marker bead layers was measured.



Results were expressed as a Ratio of $\frac{B-A \times 100}{C-A}$

Results and discussion



Increasing the pH of the Percoll gradient decreased the density of the myofibrils. A higher pH increases the electrostatic charge on the filaments and, consequently, the lattice spacing (Offer & Knight). The measured myofibrillar density therefore probably reflects the extent to which denaturation events has modified the amount of charge on the myofibrillar filaments.

Varying denaturing conditions were produced by maintaining beef muscle samples in different constant temperatures during the pre-rigor temperature. Because the rate of glycolysis, and hence pH decline, is temperature-dependent, the changes in myofibrillar density during the pre-rigor period were measured at equivalent pH values. The results clearly demonstrate that denaturation depends on the meat pH reaching values below pH 6. Furthermore, a very extreme temperature dependency was evident: although the density at ultimate pH in the 30C samples was significantly greater (?) than the 15C samples, a further 9C increased produced a very dramatic increase in density.[This next sentence assumes that the density at pH 6 is significantly greater at 39 than 42 – exclude otherwise: The significantly greater density at 39C compared with 42C when measured at pH 6 can probably be attributed to the slower rate of pH decline at the lower temperature, thereby allowing more time for denaturation to occur event though the kinetics will be slower at the lower temperature.]

Conclusions

A simple methodology is described to measure changes in myofibrillar density that can be attributed to denaturation events. The procedure can be carried out at any stage in the pre-rigor period, is quantitative and is not affected by proteolytic events.

SHIFTING SENSORY THRESHOLDS OF PRE-COOKED ENTIRE MALE MEAT USING THE MARINATING TECHNOLOGY.

Egelandsdal, B. [1, 2], Løvlund, E.[1], Choinsky, J.[3] , Koller, A.[4] and Mielnik, M.[2]

[1]Institute of Chemistry, Biotechnology and Food Science, Agricultural University of Norway; P.O. Box 5036, N-1432-Ås, Norway; [2]MATFORSK, Oslovn. 1, N-1430-Ås, Norway; [3]Gilde Hed-Opp, 2360 Rudshøgda, Norway; Gilde Norge BA, P.O. Box 397, Økern, N-0513 Oslo, Norway.

Background

The government of Norway has decided that from year 2009 castration of male pigs will no longer be accepted. Entire males are associated with an unpleasant taste and smell largely due to the presence of skatole and androstenone. The political decision in Norway has urged a need for updating the knowledge in selected areas aiming at preventing the occurrence of boar tainted meat in the marked. Such areas are the development of new, robust classification methods at the slaughterhouse, but also achieving more knowledge on processing possibilities has been encouraged.
The most common approach for processing of entire male meat is to comminute the meat and then « dilute » it to an undetectable concentration of androstenone and skatole. This works well for comminuted meat products like fresh and fermented sausages (Bonneau and Squires, 2000). However, it is believed that a substantial fraction of the entire males will be downgraded if the castration ban becomes effective. There is therefore be a need for recipes that can work well also for intact muscles. Needle injection is the most efficient technique for flavour adjustment of intact meat. It has, among other, been suggested as an efficient technology for modifying pre rigor off-flavour (Sindelar et al., 2003) plus characteristic, strong lamb flavour (Young and Ho, 1998).

Objectives

The work reported here was conducted in order to identify marinades that could be efficient with respect to reducing the sensation of boar taint.

Materials and methods

Materials: Neck chops were collected from a commercial slaughterhouse. Only samples having skatole contents > 0.21 ppm in the neck fat were selected. No attention to breed was made. 12 entire males and 4 castrates were selected one-day post-mortem. Small samples were removed for pH, fat content and androstenone determination. Thereafter the necks were vacuum-packed and frozen at -40°C. A few weeks later the samples were thawed, injected, heated and later served for sensory analysis.
Methods:
Marinades for injection: All marinades were laboratory-made based on chosen ingredients. Ingredients are given in Table 1. Water is not listed (adds up to 1000 gram). Other ingredients (see Table 1) were used in smaller quantities and appeared post-sensory testing as not relevant, and brand names were not given. Four marinades were selected among 18 different marinades by a subjective sensory panel for further evaluation by objective sensory profiling (Løvlund, 2002). The criterion of selection was that the marinades should provide tasty meat as well as reduce the sensation of boar taint. Only three of the marinades revealed interesting properties with respect to affecting boar taint, and these marinades are described in Table 1.
Analysis of pH, fat, androstenone and skatole contents: pH was measured with a Beckman ϕ31 pH meter. The fat content was measured on neck meat slices using low field Nuclear Magnetic Resonance (NMR) measurements on homogenised and dried meat (Pedersen et al., 2001). Skatole was determined using an extraction method where skatole is extracted from fat in tris-acetone and then reacted with a colour reagent before spectroscopic quantification (Mortensen and Sørensen, 1984). Androstenone was determined using a fat extraction method followed by the use of a commercial immunoassay kit (Riedel deHaen, Seelze, Germany).
Preparation of samples for sensory analysis: The meat samples were injected with 20% (w/w) increase. Thereafter the meat samples were packed individually in cook-shrink bag and chilled overnight before being

cooked to an internal temperature of 71°C. The samples were chill-stored for 10 days and then re-heated and served to a trained sensory panel. The profile used was the one defined by Dijksterhuis et al. (2000) where it is reported that androstenone relates mostly to urine, and skatole relates mostly to manure. Their profile was modified to include characteristic flavours describing the ingredients of the marinades. The panellists used intensity scores from 1-9; 9 meaning highest intensity score.

Statistics:

The data were analysed using Minitab version 14 (www.minitab.com). The routines used for analysis of variance were: General linear method for modelling and Tukey's test for comparisons.

Table 1. Important ingredients in the marinades injected in the different entire male neck muscles.

Ingredient (in grams pr kg marinade)	Marinade 1	Marinade 2	Marinade 3
Salt (NaCl)	40.0	59.4	52.8
Sodium nitrite	0.24	0.36	0.32
Ascorbate			1.6
Phosphate (E451, E450)(as P_2O_5)	14.3	18.8	16.9
Soy sauce –reduced salt (Kikkoman Corp.)	250.0	-	-
Dextrose	12.8	16.9	17.5
Fructose	3.7	3.7	3.3
Liquid smoke (Wright's, USA)	3.7	9.9	-
Garlic powder (E.H.Woree, Germany)	-	-	2.2
Oregano, oleoresin (Kalsec, USA)	-	-	0.5
Paprika, extract (Chr.Hansen, Spania)	-	1.2	-
Others	Lemon pepper	-	Tomato, onion and bacon flavour

Results and discussion

The 16 animals used were characterised as shown in Table 2. The table shows that a wide range of androstenone (A) and skatole (S) values was obtained. The correlation between A and S was low (r=0.34). To most consumers sensory threshold values for S and A of entire males would be above 0.2-0.25 mg/kg and 0.5-1.0 mg/kg, respectively (Bonneau and Squires, 2000).

Table 2. Characteristics of the entire males and castrates used.

Samples (no)	Weight (kg)	pH	Fat range (%)	Androstenone (mg/kg)	Skatole (mg/kg)
Entire males (12)	70.6-186.1	5.64-6.22	5.0-12.4	0.8 - 4.0	0.23-0.68
Castrates (4)	72.1- 86.2	5.76-6.15	13.3-18.9	0.08-0.10	0.03-0.06

The manure taste related most strongly and significantly to skatole while the urine taste related most strongly and significantly to androstenone. This agrees with previous investigations (Dijksterhuis et al., 2000). The taste and smell attributes of manure or urine were correlated (r > 0.89), and only the taste attributes were therefore chosen for presentation here.

Figure 1 shows the taste attributes with the larger standard deviations; i.e. for those taste attributes the panellists used the intensity scale to a larger extent than for other attributes.

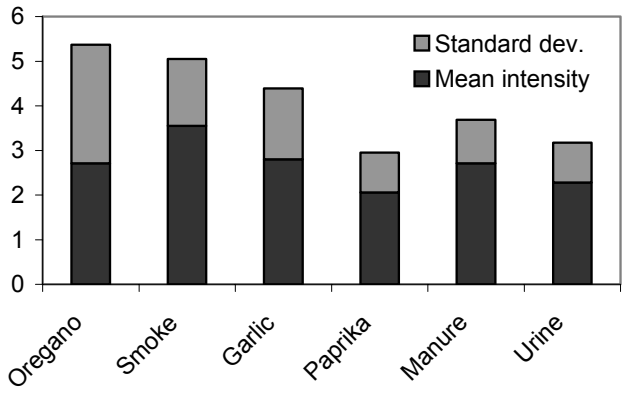

Figure 1. Mean intensity and standard deviation of different important sensory taste attributes for the 16 neck chops used (4 marinades tested).

Table 3. The intensity scores for manure and smoke taste for the 16 neck chops.

	Taste attribute	Castrates	S: 0.21-0.3 ppm	S: 0.3- 0.4 ppm	S: 0.4 -0.68 ppm
Marinade 1	**Smoke** **Manure**	**2.8** **2.1**	**2.6** **2.4**	**3.0** **2.4**	**2.6** **2.9**
Marinade 2	**Smoke** **Manure**	**6.0** **1.8**	**6.1** **1.8**	**6.0** **2.0**	**5.5** **2.3**

Marinades 1 and 2 were good at reducing manure taste. There was a significant ($p < 0.05$), and negative correlation between smoke taste and manure taste; i.e. the presence of liquid smoke appeared to be important with respect to reducing the taste of manure. Marinade 2 was significantly better ($p = 0.02$) at reducing the taste of manure than was marinade 1. Paprika also tended to reduce taste of manure but appeared much less successful compared to liquid smoke (results not shown). There was no significant difference between each skatole group. However, for marinade 1 the highest skatole group (S = 0.4-0.68 ppm) tended ($p = 0.06$) to have a higher taste of manure compared to the castrates. It was observed (not shown) that even for the castrates the panellists never rated these samples with intensity score exactly equal to 1.0 for taste of manure. The taste attribute manure therefore appeared somewhat difficult to exclude for all samples even for castrates.

The tastes of oregano, smoke and garlic were clearly detected, when these ingredients were added to marinades.

Marinade 3 gave the lowest mean intensity for taste of urine. Table 4 shows that the mean sensation of urine was reduced for marinade 3 compared to marinade 1 ($p = 0.008$). It was not possible to identify one single ingredient in marinade 3 that related significantly to androstenone level. The castrates had significantly lower taste of urine than the group that contained samples between 1-2 ppm of androstenone ($p < 0.03$). For the urine taste attribute the panellists gave intensity scores close to 1.0 for castrates, in particular for marinade 3.

Table 4. The intensity scores for oregano and urine taste for the 16 neck chops.

	Taste attribute	Castrates	A: 0.5 - 1 ppm	A: 1-2 ppm	A: 2-4 ppm
Marinade 1	**Oregano** **Urine**	**1.0** **1.6**	**1.3** **2.2**	**1.1** **2.5**	**1.3** **3.2**
Marinade 3	**Oregano** **Urine**	**6.3** **1.2**	**7.6** **1.7**	**7.7** **1.9**	**7.5** **2.3**

Conclusions

The sensory sensation of boar taint can be reduced by the addition of specific flavour components. Taste (or odour) of manure can be substantially reduced/eliminated by the use of liquid smoke. A marinade dominated by oregano and garlic flavour can reduce the sensation of urine taste.

PERFORMANCES AND MEAT QALITY OF LEPRINO VITERBESE BREED RABBIT, BRED WITH THREE DIFFERENT HOUSING SYSTEM.

Failla, S.[1], Contò M. [1], Ballico S. [1], Concetti S., Negretti P. [2]

1. Meat Department, Istituto Sperimentale per la Zootecnia. Via Salaria 31, 00016 Monterotondo (Roma), Italy.
2. Istituto di Zootecnia, Universita della Tuscia via de Lellis, 01100 Viterbo, Italy

Background

Rabbit meat consumption is important in Italy, Spain and France and in these Country different breeding systems and diets were studied, besides the increased interest in animal welfare have spurred the study of less intensive rearing systems (Dalle Zotte, 2002).
Many investigations have been carried out to study the effects of alternative housing systems on performances, meat quality and welfare of rabbit, but the results have often in conflict, (Di Lella et al. 1999, Dal Bosco et al. 2002); besides some hybrids don't adapt to extensive system, while the Leprino Viterbese has shown good performances. The Leprino Viterbese is a hybrid obtained crossing meat breeds (70 % New Zealand White; 10% Belgian Hare; 10% local breed; 5% English Lup) and Viterbo local breed. Its name derives from particular colour of fur and morphological characters that remember hare.
This hybrid is peculiar for its rusticity that allows it to be raised in extensive conditions and for the image of healthiness transmitted to the consumer by its expect.

Objectives

The aim of this work is to investigate the effects on the meat quality of three housing systems and compare the performances of Leprino Viterbese with industrial hybrid bred in intensive system.

Materials and methods

The experiment was carried out on 68 male rabbits, 51 of Leprino Viterbese and 17 of industrial hybrid, intensively reared in cages (Hi). The Leprino Viterbese animals were divided in three housing type: 17 open air (Va), 17 on the turf with mobile cages(Vt) and 17 intensively reared in cages (Vi).
The Leprino Viterbese animals, after weaning, were randomly assigned to the three experimental groups and fed the same growth food.
The industrial hybrids (Hi) were reared with the same food given to Leprino Viterbese rabbits, and the experimental animals were chosen randomly in an industrial farm which bred, in the same time and intensively, the Vi rabbits.
The animals were slaughtered at the same live weight, reaching in the average 2480 g of live weight at 89 days of age.
The carcasses were aged for 24 hours at 3°C, then they were weighed without liver and dissected to separate and to weigh the *longissimus thoracis et lumborum* muscle (LD), the thigh, the kidney fat and shoulder fat.
The thighs were dissected in order to estimate percentages of lean meat, bone and fat. On thigh the s*emitendinosus* muscle weight and length and femur length were determined.
To perform the physical and chemical analysis, both LD were divided in five samples for water holding capacity (WHC), shear force (WBS) on raw and cooked meat, colour and chemical analysis.
WHC was performed using the Grau and Hamm method (Hamm 1986).
Shear force was measured on raw and cooked meat (in water bath at 75°C for 30'), by a Warner Bratzler device mounted on Instron 1011, on 3 cores for each animal of square section 1x1 cm (Chrystall et al. 1994).
Colour coordinates were measured at four points on the surface of muscle split in horizontal. After exposure to oxygen for 1 hour, lightness (L*), redness (a*), yellowness (b*) were determinate with CIEL*a*b* System and from the colour coordinate, hue angle (H = arctang b*/a*) and chrome ($C=(a^{*2}+b^{*2})^{1/2}$) were calculated according to Cassens *et al. (*1995), using D65 illuminant with spectrophotometer Minolta CM-2600d. In the same time visual reflectance spectra (R%) between 360-740 nm (by steps of 10 nm) were measured, in this paper only the points with significantly differences among groups were referred.
The analysis of variance with GLM procedure of statistical package of SAS using a monofactorial model (housing types) was performed. The analysis included also contrast test for differences between genotypes

within the same housing type (intensive breeding, Vi *versus* Hi) and between extensive and intensive breeding (Va and Vt *versus* Vi and Hi). Finally correlation between WHC, WBS and visual reflectance spectrum was performed.

Results and discussion

Carcass weight was similar for the groups (1406.4 g in the average), because the animals have been slaughtered at fixed live weight (2500 g about). The groups, fed with same diet, reached the prefixed weight at similar age (89 days in average). Also if carcass had similar weight subcutaneous and internal sites showed different fat deposition (table 1), in fact industrial hybrid (Hi) had low fat in perirenal deposition (9.14 g), compared to the others, particularly to Va group, that showed the highest value (16.01 g), in addition to the housing effect, the two genotypes (Leprino Viterbese and industrial hybrid) had different perirenal fat. The Leprino Viterbese is more precocious than the other and therefore it tends to fatten more, while the rabbits reared extensively didn't show slower maturity as reported in in Margarit et al. (1999), when comparing classic cages with mobile cages on grass. The animals bred on open air (Va) showed a highest development on *longissimus thoracis et lomborum* weight (86.84 g), differing significantly only by Vt group (77.89 g), while the rabbits bred in intensive way had intermediate values and they didn't differ significantly from the two extensive groups. The LD weight, however was lower than that reported in Pla et al. (1996) for different genotypes. The greater body development of the group Va was confirmed also by the thigh weight, but differed significantly only by Hi (193.9 g vs 185.5 g) and was similar to the other Leprino Viterbese groups. Difference between genotypes within the same housing type was noticed, but with low significance (P=0.09). The length of femur showed the housing effect, in fact the animals bred in intensive way have developed less leg bone (9.16 cm vs 8.88cm of Va and Vt groups vs Vi and Hi), mainly due to the less physical activity.
The dissection of the thigh didn't show high differences for meat and bone percentage, but rabbits intensively bred were significantly leaner compared to the others(2.27% in average between Vi and Hi, versus 3.01% in average between Va and Vt of total fat). The general carcass fattiness of the rabbit extensively bred probably depends of genotypes and climatic influence too (Dalle Zotte, 2002).
Meat quality (table2) was influenced particularly by housing types; in fact only the water holding capacity showed little difference (P=0.07%) between the genotypes bred in intensive way.
Difference was relevant in WHC between Hi group and the others bred in an extensive way (19.68% vs 14.26% average between Va and Vt), the value of Vi was intermediate. Shear force on raw and cooked meat showed similar trend among groups. Generally the LD of rabbit bred in intensive system were significantly more tender (1.66 kg in average between the two groups in raw meat and 1.65 kg in cooked one), while Vt group was tougher than others (2.13 kg and 2.25 kg for raw and cooked meat respectively).
Animals of Hi group showed highest lightness (Dal Bosco et al., 2002; Hernàndez et al., 1998), significantly different by Vt group (56.79 vs 54.68) probably, latter group integrated the diet with blades of grass and the meat became less light and more red also if had the lower value of Hue than other groups.
The visual reflectance spectra had different trends among groups near the 470 nm and 560 nm, isobestic point for deoximyoglobin and oximyoglobin, end in Soret pick (420nm) as reported in figure 1 and in table2.

At 420 nm the curves showed different trends for intensive system compared to extensive system, while in 470nm and 560 nm significantly differences were found only between Vt and Hi.
Limited correlation was found between WHC and different data of visual spectrum reflectance (Figure 2), while the correlation coefficients were significant in all considered points after 450 nm between WBS on cooked meat and reflectance value at different wavelength, reaching maxima values after 610nm.
Also for the rabbit the spectrum of reflectance can discriminate the groups and indicate the difference in physical quality of meat.

Conclusions

The housing system influences the carcass and meat quality. Particularly the meat of industrial hybrid is different compared to Leprino Viterbese bred on the turf with mobile cages, latter therefore shows distinct characteristics of rusticity required by consumer that consider this characteristics correlated with healthiness and animal welfare.

LEVEL OF GAMMA RADIATION IN SOME MEAT PRODUCTS MARKETED IN UPPER EGYPT

Fathi, Sh.[1] , Ismail, M.[2] , Nassar, A[1]. and Afaf Mahmoud[2]

[1] Departement of Food Hygiene Fac. of Vet. Medicine, Assiut University, Egypt
[2] Departement of Medicine, Fac. of Vet. Medicine, South Valley University, Egypt

Background

Gamma radiation is electromagnetic radiation similar to light but of much higher energy. The wavelength of gamma rays is much shorter than that of visible light. Gamma rays are emitted inradioactive decay along with alpha or beta radiations (FAO, 1994). Radioactive contamination arises from both natural and artificial sources, the latter having assumed greater importance since the Second War World (Gracey *et al*., 1999). Radionuclides are readily transferred to the human population through domestic grazing meat producing animals, which are effective collectors of contamination from various vegetative sources (Gilbert *et al*., 1989, McGee *et al*., 1993), from the atmosphere (MAFF, 1994), from soil (Andersson *et al*., 2001) or from nuclear accident (Jones, 1989 and Prohl *et al*., 1989). After Chernobyl nuclear accident, the contamination of beef by radionuclides was found up to 120 Bq/Kg in 1987 (Hrusovsky *et al*., 1989). Also, it was found that the radionuclides in all examined imported lamb meat and 17 % of roast beef samples were 82 and 4 Bq/Kg,respectively (Marouf *et al*. 1991).

Objectives

The purpose of this study was to determine the level of gamma rays in some selected imported as well as locally produced meat products marketed in Upper Egypt.

Materials and methods

A total of 105 locally produced and imported meat products were collected to detect the levels of gamma radiation. Preparation and digestion of samples were applied according to the technique recommended by Gajan and Larry (1972). All prepared samples were first screened with a Geiger Muller apparatus for primitive evaluation of gamma radiation. Scaler ratemeter type 6-90 was used for the measurement of the levels of gamma radiation in each sample as count per minute (cpm). At the same time, the radiation of the background (air) was measured and subtracted from the sample reading, where the excess was converted to Becquerel unit per kilogram (Bq/Kg) (WHO, 1994).

Results and discussion

Radionuclides, which undergo significant gastrointestinal absorption by man and animals, are those of greatest concern in food chain transference. These radioactive contaminants are also readily transferred to animal products, such as milk and meat, which are then consumed by man (FAO, 1994). It was observed that the differences between the highest levels of gamma radiation in the background were lower than the maximum permissible limits recommended by Council Regulation ECC No. 1707/86. These limits were, in terms of maximum permitted levels of caesium-134 and caesium-137, 370 Bq/Kg for milk and infant feeds, and 600 Bq/Kg for other food (MAFF, 1994). It was observed that the imported canned luncheon meat from Palestine was had the most radiation (299.50 Bq/Kg), the canned beef imported from France (238.67 Bq/Kg) being the second. Lower results were recorded by many investigators, such as Hrusovsty *et al*. (1989) who found caesium radionuclides in canned meat products were up to 70 Bq/Kg, Battiston *et al*. (1991) who reported that the concentration of total caesium in muscle reached a maximum value of 156 Bq/Kg, as well as Marouf *et al*. (1991) who recorded that all imported lamb meat samples were contaminated with caesium-137 at the level of 82 Bq/Kg. The canned luncheon imported from Palestine had gamma radiation levels close to the minimum permissible limits (300 Bq/Kg) reported by FAO (1994)

Conclusions

Although most of the locally produced meat products in Egypt are manufactured from imported meat, the examined imported canned beef and canned luncheon had higher gamma radiation levels in comparison to those measured in the locally produced canned beef and canned frankfurters. Such observations may be attributed to different sources of contamination by gamma radiation, or other isotopes emitting gamma.

EFFECT OF CURRENT, VOLTAGE, FREQUENCY AND CARCASS TEMPERATURE ON IMPEDANCE MEASUREMENTS OF LAMB CARCASSES

[1]Forsyth, S., [1]Cosgrave, P., [1]Allen, P. and [2]Butler, F.

[1]Teagasc, The National Food Centre, Ashtown, Dublin 15, Ireland and [2]Department of Biosystems Engineering, University College Dublin, Earlsfort Terrace, Dublin 2, Ireland.

Background

Over recent years the livestock industry has changed from being production oriented to being consumer driven. Because people demand leaner meat, it is important to determine body composition in a non-invasive, objective and practical manner (Marchello *et al*., 1992). Bioelectrical impedance measures the resistance and reactance of a constant current as it passes through a biological mass and is related to the proportions of fat and lean. This arises because muscle and fat have different electrical properties (Marchello *et al*., 1999). Lean tissue is a highly conductive substance composed mostly of water containing electrolytes (~ 75%) (Swatland, 1984). Fat is essentially anhydrous and serves as an insulator, exhibiting impedance to the flow of an applied electrical current (Berg *et al.*, 1998). By measuring the resistance to an alternating current passed through the tissues, between electrodes separated by a known distance, the proportions of fat and lean can be estimated. The source electrodes introduce an alternating current at the base of the measuring object. The detecting electrodes measure the voltage drop due to the circuit at anatomical reference points (Bohuslavek et al., 2000). The most common BIA method involves two pairs of electrodes. The positive and negative electrodes of each pair are positioned a short distance from each other. A larger distance separates the two pairs. This four electrode or tetrapolar measurement is essential to eliminate electrode and field distribution problems associated with two electrode measurements (Bohuslavek *et al.,* 2000). Because BIA is safe, inexpensive, portable, rapid, easy to perform, and requires minimal operator training (Kushner, 1992), it would be likely to find favour in the industry. Early work on the application of BIA to measuring body or carcass composition used simple equipment developed for use on humans and operating at fixed current, voltage and frequency. Tong et al. (2001) showed that for pork carcasses impedance readings were dependent on frequency and temperature, but not on current and voltage. Furthermore, they showed that the prediction of carcass composition was improved when impedance measurements were taken at a number of frequencies. In designing a practical device for use on a lamb slaughterline it is important to choose the best combination of current, voltage and frequency and to be aware of the effect of temperature on impedance.

Objectives

The objective was to determine the effect of current, voltage, frequency and carcass temperature on BIA readings of lamb carcasses.

Materials and methods

Data on 49 lamb carcasses of varying fatness were used in this study. A laptop computer equipped with an Agilent 82357A USB/GPIB interface adapter was used to control a 4-electrode Hewlett Packard 4284A Precision LCR Meter (Agilent Technologies, www.agilent.com) to measure electrical impedance of hot carcasses, at 4 levels of alternating current (0.4mA to 1.4mA in steps of 0.3mA), 4 levels of voltage (100mV to 550mV in steps of 150mV), and 15 frequencies (8kHz to 200kHz at irregular intervals). The cranial transmitting electrode was placed proximal to the fifth cervical vertebrae. The caudal transmitting electrode was inserted into the *gastrocnemius* muscle, proximal to the Achilles tendon. The two receiving electrodes were placed 5cm cranial and 5cm caudal respectively to the transmitting electrode. Hot carcass measurements of Rs and Xc were recorded after carcass dressing, and impedance was calculated. Using the same apparatus and terminal placement, the electrical impedance of 15 carcasses was measured at deep muscle temperatures of 39, 35, 30, 25, 20, 15 and 0°C.

Results and discussion

Impedance is a measure of how current is slowed or stopped as it passes through a material. In biological systems, electrical conduction is related to water and ionic distribution in the conductor. Because fat-free mass (FFM), which includes the protein matrix of adipose tissue, contains virtually all of the water and conducting electrolytes in the body, conductivity is far greater in FFM than fat mass (Pethig, 1979). The hypothetical relationship between impedance and electrical volume was proposed by Nyboer et al. (1943) who first demonstrated that electrically determined biological volumes are inversely related to impedance (Z), resistance (R), and reactance (Xc) where,

$$Z = \sqrt{Rs^2 + Xc^2} \ .$$

Therefore, from the Rs and Xc readings from the LCR impedance (Z) was calculated. The effect of current and voltage on impedance can be seen in Figures 1 and 2. The straight lines clearly indicate that bioelectrical impedance did not change significantly over 4 alternating currents (Fig. 1) or 4 voltage levels (Fig. 2). Frequency did, however, affect impedance. As frequency increased from 8 to 200kHz, impedance significantly decreased (Fig. 3).

As carcasses were chilled from 39 to 0°C, impedance increased significantly from 200 to 380Ω (Fig. 4). This confirms that bioelectrical impedance measurements are temperature dependent. However, if impedance measurements were taken at the same point on the line, this temperature effect would be unimportant, as carcasses would be within 2°C of each other.

All these results, while preliminary, are in strong agreement with those found by Tong et al., (2001) who carried out similar work using pig carcasses.

Conclusions

These results suggest that the use of any current or voltage level in the ranges examined in this study would be appropriate to measure bioelectrical impedance in lamb carcasses. However, as frequency increased from 0 to 200kHz, impedance decreased, suggesting that there may be an optimum frequency for measuring impedance in lamb carcasses. Finally, bioelectrical impedance measurements are temperature dependent, but the effect is probably small enough to be unimportant for measuring carcasses at a fixed point on the kill line. Further work includes the investigation into the use of BIA to accurately predict saleable yield and fat-free-lean weight through carcass dissection and compositional analysis.

THE AUTOFOM AND CVT-2 FOR PREDICTING SALABLE MEAT YIELD IN PORK CARCASSES

Fortin, A., Tong, A.K.W. and Robertson, W.M.
Agriculture and Agri-Food Canada , Lacombe Research Centre, Lacombe, Alberta, Canada, T4L 1W1

Background

In Canada, the introduction in 1968 of a value-based system involving carcass weight and a ruler measurement of backfat thickness for grading pork carcasses and further refinements during the 80's (reflectance probe grading and the introduction of muscle thickness) have had a dramatic impact on the Canadian pork industry (Fortin, 1989). With these light reflectance probes (measurements of fat thickness lateral to the mid-line and the addition of muscle thickness into the prediction equations) the level of accuracy and precision improved (RMSE: from 2.6 % for the ruler to 2.1-2.2 % for the reflectance probes). Concurrent to the Canadian industry efforts to improve current grading technologies and implement new ones (Fortin et al., 2003), similar efforts were undertaken in Europe and the US. From these efforts, a new generation of grading instruments were developed. Ultrasound instruments such as the AutoFom (SFK Technology A/S, Herlev, DK) and CVT-2 (AUS, Ithaca, NY, US) are now commercially available for grading pork carcasses.

Objectives

The objective of this study was to evaluate under Canadian conditions the next generation of grading instruments which have become commercially available since the introduction in Canada in 1986 of the light reflectance probes, namely: the AutoFom (SFK Technology A/S, Herlev, DK) and the CVT-2 (AUS, Ithaca, NY, US). In addition, the reflectance probe HGP2 (Hennessey Grading Systems Ltd, Auckland, NZ) was utilized as the baseline instrument.

Materials and methods

Traditionally, grading instruments have been evaluated on the basis of the accuracy and precision of their respective equation to predict lean yield (lean and yield being defined in numerous ways). Calibration of a given instrument was done on a sample of carcasses deemed representative of the population onto which the prediction equation was going to be applied. Statistical parameters such as RMSE (Root Mean Square Error) and R^2 were used to assess these equations. Based on these parameters, that instrument was then certified for use in a national grading system if it met certain standard performance criteria. The over-riding assumption being that these equations generated from a sample of carcasses deemed representative of the population would perform as well when applied to the general population of pigs. However, in most cases, that assumption was never verified.

Hence, in this study, two independent sets of carcasses were used to evaluate the ultrasound instruments: one data set (calibration data set) to calibrate the instruments and a second data set (validation data set) to validate the fore-mentioned calibration.

The calibration data set and the validation data set consisted of 194 and 72 carcasses, respectively (Table1). Sampling was stratified by fat thickness. The boundaries for the middle category were defined as the Canadian population mean ± 0.50 standard deviation.

Two ultrasound instruments (CVT-2 System [3.5 MHz, 125 mm scanning guide], AUS, Ithaca, NY, US; and AutoFom, SFK Technology A/S, Herlev, DK) were evaluated. The reflectance probe HGP2 (Hennessey Grading Systems Ltd, Auckland, NZ) was used as the baseline instrument. For each instrument, the same operator was used for the entire study. For the CVT-2 and AutoFom, the operators were trained by the respective suppliers. The following carcass measurements were recorded: **AutoFom**: scan of the carcass as per supplier's instructions, **CVT-2**: fat thickness (average of five measurements) and muscle (*m. longissimus*) depth (average of five measurements) measured over a distance of 125 mm near the last rib, 5

cm lateral to the exposed surface of the mid-line. The muscle depth was defined as the distance between the fat-muscle interface to ribs. **HGP2**: fat thickness and muscle (*m. longissimus*) depth, 7 cm lateral to the exposed surface of the mid-line between the 3rd and 4th last ribs.

The day following slaughter, the left side of the carcasses was dissected as per the cutting procedure described by Fortin et al. (2003). Salable meat yield was defined as: 100*{(lean in picnic, butt, loin, tenderloin and ham) + belly (skinless, trimmed) + side ribs} / weight of cold side.

For the calibration phase, the models for predicting salable meat yield for the HGP2 and CVT-2 were obtained by Multiple Linear Regression analysis (Statistical Analysis System version 8.2, SAS Institute, Cary, NC, USA). The AutoFom calibration model was generated by Partial Least Squares analysis in which variables selection was done using a cross-validation procedure with 20 groups of 9-10 carcasses. The software program UNSCRAMBLER 7.6 (Camo, Trondheim, Norway), was used to generate the AutoFom calibration model.

For the validation of the calibration models, the following parameters were examined: 1) systematic bias defined as $Bias_s = 3(\lceil - Y_m) / n$ where $\lceil$ is salable meat yield predicted by the calibration model, Y_m the salable meat yield determined by the actual cutout of the side and n the number of carcasses, 2) proportional bias defined as $Bias_p = 1- b$ where b is the slope of the linear regression of predicted salable meat yield ($\lceil$) on measured salable meat yield (Y_m) [$\lceil = a + bY_m$], 3) the Mean Squared Prediction Error ($MSPE_V = 3(\lceil - Y_m)^2 / n$) and 4) and the Standard Error of Prediction ($SEP_V = \{3(\lceil - Y_m)^2 / (n–1)\}^{½}$).

Results and discussion

In Table 2 are the measurements obtained from the various grading instruments under investigation. For the AutoFom, however, the values of the fat and muscle measurements derived from the processed scan images and then used to generate the calibration models were not provided by the manufacturer. For the HGP2 and CVT-2, the following calibration model for predicting salable meat yield was selected:

Salable Meat Yield = a+ b*(fat thickness) + c*(muscle depth).

A recent Canadian study (Pomar et al., 2001) also showed that a linear calibration model for predicting yield was adequate. The calibration model for the AutoFom, provided by SFK Technology A/S, DK, is comprised of 36 variables (27 fat thickness and 9 muscle depth measurements).

The calibration parameters R^2 and RMSE assigned to each prediction model associated with the HGP2, CVT-2 and AutoFom are shown in Table 3. The CVT-2 prediction model compared favourably with the HGP2; RMSE: 1.57 % vs. 1.56 %, respectively, but was slightly better than the equation proposed for AutoFom; RMSE: 1.68 %. For each of the three instruments, all measurements retained for inclusion into their respective models were recorded over the loin muscle region: HGP2, CVT-2 and AutoFom. Consequently, it might then be argued that the high correlation between fat thickness measurements over the loin region or between muscle depth measurements over the loin region completely negated the advantage of using several variables, albeit statistically significant, over and above one fat thickness measurement and one muscle depth measurement over the loin region.

In Table 4, the validation parameters for the prediction of salable meat yield for the HGP2, CVT-2 and AutoFom are presented. For all instruments, the $bias_p$ was significantly different from zero ($P<0.01$). The AutoFom exhibited a slightly more pronounced $bias_p$ (0.39) compared to the CVT-2 (0.21); the HGP2 was intermediate (0.30). Figure 1 illustrates the respective relationship between Predicted salable meat yield and measured salable meat yield. With respect to a perfect theoretical relationship (solid line) of "Predicted salable meat yield vs Measured salable meat yield" ($Y = a + bX$ where $a = 0$, $b = 1$, $bias_p = 0$, and $R^2 = 1$) the fitted relationship (broken line) attests to an overestimation of the predicted salable meat yield for low measured salable meat yields (fat carcasses) and to an underestimation of the predicted salable meat yield for high measured salable meat yields (lean carcasses). Although a proportional bias was detected, no systematic bias ($bias_s$; $P>0.05$) was detected for all three instruments (Table 4). Standard Error of Prediction (SEP_V), another indicator of how well a prediction equation performs, was the lowest for the CVT-2 (SEP_V: 1.621),

the highest for the AutoFom (SEP_V: 2.052) and intermediate for the HGP2 (SEP_V: 1.833). Insofar as for the prediction of salable meat yield, the validation procedure revealed a slight advantage for the CVT-2 (a less pronounced $bias_p$, no $bias_s$ and a lower SEP_V).

Conclusions

With the introduction in the early to mid-eighties of reflectance probe grading, the level of accuracy and precision in predicting yield, one of the key components of any grading systems, was dramatically improved. Since then, numerous attempts to improve accuracy and precision have been made: the development of ultrasound-based instruments being one of them. In this study, two ultrasound instruments, CVT-2 and AutoFom, were evaluated and compared with the reflectance probe HGP2, the probe traditionally used in Canadian studies as the baseline probe.

Calibration and validation procedures showed that, if one was to base the assessment of these ultrasound instruments strictly on the precision and accuracy for predicting salable meat yield, the improvement over the baseline reflectance probe HGP2 would be considered rather minimal, particularly for the AutoFom. However, the major advantage of these ultrasound instruments is that they are non-invasive. Furthermore, the AutoFom, being already fully automated and requiring minimal human intervention, can easily be integrated into the operation of a processing plant in order to fully use the information generated at the time of grading.

REGULATION OF TASTE-ACTIVE COMPONENTS OF MEAT BY DIETARY PROTEIN LEVELS

Fujimura, S., Eguchi A., Kobayashi, T., Sakai, F. and Kadowaki, M
Faculty of Agriculture, Niigata University, Niigata, 950-2181 Japan

Background

Dietary nutrients play a significant part in determining growth rate and meat yield. It is known that the compositions of protein and total amino acids of meat are constant with respect to feeding treatment, hence the meat taste is considered to be constant in that regard as well. However, the relationship of taste components of meat with nutrients is not fully elucidated, and there have been few reports on the effect of feeding treatments on taste-active components of chicken meat. Previously, restricted feeding and dietary low metabolizable energy levels decreased the free Glu content of meat, and the meat taste was deteriorated. Therefore, meat taste can be affected by diets. In this study, the increase in free Glu and sensory score of meat by the diet was studied.

Objectives

In this study, the relationship of dietary crude protein (CP) levels with taste components in chicken meat extract was studied, focusing in particular on the taste-active components. Three experiments were conducted, Experiment 1: meat type chickens were fed graded CP level diets for 10 days, and the meat composition, free amino acids and ATP metabolites were measured. Experiment 2: meat taste was evaluated by a sensory panel. Experiment 3: taste components and Glu-related enzymes of meat were measured at 0, 3, 5 and 10 days.

Materials and methods

Experiment 1: The 14-day-old female Cobb strain broiler chickens were divided into four groups of twelve chicks. The chicks were fed CP 17.6, 26.4, 30.8 and 35.2% diet. All the chickens were kept in individual wire cages. Free amino acids and ATP metabolites of the pectoral meat extract were measured. Experiment 2: Two sensory evaluations, paired comparison test and Scheffe's paired difference test, were conducted between meats of the CP17.5% and 30.8% groups. Experiment 3: The 14-day-old broiler chicks were fed CP 30.8% diet for 10 days. At day 0, 3, 5 and 10, free Glu and Glu-relate enzymes in muscle were measured. For the investigation of Glu regulation mechanism, glutamate dehydrogenase (GDH), kidney type glutaminase (KGA), glutamine synthetase (GS) and alanine transaminase (ALT) activities were measured by enzymatic methods (Bergmeyer, 1974).

Results and discussion

In Experiment 1, free Glu of meat significantly increased in the high CP diet, while 5'-inosinic acid (IMP) was constant. Because free Glu content of meat were above the taste threshold value of Glu, these variations were considered to have affected the taste. In the sensory evaluation (Experiment 2), the taste of the meat of high CP diet group was found superior ($P<0.01$) to that of the control group, especially in overall preference, thickness and umami taste. These results suggested that, dietary CP levels could affect taste-active components, especially free Glu. In experiment 3, after 3 and 5 days on high CP diet, free Glu of muscle was higher than that of 0 day, and tended to decrease after 10 days. KGA activity, with respect to the CP 30.7% diet, was lower than that of the control ($P<0.05$). There were no differences in GDH, GS and ALT activities. KGA was considered to contribute to the free Glu increase. Feedback inhibition of GA activity by high Glu concentration at day 5 may have affected the free Glu concentration of muscle at day 10.

Conclusions

Free Glu and sensory scores of chicken meat increased by dietary CP levels. Because the variation of the taste component improved the taste of meat, the feeding regime may be one of the important factors affecting

the taste of chicken meat. We thus conclude that short-time feeding of high CP diet, especially for 3 to 5 days, may well be an appropriate measure to improve the taste of meat.

EARLY PREDICTION OF CARCASS YIELD GRADE BY ULTRASOUND IN KOREAN HANWOO CATTLE

Song, Young Han[1], Kim, Jee Yong[2] Rhee, Yong Joon[2] and Lee, Sung Ki[3]
[1]Division of Animal Resource Science, [2]Institute of Animal Resources, [3]Department of Food Science and Technology in Animal Resouces, Kangwon National University, Chunchon, 200-701, South Korea.

Background

Real-time ultrasound instruments have been shown to be an accurate predictor of carcass 13th-rib fat thickness and longissimus muscle area (LMA) in beef cattle (Perkins et al., 1992; Robinson et al., 1992; Song et al., 2002). Smith et al. (1992) found that correlation coefficients between live animal ultrasound and carcass measurements of BFT and LMA varied from 0.81 to 0.82 and from 0.43 to 0.63, respectively. Research has also shown that accuracy is highly dependent on the technician and level of experience that the person possesses (McLaren et al., 1991). However, limited information has been published on the accuracy or precision of these systems (Brethour, 1994; Herring et al., 1998). Since 1992, the Korean Livestock Cooperatives Federation has provided a beef grading system for quantifying meat yield and quality factors by subjective evaluation. The possibility of using ultrasound to precisely and accurately estimate carcass measurements in live animals might be beneficial to the beef industry, allowing it to move away from the current practice of pricing cattle on pen averages towards a value-based marketing system.

Objectives

The objective of this study was to evaluate early prediction of yield grade by using ultrasound measurements.

Materials and methods

Two hundred and twenty three Korean Hanwoo cattle of 18, 21 and 24 months of age were ultrasonically scanned by Super-eye Meat (FHK Co. Ltd., Japan) with an electric linear probe (2 MHz frequency: 27 X 147 mm) at the 13th rib of their left longissimus muscle. Vegetable oil was used on the probe to obtain adequate acoustic contact. Scanned images were obtained using double frame display capabilities of the equipment. A transducer guide was used to minimize error that might occur due to animal back line curvature or the overlapping step required to produce one complete image of the longissimus muscle. The resulting ultrasound images were recorded on portable personal computer and later viewed on a display monitor to estimate both back fat thickness (BFT) and longissimus muscle area (LMA) using computer software (Image-Pro Express, Media Cybernetics, USA). In this study, ultrasonic estimate was compared to carcass value for increased prediction accuracy by two prediction methods: regression and decision tree. Regression techniques (SAS, Ver. 8.1; 2000) were used to evaluate the best-fit equation to explain variation in retail yield components (BFT, LMA and live weight (LW)) from ultrasonic. Decision trees that have too many nodes have great probability of prediction error when it is applied to new data. Thus, inappropriate branches were removed from the decision tree, and the remaining tree structure was used as a model for prediction.

Results and discussion

Differences in the ultrasonic and actual carcass measures in BFT and LMA are presented in Table 1. Ultrasonically measured value indicated thinner back fat and smaller longissimus muscle area. Regression equations for prediction carcass yield grade at different months of age are presented in Table 2. Table 3 presents the prediction accuracy of the regression method on the mean yield grade, which was predicted with 73.1% accuracy at 18 months, 83.2% at 21 months and 89.2 % at 24 months of age. However, different grades (A-C) were not predicted equally well at all ages, yield grade A being most predictable. Prediction accuracy was 75.2% for yield grade A and 72.3% for yield grade B at 18 months, 88.9% and 69.2% at 21 months, and 92.8% and 81.5% at 24 months, respectively. By using the decision tree method for carcass yield grades at 24 months of age, 75.8%, 84.8% and 91.0% of prediction accuracy were obtained at 18, 21 and 24 months of age, respectively. Also, if live weight was unknown (as in small farms), the decision tree method enabled prediction only using ultrasonic measurements (BFT and LMA).

Conclusions

The results of the present study suggest that the decision tree method predicted the yield grade of meat with 91% accuracy. The results obtained on image texture suggest that interfacing a computer with an ultrasound system may improve accuracy and precision of the procedure of estimating carcass quality. Such technology might thus serve as a useful tool and predicting aid in mechanical meat grading.

REGULATION OF TASTE-ACTIVE COMPONENTS OF MEAT BY DIETARY BRANCHED-CHAIN AMINO ACIDS

Imanari, M.[1], Kadowaki, M.[2] and Fujimura, S.[2]

[1]Graduate School of Science and Technology, Niigata University, Niigata, 950-2181 Japan
[2]Faculty of Agriculture, Niigata University, Niigata, 950-2181 Japan

Background

Regulation of taste active components of meat is important for the improvement of meat quality. It has been generally believed that it is possible to regulate aroma and storage stability by diet, while regulation of meat taste is difficult. In previous study (2001), we suggested that the main taste-active component of meat, free glutamate (Glu) content, could be controlled by dietary restriction and metabolizable energy. However, there were no reports about the effects of other dietary factors on the taste components of meat.

Zhou and Thompson (1996) reported that glutamate dehydrogenase (GDH) activity in the muscle was regulated by branched-chain amino acids (BCAA) *in vitro*. BCAA, leucine, valine and isoleucine, are known as essential amino acids, and mainly metabolized in the muscle, not in the liver. Therefore, we considered that dietary BCAA may affect the Glu contents of meat *in vivo*.

Objectives

In this study, the effect of dietary BCAA, especially leucine (Leu), level on meat quality was studied. The meat quality was estimated by free amino acids, ATP metabolites and sensory evaluation. As a result, the Glu level and sensory score were changed by dietary Leu level. Then, the Glu-related enzyme activities in muscle were measured to elucidate the regulatory mechanism of Glu in the muscle.

Materials and methods

28-day-old female Cobb strain broiler chickens were divided into 4 groups. Leu contents of experimental diet were 70, 100, 130 (control) and 150% of the NRC (1994) requirement of Leu. Because commercial diet include 130-150% of NRC requirement, we considered Leu130% as control. The 4 groups of chickens were kept on these diets *ad libitum* for 10 days. On day 11, all chickens were slaughtered, and breast muscles (*M. Pectoralis superficialis*) were taken for analyses. Concentrations of free amino acids and ATP metabolites in meat extract were measured by HPLC. Sensory evaluation was carried out with 12 trained panellists using paired difference test and Scheffe's paired comparison test. For the investigation of the mechanism of Glu regulation, the muscle GDH, glutaminase (GA) and glutamine synthetase (GS) activities were measured by enzymatic methods (Bergmeyer, 1978).

Results and discussion

On the Leu70% diet, growth performance, weight gain, feed intake and feed efficiency of chicken decreased significantly compared to those on the other diets ($P<0.05$). Therefore, we considered that Leu70% diet was inappropriate in meat production.

The muscle amino acid analysis showed that free Leu contents increased with an increase in dietary Leu level. On the other hand, free Glu contents of the Leu100% diet increased by 34% compared to that of the control (Leu130%) ($P<0.05$). With a decrease in dietary Leu levels, free Glu of muscle tended to increase. There were no differences in the 5'-inosinic acid contents of muscle in all groups.

In sensory evaluation, all panellists found a difference in meat taste between Leu100% and the control ($P<0.01$) in the paired difference test. Furthermore, compared to the control, the Leu100% group got a significantly higher score in overall preference, chicken like taste and umami taste in Scheffe's paired comparison test ($P<0.01$). On the other hand, there were no differences between groups in aroma and taste intensity. These results suggest that the taste of meat in Leu100% group was superior to that in the control group.

The GDH activity of Leu100% and 150% groups was lower than that of control ($P<0.05$). In contrast, the GA activity decreased with an increase in dietary Leu level ($P<0.05$). There were no differences in the GS activity in each group. From these results, we considered that the GDH and GA activities contribute to the regulation of the free Glu content of muscle by dietary Leu level.

Conclusions

From these results, we conclude that the dietary Leu level affected the free Glu contents in muscle. The decrease in dietary Leu induced an increase in the free Glu of muscle. In sensory evaluation, the taste of meat improved with low dietary Leu level. The muscle activities of GDH and GA were also affected by the dietary Leu level. We conclude that dietary Leu level regulates the free Glu content in muscle, and the taste of meat can be improved by low dietary Leu level.

EFFECTS OF DIETARY LINSEED OIL ON FATTY ACID COMPOSITION OF LAMB MEAT

Caputi Jambrenghi, A., Giannico, F., Sanapo, S., Bozzo, F., Colonna, M.A., Vicenti, A. and Vonghia, G.
Department of Animal Production, Via G. Amendola 165/A - 70126 Bari, University of Bari, Italy

Background

Fatty acids are involved in various "technological" aspects of meat quality. Since they have very different melting points, variation in fatty acid composition has an important effect on firmness and softness of the fat in meat. Moreover, interest in meat fatty acid composition stems from the need to find ways to produce healthier meat, which has a higher ratio of polyunsaturated (PUFA) to saturated (SFA) fatty acids and a more favourable balance between ω-6 and ω-3 PUFA (Wood *et al.,* 2003).

The differences in the physiological effects on humans of ω-6 and ω-3 PUFA were unknown until 1980. Nowadays, evidence from epidemiological, clinical and biochemical studies demonstrates that ω-3 PUFA exert a protective effect against some common cancers such as breast, colon and perhaps prostate (Rose and Connolly, 1999), reduce some types of cardiovascular disease, improve rheumatoid arthritis and inflammatory bowel diseases and minimize episodes of rejection (Alexander, 1998).

Nutritionists have focused on the type of PUFA and the balance in the diet between ω-3 PUFA formed from α-linolenic acid (C18:3) and ω-6 PUFA formed from linoleic acid (C18:2) (Williams, 2000). The ratio of ω-6/ω-3 PUFA is considered a risk factor in cancers and coronary heart disease, especially in the formation of blood clots leading to a heart attack (Enser, 2001).

Some international agencies (British Nutrition Foundation, 1992; Department of Health, 1994) concerned with human health have considered the benefits of dietary long chain ω-3 PUFA, establishing a ω-6/ω-3 ratio of less than 4 to improve human health status. Consequently, there have been many attempts to manipulate feeds in order to increase the ω-3 fatty acid content in rabbits (Lopez-Bote *et al*., 1997), poultry (Chanmugam *et al.,* 1992), pigs (Enser *et al.,* 2000; D'Arrigo *et al.,* 2002a, 2002b) and ruminants (Ponnampalam *et al.,* 2002a, 2002b).

Ruminant meats are a relatively good source of ω-3 PUFA, due to the presence of C18:3 in grass. In Mediterranean areas where grazing lands are scarce and on farms where livestock is reared in sheds, it is possible to increase ω-3 PUFA content of ruminant meats by feeding animals on grain-based diets including whole linseed.

Objectives

The present study observed the effects on the fatty acid composition of lamb meat when linseed oil was used in feed.

Materials and methods

Twenty male Gentile di Puglia lambs were weaned at the age of 45 days and immediately divided into two homogeneous groups of 10. Control group lambs were fed on hay and commercial concentrated feed containing soybean oil (30 g kg^{-1}); experimental group lambs on hay and commercial concentrated feed containing linseed oil (30 g kg^{-1}). Energy, protein and fibre contents of both diets were the same.

Lambs were slaughtered at 100 days. The carcasses were refrigerated at 4°C for 24 hours. *Longissimus lumborum* (Ll) muscles were taken from right half-carcasses. Representative sub-samples were taken from Ll muscles and divided into two pieces. One piece was cooked in a ventilated electric oven at 180°C until an internal endpoint temperature of 75°C was reached in the geometric centre of the meat cut. The

temperature was recorded by a thermocouple (Hanna Instruments) inserted into the meat sample placed at the centre of the wire rack (ASPA, 1996).

Raw and cooked meat samples were homogenized in a grinder to perform chemical analysis (ASPA, 1996). Lipids were extracted from both raw and cooked samples according to the method suggested by Folch *et al*. (1957) using a chloroform/methanol 2:1 (v/v) solution. Fatty acids were methylated using a BF_3/methanol solution (12% v/v) and analysed by gas chromatography (Chromopack CP 9000) using a 60 m silicated glass column with a 0.25 mm internal diameter and 0.2 μm film thickness.

The atherogenicity and thrombogenicity indexes (Ulbricht and Southgate, 1991) and the PCL/PCE (plasma cholesterol lowering/plasma cholesterol elevating) ratio (Reiser and Shorland, 1990) were also calculated.
Analysis of variance was carried out on the data using the GLM procedure of SAS. The model considered diet, cooking and their interaction as main effects. Means were compared using Student's t test (SAS, 1999/2000).

Results and discussion

Feed containing linseed oil did not modify the chemical composition of raw and cooked meat when compared to feed containing soybean oil, as found also for 75-day-old lambs (Caputi Jambrenghi *et al*., 2004a). Regardless of diet, cooking lowered the moisture content of meat and increased the levels of protein, ash and N-free extract (P<0.01), without any alteration to the ether extract content (Table 1).

Table 1. Chemical composition of raw and cooked meat (% wet matter)

	Control group		Experimental group		SED	Significance of main effects	
	Raw	Cooked	Raw	Cooked	(DF = 36)	Diet	Cooking
N (samples)	10	10	10	10			
Moisture	75.13^{M}	65.98^{N}	74.99^{M}	65.74^{N}	2.494	ns	**
Protein	19.14^{N}	26.79^{M}	18.84^{N}	26.55^{M}	1.158	ns	**
Ether extract	3.49	3.43	3.94	4.12	1.464	ns	ns
Ash	1.06^{N}	1.70^{M}	1.10^{N}	1.67^{M}	0.142	ns	**
N-free extract	1.18^{N}	2.10^{M}	1.12^{N}	1.92^{M}	0.243	ns	**

Differences between raw and cooked meat within each group: M, N: P<0.01
Significance of main effects: **: P<0.01; ns: not significant

Feed containing linseed oil brought about an increase in the C18:3 ω-3 content of the raw (1.54 *vs* 0.86; P<0.01) and cooked meat (1.12 *vs* 0.42; P<0.01), thus confirming the results obtained with 75-day-old lambs (Caputi Jambrenghi *et al*., 2004b), and in the C22:6 ω-3 level of the cooked meat (0.14 *vs* 0.01; P<0.01) (Table 2).

It also increased total PUFA in the cooked meat (7.24 *vs* 5.96; P<0.01), total ω-3 in the raw (2.12 *vs* 1.64; P<0.01) and cooked meat (1.94 *vs* 0.86; P<0.01), and lowered the ω-6/ω-3 ratio of the cooked meat (2.88 *vs* 6.34; P<0.01) bringing it to below 4, as recommended by the Human Nutrition Society (Carnovale and Marletta, 1997).

On the cooked meat, feed containing linseed oil raised the PUFA/SFA ratio (0.15 *vs* 0.13; P<0.01), bringing it closer to the 0.45 level recommended by the Department of Health (1994), as well as lowered the thrombogenicity index (1.43 *vs* 1.55; P<0.01).

Cooking reduced the level of C18:3 ω-3 (P<0.01) in meat produced with either feed. However, cooking increased the level of C22:6 ω-3 in the experimental group meat (0.14 *vs* 0.06; P<0.01), unlike the control group meat where the level was lowered (0.01 *vs* 0.14; P<0.01).

Cooking had a positive effect on meat produced with the linseed oil feed regarding total SFA (47.62 *vs* 49.68; P<0.01), total MUFA (45.14 *vs* 42.36; P<0.01), total UFA (52.38 *vs* 50.32; P<0.01), the UFA/SFA ratio (1.10 *vs* 1.01; P<0.01), the thrombogenicity index (1.43 *vs* 1.54; P<0.01). Cooking had a negative

effect on meat produced with the soybean oil feed regarding total PUFA (5.96 *vs* 7.66; P<0.01), total ω-3 (0.86 *vs* 1.64; P<0.01), the ω-6/ω-3 (6.34 *vs* 3.83; P<0.01) and PUFA/SFA ratios (0.13 *vs* 0.16; P<0.01).

Conclusions

The use of linseed oil in the production of 100-day-old lambs does not modify the chemical composition of the meat. It improves, however, the dietary characteristics, especially in cooked meat, increasing the C18:3 ω-3, C22:6 ω-3 and total ω-3 contents and improving the ω-6/ω-3 and PUFA/SFA ratios and the thrombogenicity index.

VACUUM COOLING OF COOKED MEATS

T. X. Jin H. M. Zhu H. D. Feng L. Xu

Institute of Refrigeration & Cryogenics, Shanghai Jiao Tong University,
1954 Hua Shang Road , Shanghai 200030, China

Background

Meat is chilled immediately after slaughter. Most of the subsequent operations in the cold chain are designed to maintain the temperature of meat. Cooking is very common operation in the production of many meat products. The aim of any cooking process for meat/meat products is to ensure the destruction of vegetative stages of any pathogenic microorganisms. However, there is always the possibility that the cooking process will not kill some microorganisms that produce spores or that the food can become recontaminated. Therefore, microbiologists recommended that the temperature of the meat should be rapidly reduced, especially from approximately 60 and 5℃, to prevent multiplication of exiting or contaminating bacteria. Rapid cooling is also desirable with cooked products to maintain quality by eliminating the overcooking that occurs during slow cooling.

Some European countries have some similar food safety regulations. Both Irish (Food Safety Advisory Committee, 1991)and UK (Department of Health and Social Security, 1989) government guidelines recommend that cooked meat joints should be cooled from a core temperature of 74℃ to below 10℃ in 2.5h. Chinese government has also made the similar regulations in meats and cooked meats processing (China GB 12694-90). A rapid cooling treatment after cooking can minimize the growth of surviving organism (Burfoot, D, Self, K. P, Hudson, W. R., Wilkins, T. J, & James, S. J. 1990).

Vacuum cooling as rapid evaporative cooling method has been extensively used as an effective method to remove field heat and thus to extend shelf and improve quality for many types of horticultural and floricultural products such as lettuce (Haas & Gur, 1987; Rennie, Raghavan, Vigneault, & Gariepy, 2001), mushroom (Atkins 974), and cut flowers (Sun & Tadhg. Brosnan, 1999). Research has indicated that vacuum cooling can meet both European and USA guidelines. Wang and Sun (2002 part1; 2002 part2; 2004) have developed a mathematical model for describing the vacuum cooling process of large cooked meat joints.

Objectives

In this current study, the previous model is modified and the modified model is further used to analyze the performance of vacuum cooler and the vacuum cooling process of cooked meats.

Mathematical models

Vacuum cooling process includes two fairly distinct phases: (a) the removal of the air in the vacuum chamber from the atmospheric pressure to the saturation pressure at the initial temperature of cooked meats, and (b) the drop of the pressure in the vacuum chamber continuously to the final vacuum pressure. The maximum pressure in the chamber, which can cause water in cooked meats to boil, is the saturation pressure of the water vapour at the initial temperature of cooked meats. The relationship for the saturation pressure of the water vapour in cooked meats and the temperature of cooked meats is determined by (Wang & Sun 2002 part1):

$$P_{sat} = \exp\left(23.209 - \frac{3816.44}{T_K - 46.44}\right) \quad (1)$$

The total pressure in the vacuum chamber is the sum of the partial of air and water vapour:

$$P_{vc} = P_a + P_v \quad (2)$$

The decrease rate of total vacuum pressure in the chamber can be calculated by:

$$\frac{dP_{vc}}{dt} = -\frac{S \cdot P_{vc}}{V_f}$$

(3)

In developing the heat and mass transfer models, cooked meats are assumed to be cylindrical in shape with the internal cooling generation due to evaporation. The assumptions of the mathematical models developed can be summarized as follows:

- The initial temperature and moisture content of cooked meats are constant;
- Cooked meats is homogeneous and isotropic;
- The thermal properties of cooked meats are constant;
- The governing equations for the heat and mass transfer are considered as transient.

With the above assumptions, the differential equation for the transient heat transfer can be expressed as:

$$\rho C \frac{\partial T}{\partial t} = \frac{\partial}{\partial r}\left(\lambda \frac{\partial T}{\partial r}\right) + \frac{\lambda}{r}\frac{\partial T}{\partial r} + q_v$$

(4)

The initial and boundary conditions for Eq. (4) are:

$$t = 0 \quad , \quad T = T_0$$

(5)

$$t > 0 \quad , \quad r = 0 \quad , \quad \frac{\partial T}{\partial r} = 0$$

(6)

$$t > 0 \quad , \quad r = \frac{D}{2} \quad , \quad -\lambda \frac{\partial T}{\partial r} = \sigma \cdot \varepsilon \cdot (T_{sf}^4 - T_{vc}^4) + q_{sf}$$

(7)

Under vacuum, the heat released from cooked meats to the cooling medium by convection is negligible. The radiative heat transfer is considered. In Eq. (4), q_v is the inner heat per unit volume generated due to water evaporation, q_v can be given by:

$$q_v = -h_{vg} \cdot \dot{m}_v$$

(8)

In Eq. (7), the evaporation heat per unit surface area, q_{sf} can be expressed by:

$$q_{sf} = \frac{D}{4} \cdot q_v = -\frac{D}{4} \cdot h_{vg} \cdot \dot{m}_v$$

(9)

During vacuum cooling, water evaporation occurs from cooked meats, the evaporation rate pre unit volume of cooked meats can be calculated by:

$$\dot{m}_v = \frac{4}{D} h_m (P_{sat} - P_{vc})$$

(10)

Where D is the diameter of the cylindrical cooked meats; P_{sat} and P_{vc} are respectively given in Eq. (1) and Eq. (2). The boiling coefficient, $h_m = 8.4 \times 10^{-7}\, kg \cdot Pa^{-1} \cdot m^{-2} \cdot s^{-1}$ (Wang & Sun 2002 part2).

In the models, the thermal properties of cooked meats are assumed to be a constant. However, the thermal conductivity and specific heat of cooked meats can be expressed as functions of compositions. The thermal properties strongly depend on the water content of products. The relationships between the thermal properties and water content of products have been summarized as follows (Sweat, 1986):

$$\lambda = 0.148 + 0.493w$$

(11)

$$C = 1.381 + 2.93w$$

(12)

Models validation

The raw meats are brought from the local supermarket. Then, the meats are cooked through the oven (Type of oven is RF-P130Y, China). The diameter of cooked meats is 80 mm. The samples are weighed by the electric balance and weight transducer. A set of T-type copper/constantan thermocouples with an accuracy of ± 0.1℃ are used to record the temperature distribution of cooked meats and the temperature of vacuum chamber. The core temperature and the surface temperature of cooked meats are measured respectively during vacuum cooling. The vacuum pressure in the vacuum chamber is measured through the pressure gauge. The data were obtained through the data acquisition system (Agilent 34970A, Agilent Technologies, USA). The free volume of the vacuum chamber is $0.02\,m^3$, and the vacuum pump speed is $14.4\ m^3/h$. The ambient temperature is 20 ℃. The diameter of cooked meats is 40 mm. Thermal conductivity is 0.5055 $W \cdot m^{-1} \cdot K^{-1}$. Specific heat is 3505.5 $J \cdot kg^{-1} \cdot K^{-1}$. Density is 1093 $kg \cdot m^{-3}$.

Results and discussion

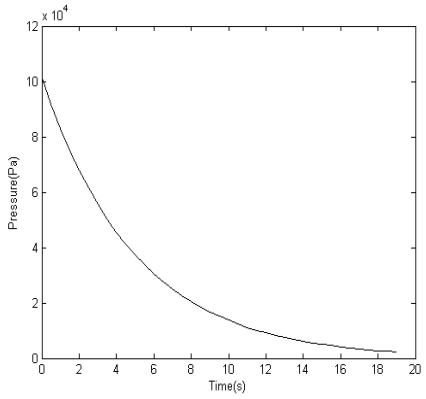

Fig. 1. The vacuum pressure in the vacuum chamber during the first cooling phase

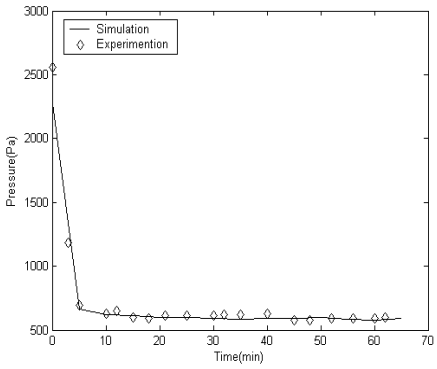

Fig. 2. The variation of vacuum pressure during the final cooling phase

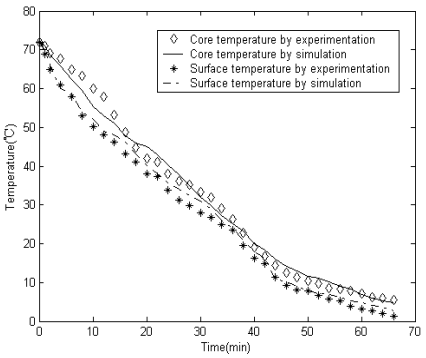

Fig. 3. The variation of temperatures during vacuum cooling

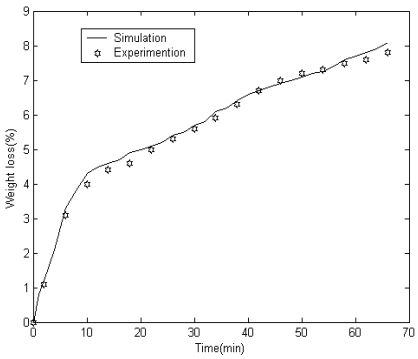

Fig. 4. The variation of weight loss during vacuum cooling

During vacuum cooling, it is assumed that the initial temperature of cooked meats is homogeneous. The curves of vacuum pressure in the vacuum chamber are shown in Figs. 3 and 4. It can be seen that the vacuum pressure in the vacuum chamber ranges from 101325 to 2272.2 Pa in Fig. 3. The pumping time to the flash point is only 19 seconds, which is called the first cooling phase. There is hardly cooling effect in the first phase. Then, the vacuum pressure is reduced from 2272.2 to 620 Pa. The variation of vacuum pressure during the second cooling phase is shown in Fig. 4. It can be seen that the predicted pressure agrees with the experimental value well. However, it can be also found that the experimental pressure can occurs some fluctuations shown in Fig. 4, which is due to the air leakage. Because the defined vacuum pressure, 620 Pa, is maintained by opening the bleeding valve of the vacuum chamber. After the flash point, water in cooked meats begins to evaporate. Therefore, the cooling effect occurs, and the temperature of the cooked meats can

reduce because of evaporation of water. It is during the second cooling phase that the cooked meats are cooled until the defined temperature of the cooked meats is reached.

Fig. 5 shows the surface and the core temperature profiles of the cooked meats by experimentation and simulation. The cooked meats are cooled from 72℃ to 5℃ within 70 min. Generally, the conventional cooling methods, such as slow air cooling and air blast cooling, are about form 6 to 10 hrs. Therefore, vacuum cooling is a rapid cooling method compared with the conventional cooling methods. It is shown that the theoretical simulation results agree with the experimental data well in Fig. 5. The differences of temperatures between the simulation and the experimentation are within 5℃. During the simulation of vacuum cooling, the specific heat, the practical thermal conductivity and the density of cooked meats are assumed to be constant. However, the thermal properties of cooked meats vary during the cooling phase. Consequently, the deviation between the simulation and the experimentation occurs. At the same time, because of the inner thermal conductivity of cooked meats, it can be found that the surface temperature is lower than the core temperature during the cooling phase. The final surface temperature of cooked meats is 1.2℃, and the final core temperature of the cooked meats is 5.5℃. During the cooling stage, the temperature of the cooked meats is above 0℃ to avoid freezing in the surface of cooked meats, which can be seen in Fig. 5.

When the vacuum pressure in the vacuum chamber reaches the saturation pressure, the water in cooked meats will boil. Therefore, evaporation of water occurs during the vacuum cooling, which leads to the reduction of weight of the cooked meats, as is shown in Fig. 6. The variation of weight loss during vacuum cooling is shown in Fig. 6. The simulated weight loss result is 8.1%, and the experimental weight loss value is 7.8%. The simulation result of weight loss of cooked meats agrees with the experimentation data. The deviation between the simulation and the experimentation is about 4%.

Conclusions

This paper describes the vacuum cooling of cooked meats. A modified mathematical model is developed to analyze the performance of vacuum cooler and the vacuum cooling process of cooked meats. The model is based on the assumption that the thermal properties of cooked meats are constant. The mathematical model is solved by the Crank-Nicolson method. The model is used to predict the variation of the vacuum pressure in the chamber and the temperature and weight loss profiles of the cylindrical cooked meats.

In order to validate the model, the cylindrical cooked meats are cooled by vacuum cooling from 72℃ to 5℃. The cooling time is only about 70 min, which indicates that vacuum cooling is a rapid cooling method compared with the conventional cooling methods, because the conventional cooling methods are about 6~10 hrs. The experimental data are compared with the simulated results, it is found that the differences of the temperature between the simulation and the experimentation are within 5℃, and the deviation of weight loss between the simulation and the experimentation is 4%. Anyway, the simulation results agree with the experimental data well, which indicates that the developed modified model can predict the variation of the pressure in the vacuum chamber, the temperature and weight loss of cooked meats.

CHEMICAL PROPERTIES OF THE MEAT AND BLUBBER OF THE CAPE FUR SEAL (*ARCTOCEPHALUS PUSILLUS PUSILLUS*)

K.S.C. Koep[1], L. C. Hoffman[1#], E. Slinde[3] and L. Dicks[2]

[2]Department of Microbiology, University of Stellenbosch, Private Bag X1, Matieland, 7602, South Africa,

Background

The Cape fur seal is harvested commercially in Namibia on the south-west coast of Africa. At present, there is a large demand for the hides of the pups and bulls, but the rest of the carcass is processed to carcass meal, which was traditionally used to supplement the diets of ruminants. Due to the occurrence of BSE in previous years, there has been a decrease in the use of animal by-products in any animal feed. Therefore, an alternative use of the meat is desirable. As the meat has shown to be a healthy, lean meat which contains high amounts of macro-minerals such as calcium and phosphorous, as well as iron and selenium (Robinson, 1996), there is reason to process the meat into a human food source. This would make the harvesting a more acceptable occurrence, as it would mean that the entire carcass of the animal would be utilised to its full extent and that this would be a supply of nutritious meat to the consumer.

There has been very little research done on the meat qualities of marine mammal meat, and none could be sourced on the meat of the Cape Fur Seal (*Arctocephalus pusillus pusillus*). There is some literature available on other pinnipeds, their physiology, geography, environment and life cycles. Some of it is comparable to the Cape fur seal, but as the Cape fur seal is a sub-species of sea lion, there are characteristics, which do not compare to other marine mammals.

Fish oil capsules have become a sales success in the pharmaceutical industry and a well-established supplement in the diet of many people around the world. The omega-3 fatty acids in fish oil have been proven to have a prophylactic action on thrombosis as well as the hardening of arteries. Experiments have shown that the consumption of whale and seal oils leads to a less aggressive immune system and that it also influences the viscosity and coagulative properties of the blood (NAMMCO, 1998).

There are already a few seal products, such as leather products as well as meat products, available elsewhere in the world, which are sold commercially. Seal meat is canned, or processed into salami as well as other products. The seal oil is widely used in the cosmetic industry as an ingredient in medical products. The leather from the hides of mostly male animals is used to make briefcases, purses, wallets and other clothing items. In Namibia, shoes are already being produced successfully from the hides of harvested bulls. The fur of the pups is used in the clothing industry and is used in coats, hats and boots.

The Cape fur seal is harvested commercially each year in Namibia, and this sustainable harvesting is destined to continue. The current culling numbers are 30 000 pups per year and 3000 bulls. The harvesting is done according to regulations and is strictly monitored.

Objectives

Maximising these seal resources would benefit Namibia as well as the rest of the world. Information is needed on the dress out percentages, chemical characteristics of the meat and blubber and how these would influence any processing methods used in a production line. The age and gender of the animals used for production purposes will also play a role, and this also requires research and information. The present investigation determines the proximate chemical composition of the *Pectoralis* muscle and the blubber of mature male bulls as well as pups.

Materials and methods

Ten Cape fur seal pups, approximately eight months old, of both sexes as well as ten Cape fur seal bulls, between two and four years of age were used for this investigation. As selective harvesting is not allowed,

the pups were not separated into different gender. All pups were of similar age, all at point of weaning. The bulls were also of similar age although none were sexually mature.

The animals were harvested using standard procedures. This includes being stuck in the heart to bleed within 30 seconds of being stunned by clubbing. The animals were eviscerated and the hide removed. At this point 100g samples of meat was collected from the *Pectoralis* muscle as well as 100g of blubber from the ventral side of the carcass. Samples were collected in separate plastic bags and marked according to animals, vacuum packed and frozen at –5°C once the meat samples had all reached room temperature (26°C).

Fat extraction

Fat was extracted using samples that had been defrosted. Samples were homogenised in a blender and a chloroform:methanol (2:1) extraction was used (Lee *et al*, 1990).

Protein determination

Dried samples, excluding fat and moisture were used and ground in a mortar with a pestle till a fine powder was obtained. An amount of 0.1mg was weighed off per animal and inserted into a foil wrap designed for the Leeko protein analyser. The protein was determined as Nitrogen, which was multiplied by 6.25 to determine the protein concentration in the sample.

Moisture determination

Standard procedures were used in the determination of moisture content of the sample. 2.5g of wet sample was desiccated in an oven at 100°C for twelve hours. The dried sample was weighed and the moisture content determined (AOAC, 1990)

Results and discussion

It was noted that the carcasses of seal pups dress out to very low percentages (49%) compared to the carcasses of other species such as cattle, sheep and pigs. The dress out percentage in this case, includes the head as well as the flippers. All viscera is removed as well as the hide. This is because at present, the whole carcass is used for the production of carcass meal, and no particular cuts are required. If one were to remove the head and flippers as is done with other seal species, this value would decrease even more. It can bee seen from the dressing that most of the energy taken in with their diet goes towards insulation in the form of a thick, snow-white layer of blubber which covers most of the underneath of the tail. In the bulls, these dress-out percentages would be higher as more muscle has been formed in order to move around in the search of food. As the pups were at the point of weaning, none of them would have had to dive deep or swim far to find a source of food, therefore, their bodies had not had time to get accustomed to maintaining high levels of oxygen in their muscles. This was clear to see from the light colour of their meat compared to the dark red colour of the meat of the adult animals. Their staple diet had consisted of milk till then, and thus no other food sources, *e.g.* fish, would have been consumed to affect the colour or flavour of the blubber or meat.

Meat samples were taken from the *Pectoralis* muscle of freshly culled carcasses of ten cape fur seal pups and ten cape fur seal bulls. Blubber samples were taken from the same animals. All pups were approximately eight months of age, whilst the bulls were between two and four years old. As seen in Table 1, the meat of the pups contained a higher percentage fat (4.2g/100g) than that of the bulls (2.4g/100g), but a very similar percentage of protein (23.2g/100g). The blubber samples of the bulls contained a higher percentage of protein (26.6g/100g) than that of the pups (14.6g/100g) but a lower fat percentage (67.1g/100g) than that of the pups (77.2g/100g). Seal meat could therefore be considered as a healthy food commodity due to its lean meat content with most of the fat being blubber and thus stored sub-cutaneously. The moisture content of both the meat as well as the blubber of pups as well as bulls is very similar.

Table 1. Mean values of the chemical composition of the meat and blubber of 10 Cape fur seal pups and 10 Cape fur seal bulls.

	Meat			Blubber		
	Moisture%	Protein %	Fat %	Moisture%	Protein %	Fat %
PUPS	73.0±1.6	23.2±1.5	4.2±1.7	8.0±1.9	14.6±3.0	77.2±1.9
BULLS	74.2±1.6	23.5±1.5	2.4±0.8	5.9±1.6	26.6±4.3	67.±5

Conclusions

Countries with concessions to harvest seals, in this case Namibia, could benefit from full utilisation of the animal. The chemical composition of the meat shows that it is lean meat with a very high protein content and that most of the blubber lies subcutaneously, as in pork. This makes it nutrient dense meat for the consumer to use as an alternative source of red meat.

METABOLIC MECHANISM OF COMPENSATORY GROWTH IN PIGS

Lametsch, R[1]. Kristensen, L[1]. Therkilsen[2], M. Oksbjerg, N[2]. Larsen, MR[3]. and Ertbjerg, P[1].

[3]Department of Biochemistry, Campusvej 55, 5230 Odense M, University of Southern Denmark

Background

It has been known for decades that compensatory growth occurs in pigs following a period of feed restriction. Recent studies have shown that compensatory growth also results in more tender meat (Kristensen et al. 2002). However, it is still unclear why compensatory growth would lead to an increase in meat tenderness. It has been hypothesized that the improved tenderness is a result of increased post mortem protein degradation as a consequence of elevated protein turnover during compensatory growth.

Objectives

The aim of the present study was to investigate changes in the proteome of the muscle due to compensatory growth in pigs by analyzing muscle samples taken at slaughter and 48 hours after slaughter.

Materials and methods

Sixteen female pigs were divided into two groups, that either had free access to the feed (control) or were fed restricted from d 28 to d 80, after which had free access to the feed (compensatory). The pigs were slaughtered at d 140. Meat tenderness was analyzed by a sensory panel. Muscle samples from longissimus dorsi were taken at slaughter and 48 hours after slaughter. The muscle samples were homogenized in 0.1M Tris pH 8.0 added protease inhibitor (complete, Roche). The samples were centrifuged 20min, 25000xg, 4ºC and the supernatant was used for two-dimensional gel electrophoresis (2DE). Eleven cm, pH 4-7 IPG strips and 8-16% gel (Criterion, Bio-Rad) were used for the first and second dimension, respectively. The proteins were visualized with silver staining. ImageMaster 2D Platinum software v5 was used for image analysis and the 2D gels were analyzed in two groups, one containing the samples taken at slaughter and the other the samples taken 48 hours after slaughter. ANOVA (SAS) was used to analyze effect of compensatory growth. The proteins of interest were identified with the use of a MALDI-TOF-TOF instrument (4700 Proteomics analyzer, Applied Biosystems).

Results and discussion

The sensory analysis showed that compensatory growth resulted in a significant ($p<0.05$) increase in meat tenderness compared to meat from control pigs.

At slaughter, eight different proteins were found affected by compensatory growth of the pigs (see fig. 1). The stress proteins HSP70 and HSP27 that both are believed to participate in the organization and protection of the myofibrils (Liu and Steinacker, 2001) and may also have an important role in stabilization of the myofibrils post mortem. Therefore, it can be speculated that these proteins also have an impact on meat tenderness. Changes of proteins Enolase 3 and Glycerol-3-phosphate dehydrogenase, both part of the glycolytic pathway, were also observed. These changes are probably a consequence of regulation in the energy metabolism as the pigs showing compensatory growth have a higher protein turnover compared to control pigs. Changes in the *in vivo* glycolytic metabolism may also lead to changes in the post mortem metabolism. It is well established that the post mortem metabolism has an effect on meat tenderness and the relation between compensatory growth and meat tenderness could be a consequence of changes in the glycolysis. The relation of aldehyde dehydrogenase E2, aldehyde dehydrogenase E3 and biphosphoglycerate mutase to compensatory growth is unclear.

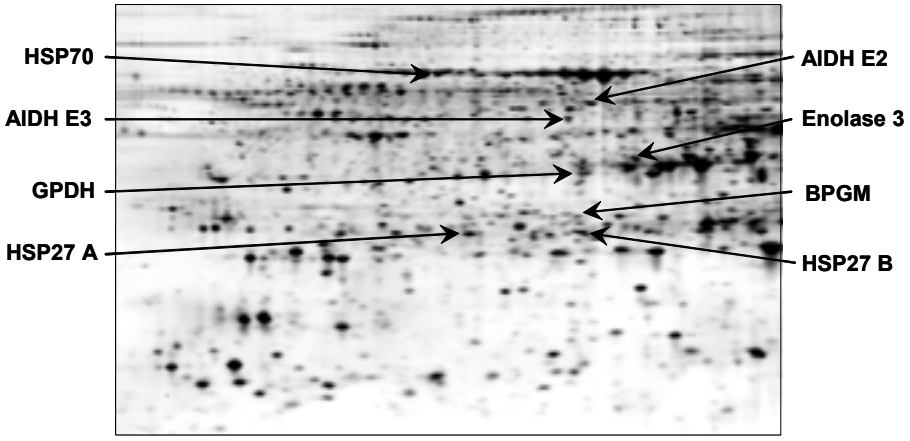

Figure 1. Effect of compensatory growth at slaughter. The arrows show the identified protein changes between pigs showing compensatory growth and kontrol. Heat AlDH E2; Aldehyde dehydrogenase E2. AlDH E3; Aldehyde dehydrogenase E3. GPDH; Glycerol-3-phosphate dehydrogenase. BPGM; 2,3 biphosphoglycerate mutase.

Figure 2A shows that the proteins found to be affected by compensatory growth at slaughter all have higher intensity when the pigs were fed ad libitum. It was presumed that the intensity of some effected spots would be higher in muscle samples from pigs that were fed compensatory as a consequence of the elevated protein turnover. The intensities of the proteins do not necessary reflect the activity of the identified enzyme, as the protein spots could also be an inactive isoform. Furthermore, only the sarcoplasmic protein fraction was used in the present study. Another explanation could be that mainly the amount of myofibrillar proteins increases during compensatory growth, and as a result, the relative amount sarcoplasmic proteins will decrease. However, compensatory growth did not affect the protein concentration of the sarcoplasmic protein extracted from the muscle, and the analysis of the sarcoplasmic protein fractions with 1D gel electrophoresis showed no effect on the relatively small amount of actin and myosin. Finally, the same intensity pattern was not observed in the samples taken 48 hours after slaughter (Fig. 2B).

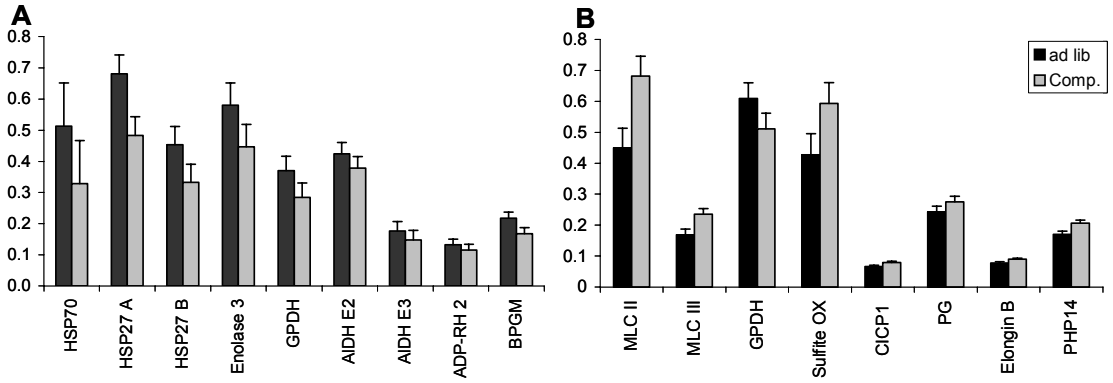

Figure 2. Intensity at slaughter (A) and 48 hours post mortem (B) of proteins that were found to be affected by compensatory growth. AlDH E2; Aldehyde dehydrogenase E2. AlDH E3; Aldehyde dehydrogenase E3. GPDH; Glycerol-3-phosphate dehydrogenase. BPGM; 2,3 biphosphoglycerate mutase. ClCP 1; Chloride intracellular channel 1. Sulfite OX; Sulfite oxidase. MLC II; Myosin light chain II. PHP14; Phosphohistidine phosphatase 14. MLC III; Myosin light chain III.

Muscle samples of longissimus dorsi taken 48 hours post mortem were also analyzed (Fig. 3) as post mortem protein changes have a great influence on the tenderness of meat. A hypothesis of the influence of compensatory growth on meat tenderness has been that it was a consequence of increased post mortem protein degradation. Therefore, it was presumed that the intensity of some protein fragments would be affected by compensatory growth. However, the proteins that were found affected by compensatory growth

at 48 hours post mortem were all full-length. Hence, the results from the present study could not confirm the hypothesis. It was found that the intensity of both Myosin light chain (MLC) II and III were affected by compensatory growth 48 hours after slaughter. MLC have an important role in the structure of the muscle cell, and it has previously been reported that MLC II is related to tenderness (Lametsch et al. 2003). However, it is not clear if the impact MLC has on tenderness is a consequence of post mortem proteolyses or modification (Lametsch et al. 2003). Recently, it was reported that MLC is dephosphorylated *post mortem* and that the dephosphorylation is related to the *post mortem* metabolism (Morzel, M. et al. 2004). The mitochondrial protein sulfite oxidase and the two nuclear proteins elongin B and chloride intracellular channel 1 increase in intensity 48 hours after slaughter as an effect of compensatory growth. An explanation of this observation could be that the number of mitochondria and satellite cells is increased as a consequence of the increase in protein turnover, and that the proteins from these two organelles leaked into the sarcoplasma *post mortem*. The effect of compensatory growth at 48 hours after slaughter on protein gamma and phosphohistidine phosphatase 14 is unclear.

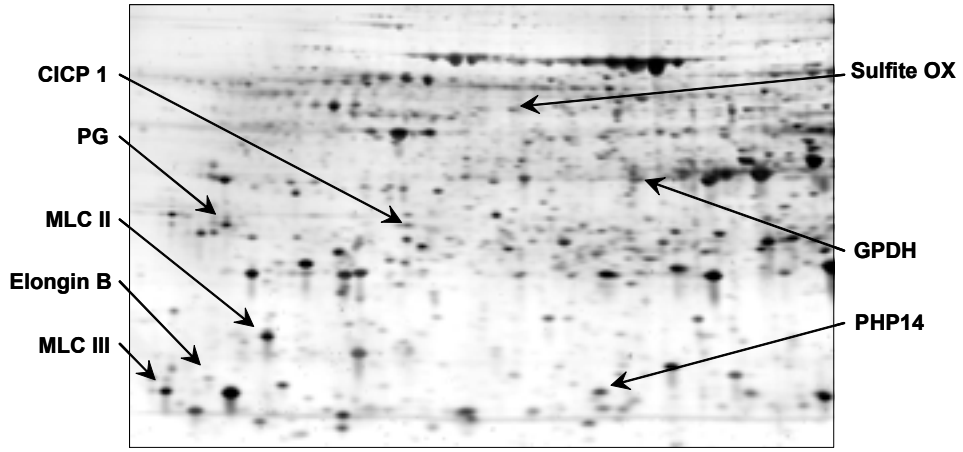

Figure 3. Effect of compensatory growth 48 hours after slaughter. The arrows show the identified protein changes between pigs showing compensatory growth and kontrol. ClCP 1; Chloride intracellular channel 1. Sulfite OX; Sulfite oxidase. GPDH; Glycerol-3-phosphate dehydrogenase. MLC II; Myosin light chain II. PHP14; Phosphohistidine phosphatase 14. MLC III; Myosin light chain III.

Conclusions

The results of the present study could not confirm the hypothesis that the impact of compensatory growth on meat tenderness is a consequence of increased post mortem protein degradation. Compensatory growth affected the at-slaughter level of the two stress protein HSP70 and HSP27. At 48 hours post mortem the protein isoforms myosin light chain II and III showed increased intensity in the sarcoplasmic fraction. It can be speculated that these changes could have an effect on the meat texture. Further studies are needed to clear this and reveal the precise effect of compensatory growth on the activity of the identified protein.

MEAT QUALITY OF HEIFERS AS INFLUENCED BY GRAZING, FINISHING FEEDING AND CARCASS SUSPENSION METHOD

Maria Lundesjö Ahnström[1], Ann-Charlotte Enfält[1], Anna Hessle[2], Lisbeth Johansson[3] & Kerstin Lundström[1]

[1]Dept. of Food Science, P. O. Box 7051, 750 07 Uppsala, [2]Dept. of Animal Environment and Health, Swedish University of Agricultural Sciences and [3]Dept. of Domestic Sciences, Uppsala University, Sweden
e-mail: Maria.Lundesjo.Ahnstrom@lmv.slu.se;

Background

In Sweden, the beef production is depending on the seasons. The summer allows grazing and the winter requires indoor housing and feeding. Swedish beef production is based on forage feeding with or without finishing feeding complemented with grain. In order to maintain biodiversity and an open landscape, a production system including the use of semi-natural grasslands is of great importance. Today, within EU, farmers receive subsidies for the commitment to keep semi-natural grasslands open, which will contribute to maintain beef production in Sweden. This production strategy will possibly give a higher proportion of animals slaughtered directly after the grazing period to avoid a second indoor period, which could affect the meat quality.

Steen and Kilpatrick, (1995) showed that finishing feeding at 80% of *ad libitum* intake gave a higher carcass weight while maintaining a constant carcass fat content. That could be of importance since the interaction between those two parameters is in focus in the specifications from the retailers. The consumer is mostly interested in the sensory parameter of tenderness, although beef palatability also depends on juiciness and flavour (Huffman *et al.*, 1996). The great variation in beef quality can be explained by the fact that tenderness and other quality attributes are highly dependent on breed, gender, age, physical activity and rearing system of the animal (Harper, 1999). Lundesjö *et al*. (2002) diminished the variation in meat quality of beef by the use of Pelvic suspension.

Objectives

The aim of this study was to compare the sensory and technological quality of meat from grazing heifers on different indoor feed intensity and slaughter age. A further objective was to study the effect of pelvic suspension.

Materials and methods

Two groups of heifers, of at least 75% Charolais (n = 41) or Aberdeen Angus (n = 40) breed respectively, were used. The experiment had a factorial design, where two levels of indoor feed intensity and two levels of slaughter age were used. All animals had one indoor period followed by a grazing period. Half of the heifers were slaughtered at 18 months of age directly after grazing, whereas the other heifers were slaughtered at 22 months of age after a second indoor period. During the indoor periods the two groups were divided and subjected to two different feed intensities (low and high). For Charolais the low intensity was *ad libitum* intake of grass/clover silage and the high intensity was *ad libitum* intake of silage combined with 2 kg of mixed grain (65% oat and 35% barley). For Aberdeen Angus the low intensity was 80% of *ad libitum* intake of silage and the high intensity was *ad libitum* intake of silage.

The left side of each carcass was rehung from the pelvic bone, while the right side was left hanging in the Achilles tendon. The whole *M. longissimus dorsi* from both sides was vacuum-packed and aged for 7 days at +4 ^{O}C. The pH-value was measured and samples for intramuscular fat analysis (IMF), sensory evaluation and instrumental tenderness (Warner-Bratzler (WB)) measurements were frozen at –20 ^{O}C. Additional samples for sensory analyses and WB measurements were aged for another 7 days before being frozen. Freezing and cooking losses were calculated from the WB samples. A selected and trained panel performed a descriptive sensory analysis. Statistical evaluation was performed using the Procedure Mixed in SAS (Ver. 8e, SAS Institute Inc., Cary, NC, USA).

Results and discussion

The production results from this experiment have been described elsewhere (Hessle *et al.*, 2004). It has previously been showed that instrumental tenderness is improved in different genders by finishing feeding or by intensive compared with more extensive feeding (Bowling *et al.*, 1977; Bowling *et al.*, 1978; Schroeder *et al.*, 1980; Dubeski *et al.*, 1997; Hoving-Bolink *et al.*, 1999a). There are also studies that show no difference in shear force depending on finishing feeding (Harrison *et al.*, 1978; Bruce *et al.*, 2004). This study indicated no significant improvement in shear force for heifers on finishing feeding but a significant improvement with pelvic suspension (Table 1), which agrees with Lundesjö *et al.* (2002). For Charolais heifers, there was an improvement in instrumental tenderness for pelvic suspended sides at 7 days, but no differences could be seen after additional ageing to 14 days. Angus heifers had an improvement in instrumental tenderness for pelvic suspended sides after 14 days of ageing.

For the Charolais heifers, the high feed intensity had positive effects on tenderness with a 23% decrease in bite resistance and a 14% increase in tenderness compared with less intensive feeding. The high feed intensity also led to lower freezing and cooking losses after 7 days of ageing, but not after 14 days of ageing. The pH value was lower in meat from animals of the high feed intensity. The results agree with Hoving-Bolink *et al.* (1999a) who found that intensive feeding resulted in a better eating quality than less intensive feeding. For the Angus heifers, a significant decrease in stringiness was observed for the high feed intensity ($P = 0.008$) together with a slight decrease in acidity ($P = 0.06$). This could be due to finishing feeding after grazing inducing an overall improvement in meat quality, and the level of feeding would be of less importance. Vestergaard *et al.* (2000) showed that extensively fed young bulls, after a finishing period of 10 weeks, showed higher instrumental tenderness as well as sensory scores for tenderness, taste and juiciness, reaching the level of intensively fed young bulls. In the present study did higher carcass weight and higher scores for carcass conformation did not lead to an economic advantage in comparison with the lower slaughter weight (Hansson and Hessle, 2003).

Suspension method combined with slaughter age significantly affected most traits. For the evaluated sensory traits in meat from both the Charolais and Angus heifers only few traits were improved after postponed slaughter until the age of 22 months (Figure 1 and 2). This is contradictory to Harrison *et al.* (1978), where all sensory traits improved after a longer feeding period. However, in the present study, suspending the carcasses by the pelvic bone at the slaughter age of 18 months gave the best eating quality. No additional improvement in meat quality was found at the higher slaughter age in Achilles suspended carcasses except for a higher marbling score. This confirms the results by Hoving-Bolink *et al.* (1999b), where a significant increase in intramuscular fat content did not result in better sensory characteristics. Generally a high marbling score is believed to improve the flavour and juiciness of beef, as Harrison *et al.* (1978) found for grain fed beef. However, Bruce *et al.* (2004) concluded that pasture-finished beef had the highest overall quality because of increased tenderness and juiciness despite the fact that the pasture-finished beef had a lower intramuscular fat content. Of interest in the present study was the decrease in visible marbling in meat from pelvic suspended heifers when slaughtered at 18 months of age in comparison with Achilles suspended carcasses at the same age. In Angus heifers, this was also accompanied by a slight decrease in fatty taste ($P = 0.07$).

Conclusions

An extended rearing period with finishing feeding and/or high indoor feed intensity will probably lead to an improved sensory quality of meat from heifers. However, the effect of pelvic suspension exceeded the other factors by improving the meat quality of heifers slaughtered directly after grazing to the level of finishing fed heifers. Pelvic suspension can therefore be recommended in order to produce beef with a consistent quality.

QUALITY CHARACTERISTICS OF MEAT FROM PODOLICA AND CROSSBRED CALVES REARED ON FEED CONTAINING GRAPE SKINS

Marsico G., Dimatteo S., Ragni M., Rasulo A., Di Turi L. and Vicenti A.
Department of Animal Production, Via G. Amendola, 165/A - 70126 University of Bari, Italy

Background

During the last few years, an acceleration in the disappearance of livestock breeds has occurred, due to the replacement of traditional rearing systems with simplified industrial production systems. The Rio de Janeiro "International Bio-diversity Conference" formulated proposals to contrast this trend, consisting of a series of operations and incentives aimed at recovering breeds in danger of extinction.

Podolica cattle are an indigenous Italian genotype, which recently received the status of "breed" with the establishment of a Genealogical Register. The intrinsic features of this breed merit particular attention, and consist of great adaptability to difficult climatic and environmental conditions, together with the quality and dietary characteristics of its meat. Farming of Podolica cattle is concentrated in the "inland" areas of southern Italy (Apulia, Abruzzo, Basilicata, Calabria, Campania and Molise), with about 100,000 head (AIA, 2002). This breed still contains several local varieties and up until a few years ago was used almost solely for heavy farm work. With the advent of mechanisation, its importance disappeared and numbers fell constantly. The outstanding flavour and appearance of Podolica meat have earned it the "5R" grade of certified origin, the same as four other indigenous national genetic types (Chianina, Marchigiana, Maremmana and Romagnola). The ability of this breed to exploit foodstuffs with a low nutritional content may be used in order to exploit alternative food sources such as agri-industrial by-products. In Italy, where a great amount of animal feed is imported from abroad, there is a growing interest in these by-products for livestock feed, because they are inexpensive and easy to obtain. Furthermore, the following advantages derive from their use: - reduced pollution due to lack of environmental impact; - reduced production costs to the breeder; - a considerable alternative supply of nutrition; - probable improvements in the flavour and appearance, physical and chemical characteristics of the animal products (D'Urso et al., 1984; Bosi et al., 1985). The choice of by-products is vast, and grape skins are of particular interest because of their suitable chemical composition (12.76% raw protein, 7.73% fat, 46.70% N-free extracts) low cost and, in Apulia, wide availability. Grape skins have already been tested on lambs without negative repercussions on productive performances, or quantity and quality traits. Moreover, when this by-product was added to lamb feed together with grape-seed oil and safflower oil, it determined a higher level of unsaturated and monounsaturated fatty acids (Chiericato and Rioni, 1983; Bittante et al., 1985; Bosi et al., 1985; Vicenti et al., 1996; Ragni et al., 1997; Ragni et al., 1998; Vicenti et al., 1997).

Objectives

The study aims to evaluate the influence of a feeding treatment containing 20% grape skins on the chemical composition and on the fatty acid profile of meat from thoroughbred and crossbred (Marchigiana x Podolica and Chianina x Podolica) Podolica calves.

Materials and methods

24 male calves were used for this study, 8 Podolica (Pod), 8 Chianina x Podolica (Ch x Pod) and 8 Marchigiana x Podolica (Mar x Pod), weaned at about 6 months. Each genotype was divided into 2 groups, with each group containing 4 animals. The animals were fed a diet made of feed (about 60% of the dry matter of the diet) and of hay from permanent pasture (about 40% the dry matter of the diet). One group of each genotype (Test) was fed a control feed with no grape skins, whereas the other groups (Grape skin) received a feed containing 20% grape skins. Table 1 shows the chemical composition of the feeds, carried out in accordance with A.S.P.A. regulations (1980). The calves were slaughtered at a live weight of 450 kg to 500 kg, when breeders and the local market consider them mature. The *Longissimus dorsi* (LD) and *Biceps femoris* (BF) muscles were removed from all carcasses and assessed for pH, using a glass electrode at slaughter. Samples of both the muscles examined were evaluated for meat colour and tenderness. A representative sample was used for chemical analysis (ASPA, 1996) and fatty acid profile. Lipids were

extracted according to the 2:1 chloroform-methanol method described by Folch *et al.* (1957), whereas the acidic profile was assessed using a Chromopack CP 9000 gas chromatograph. Meat colour was estimated by the Hunter Lab system using a colorimeter (illuminant D 65), which measures the values of Lightness (L), Redness (a) and Yellowness (b) by making 5 readings for each meat sample, approximately 2.5 cm thick. Tenderness was measured using a Warner Bratzler shear device applied to an Instron 5544 and expressed as the cutting force (kg/cm^2) required to shear perpendicularly to the direction of the fibres half an inch diameter cylinders of raw meat, taking three measurements for each muscle per subject. The atherogenicity and thrombogenicity indexes were calculated accordingly to Ulbricht and Southgate (1991). The PCL/PCE (plasma cholesterol lowering/plasma cholesterol elevating) ratio was also determined (Reiser and Shorland, 1990). Data were analyzed for variance using the GLM procedure of SAS (1999/2000).

Results and discussion

The effect of diet on the physical parameters (Tab. 2) of the LD and BF muscles was limited, since it had a significant effect only on the lightness index ($P<0.05$) and the shear force WBS ($P<0.01$) of the LD muscle. Genotype had a significant effect only on the yellowness index b ($P<0.05$) and tenderness ($P<0.01$) of the LD muscle, and on the pH ($P<0.05$) of the BF muscle. Considering the effect of the interaction diet x genotype, it is seen that Pod bullocks fed on grape-skins present LD muscle which tends to be less light ($P<0.05$) and the BF muscle with less red and yellow intensity ($P<0.05$ and $P<0.01$). The degree of acidity of the LD muscle was not influenced by genotype and diet, unlike the BF muscle; the BF muscle from Mar x Pod bullocks fed on grape-skins presented the highest pH values ($P<0.01$ and $P<0.05$). However, the type of feed produced different effects among the three genotypes regarding the shear force of the LD muscle. The feed containing grape-skins significantly ($P<0.01$) increased the hardness of the Pod meat when compared to the Ch x Pod and Mar x Pod meat. The use of grape-skins caused significant variations in the chemical composition of the meats (Tab. 3). Both diet and genotype produced considerable differences in the content of water, fat ($P<0.01$ and/or $P<0.05$) and protein. The combined effect diet x genotype gave rise to effects on the water content of meat from animals fed on the grape-skin diet. In the Ch x Pod and Pod bullocks this was significantly reduced ($P<0.01$ and $P<0.05$). The protein content of the meats from the different genotypes was influenced by the type of diet. In particular, the grape-skin diet led to a reduction in the protein content of meat from bullocks. The fat content of meat was also influenced by both genotype and feed, since the grape-skin diet caused a highly significant increase ($P<0.01$) in the lipid content of Pod meat. The acid composition of the fat (Tab. 4) was affected by the type of diet, with significant variations in the contents of saturates, unsaturated, monounsaturated and ω3, the unsaturated/saturated ratio and the thrombogenicity index. The genotype also has a significant effect on all parameters of acid composition of fat, except for the ω3/ ω6 ratio. The diet x genotype interaction has also shown significant variations in almost all the parameters considered. It can be seen how the grape-skin diet favoured ($P<0.01$ and/or $P<0.05$) a greater accumulation of unsaturated and monounsaturated fatty acids in the Pod bullocks, and reduced the accumulation of saturated fatty. The ω6 and ω3 contents were affected in different ways by the grape-skin diet, which reduced both acids in the Pod bullocks ($P<0.01$and $P<0.05$). Finally, the effect of the grape-skin diet was pronounced on the dietetic indexes. Meat from Pod bullocks showed, mostly on Grape skin diet, better thrombogenic index ($P<0.01$) than the other groups.

Conclusions

The experimentation showed that the use of feed containing 20% grape-skins in the diet of different genotypes of meat bullocks generally produced good quality meat and dietary characteristics. With reference to the Podolica breed, an indigenous genotype typical in Southern Italy, it was seen that a grape-skin diet produced meat with a higher content of unsaturated and monounsaturated fatty acids, reduced saturated acids, and led to an improvement in the dietary indices considered beneficial for human health.

DECOCTIONS OF NORWEGIAN HERBS STABILISE MARINATED TURKEY THIGHS

Maria B. Mielnik[1], Signe Sem[2], Bjørg Egelandsdal[1,2], Grete Skrede[1]

[1]Matforsk AS – Norwegian Food Research Institute, Osloveien 1, N-1430 Aas, Norway.
[2]Institute of Chemistry, Biotechnology and Food Science, Agricultural University of Norway, P.O. Box 5036, N-1432 Aas, Norway

Background

One of the major problems during the processing and storage of meat and meat products is lipid oxidation. This process initiates several changes, which adversely affects the products' colour, flavour, texture and nutritional value. Rancidity in pre-cooked products, especially made from turkey meat, is a great challenge for the food industry. Lipid stability in processed poultry meat may be improved by various components added or injected into the meat during a marination process (Mielnik *et al.,* 1996). The composition of the brine influences the course of chemical reactions, which in turn affect oxidative stability.

The major strategies for preventing lipid oxidation are the use of free radical scavengers such as phenolic antioxidants. In the past few years a variety of plant materials containing phenolic compounds has been proved to be effective antioxidants in model systems. Herbs and spices were traditionally added to food for improving sensory properties and as antioxidants and preservatives. Many herbs and spices rich in polyphenols exhibit antioxidative activities similar to those of synthetic phenolic antioxidants (Cuvelier *et al.,* 1996). Since ancient times, herbs and spices have been used to prolong shelf life and improve the taste of meat products. In various studies, herbs of the mint family (*Labiatae*) have exhibited powerful antioxidant activity (Madsen and Bertelsen, 1995; Herrmann, 1981; Chipault *et al.,* 1956). Marination, originally used for the preservation and tenderisation of meat, is nowadays applied by industry and restaurants to give meats new and exciting tastes and appearances. Marketing of marinated poultry parts is one of the fastest growing segments of the food industry around the world.

Objectives

The presented study was carried out to examine the effect of marinades made with decoction from rosemary, sage and thyme on the oxidative stability of turkey thighs, pre-cooked and chill-stored for one week.

Materials and methods

Marinating of turkey thighs

The turkey thighs were obtained from a local processing plant the day after slaughter. Cuts of thigh meat without skin were soaked in one of five different marinades. Decoctions of rosemary, sage and thyme obtained from Norske Eteriske Oljer A/S were used to prepare three of them. These marinades consisted of decoction with 12% salt. The fourth marinade consisted of 12% salt and 160 mg/L butylated hydroxyanisole (BHA) in water. Water with salt (12 %) and no antioxidant was used as a control. The turkey meat cuts were wiped with paper towel after overnight marination and were vacuum packed in plastic bags (ca 450 g). The samples were cooked in a water bath at 85 °C for 30 min and cooled for 45 min in running water. The meat cuts were divided into smaller portions, transferred to plastic boxes covered with aluminium foil to get air-exposure, and stored for 7 days in the dark at 4 °C.

Chemical methods

Antiradical power (ARP)

The antioxidant activity of the different marinades were determined by using the 2,2-diphenyl-1-picrylhydrazyl ($DPPH^{\cdot}$) method according to the procedure described by Brand-Williams *et al.* (1995) with some modifications (Mielnik *et al.*, 2003). Antioxidant activity was expressed as antiradical power (ARP) in units of mg $DPPH^{\cdot}$/ml marinade.

Thiobarbituric acid reactive substances (TBARS)
The TBARS values were determined by the extraction method according to Sørensen and Jørgensen (1996). Results expressed as mg malondialdehyde (MDA)/kg meat, were calculated from a standard curve of TEP (1,1,3,3-tetraethyoxypropane). TBARS values were examined before and after marinating, directly after cooking and after 1, 3, 5 and 7 days of chill-storage at 4 °C in the dark.

Hexanal
Analysis of hexanal formed during 5 days of storage at 4 °C in marinated cooked turkey thighs was performed by a dynamic headspace technique as described earlier (Mielnik *et al*., 2002). Semi-quantitative amounts of the volatile compound were obtained by relating peak intensities to that of the internal standard ethyl heptanoate (ng), weight of meat sample (g) and total volume of purging gas (L), giving the units ng/g x L.

Sensory analysis
The marinated cooked turkey thighs were evaluated after 5 days of storage at 4 °C. Prior to serving, meat samples sealed in vacuum pouches were heated in a water bath at 70 °C for 30 min. Sensory analysis was performed according to international standard methods (ISO 1985). The panel, consisting of eleven trained assessors, carried out a descriptive test (ISO 1985). Prior to the analysis the panel was trained in the definition and intensities of odours (turkey, acidulous, spicy, rancid), flavours (turkey, acidulous, salt, spicy, bitter, metallic, rancid), colour (whiteness, hue, intensity) and texture attributes (hardness and juiciness). Samples from each marinade were served twice in a warm steel cup with a lid. Serving order was randomised according to sample, replicate and assessor. Each panellist evaluated the samples at individual speed on a computerised system for direct recording of data (CSA, Compusense, Version 4.2, Guelph, ON, Canada) using value 1.0 for the lowest intensity and value 9.0 for the highest intensity of each attribute.

Data analysis
Two replications were carried out with all samples. Effects of marinade and storage time on TBARS values were analysed by ANOVA. The main trends of variation among the samples were studied by principal component analysis (PCA) using the Unscrambler version 8.05 software program (CAMO, Oslo, Norway). The variables were mean-centred prior to PCA. All variables were standardised by 1/standard deviation and full cross-validation was used for the model validation (Martens and Næs, 1989).

Results and discussion

Antiradical Power (ARP) of marinades
The $DPPH^{\cdot}$ radical scavenging activities of the marinades applied in the present study are shown as antiradical power (ARP) in Table 1. The rosemary marinade showed the highest ARP values which means that this marinade had the highest antioxidative activity. Thyme and sage marinades showed considerably lower antioxidative activity compared with the rosemary marinade; 36.9 % and 10.7 % lower, respectively. The BHA marinade had the lowest antiradical power.

Table 1. ARP (mg DPPH/ml marinade) for tested marinades

Marinade	Rosemary	Sage	Thyme	BHA
ARP	85.7	9.2	31.6	1.2

TBARS values
TBARS values measured in the turkey thigh meat showed that both the marinating process and the heat treatment affected the oxidation rate (Table 2). The control samples soaked in 12% salt solution had significantly higher TBARS values than samples soaked in 12% salt solution with decoction of herbs or BHA. TBARS values in control samples were 13 times higher than in the other samples. The differences between turkey thighs marinated with various antioxidants were not significant.

Table 2. Evolution of TBARS values (mg malondialdehyd/kg meat) in turkey thighs during marination, cooking and dark storage at 4 °C in air

Marinade	Raw meat	Marinated meat	Cooked and stored meat (days)				
			0	1	3	5	7
Rosemary	0.15	0.14 ^{b}	0,12 $^{c}{}_{v}$	0,39 $^{e}{}_{w}$	0,82 $^{e}{}_{x}$	1,45 $^{e}{}_{y}$	2,33 $^{e}{}_{z}$
Sage	0.15	0.12 ^{b}	0,63 $^{b}{}_{v}$	0,75 $^{c}{}_{w}$	2,40 $^{b}{}_{x}$	2,55 $^{c}{}_{y}$	3,87 $^{c}{}_{z}$
Thyme	0.15	0.14 ^{b}	0,09 $^{c}{}_{v}$	0,66 $^{d}{}_{w}$	1,50 $^{d}{}_{x}$	1,77 $^{d}{}_{y}$	3,35 $^{d}{}_{z}$
BHA	0.15	0.12 ^{b}	0,18 $^{c}{}_{v}$	1,09 $^{b}{}_{w}$	1,88 $^{c}{}_{x}$	3,21 $^{b}{}_{y}$	4,15 $^{b}{}_{z}$
Control	0.15	1.91 ^{a}	7,38 $^{a}{}_{x}$	7,32 $^{a}{}_{x}$	7,69 $^{a}{}_{yx}$	8,28 $^{a}{}_{zy}$	8,45 $^{a}{}_{z}$

$^{a\text{-}e}$ Means with different letters within a column are significantly different at $p < 0.05$.
v-z Means with different letters within a row are significantly different at $p < 0.05$.

The highest TBARS values, measured directly after cooking, were obtained in the control samples without antioxidant. The increase was about four fold compared to raw meat soaked in salt solution, while turkey thigh marinated with rosemary and thyme showed no increase in TBARS values from raw state through marinating and cooking. Meat marinated in rosemary or thyme marinades had the lowest TBARS values; 1.6% and 1.2% of the TBARS value noticed in control samples, respectively. The results demonstrated that marinating with herbs reduced oxidation both during marinating and cooking. However, cooked meat marinated in sage showed significantly higher TBARS values compared with raw and marinated samples and with meat treated with the other herb marinades.

Oxidative rancidity measured as TBARS values increased during storage in all samples. The highest rises in TBARS over time were seen in the control samples without added antioxidant. Meat from the rosemary marinade had the lowest TBARS values throughout the storage period although the development in oxidation increased continually. TBARS values in meat marinated with thyme, sage and BHA also increase during storage, but the TBARS values were significantly higher than those with rosemary. BHA had the lowest stabilising effect among the antioxidants.

Hexanal, a typical off-flavour volatile is often used as an indicator for lipid degradation and rancidity. In raw and marinated turkey thigh meat the amount of hexanal was negligible until cooking (results not shown). After cooking and later during chill storage, the amount of hexanal increased considerably especially in the control samples. The rosemary decoction was most efficient in retarding the formation of hexanal.

The PCA showed that the two first principal components described 81% of the variation between samples treated with different marinades. The loading plot (Fig.1) illustrates contributions of the scaled variables to the PCs. The first principal component appears to be composed of spicy and acidulous flavour together with juiciness on one side. These variables were highly correlated to each other and gave high negative loadings. On the opposite side, rancidity attributes like rancid and metallic flavour, TBARS and hexanal as well as hardness contributed to the positive loadings. The second principal component was mainly related to bitter flavour. The pattern in the score plot showed that control samples were strongly related to the variables describing development in oxidation while the meat marinated with decoction of herbs, especially rosemary, had high scores for spicy and acidulous flavour. However, the turkey thigh marinated with rosemary was assessed as the most bitter among the samples.

Conclusions

Utilisation of herb decoctions may have a great potential in the catering sector in order to prevent the development of rancidity in stored heat-treated meat products. This study showed that decoctions, as by-products from distillation of essential oils, could be used as a source of antioxidants in marinades. However, procedures need to be standardised, and the decoction should undergo further processing before being used commercially.

Background

Meat color, visible fat content and odour are variables that the consumers judge at the time of purchase. However, when meat is being consumed, tenderness, juiciness and flavour became the main characteristics. Meat quality, as a general concept, is difficult to define, because it can have different meanings for different consumers. Given this consumer behaviour variability, it is not common to study this concept based on just one characteristic of meat quality. Instead, it should be considered on a broader manner, taking into account a number of characteristics measured objectively. Despite of this approach of scientific studies, one must consider that for consumers, the general concept or impression is what really matters (Purchas, 1994). In the actual export markets under high competitive pressure and particularly in the food industry around the world, marketing strategies have to be based on solid scientific means to certify and assure food safety and product quality. It is also known, that other attributes associated with the environment sustainability, animal welfare and social aspects, where animal are produced, constitute other important aspects of the promotion strategies and development of market niches for each country (Montossi *et al.*, 2003).

Objectives

The purpose of this study was to evaluate the effects of forage legume (*Lotus pedunculatus* cv. Maku, *Lotus subbliflorus* cv. El Rincón, *Lotus corniculatus* cv. Draco and *Trifolium repens* cv. LE Zapicán), condensed tannins (CT) and stocking rates (8 and 12 lambs/ha) on meat quality in Uruguayan Corriedale lambs.

Materials and methods

Description of the experiment

One hundred and twenty eight castrated male Corriedale lambs (9 months old), born in August-September 2000, were used for this study. At the beginning of the experiment, the average liveweight (LW) and condition score (CS) were 23,8 ± 2,1 kg (fasted) and 2,2 ± 0,3 units, respectively. The selected lambs were divided into balanced groups according to LW and CS. Half of the lambs received two oral administrations (0730 and 1730 hours) of polyethylene glycol (PEG; MW 6000) to inactivate CT (2 g of PEG per 1 g of CT), whilst the remaining lambs received oral administration of water. PEG supplementation was used to study the interaction between condensed tannins (CT) and proteins (Jones and Mangan, 1977; Barry and Manley, 1986; cited by Barry *et al*., 2001), because of its capacity to make strong binds with CT.

Animal measurements

Objective parameters of meat and carcass quality were measured on half of the animals (n=64): meat temperature and pH at 1, 3 and 24 hours *pos mortem*, between 12th and 13th rib (*Longissimus lumborum* muscle; LL). The muscle pH was measured using a hand-held pH meter (Orion A 230) with a probe type electrode (BC 200, Hanna Instruments), standardized against two pH buffers (4 and 7). The probe was cleaned with alcohol and rinsed with water between uses. The temperature was determined by a thermometer (Barnant 115) with stainless steel thermocouple (type E). Muscle and fat color measurements were made using a Minolta Colorimeter (model C-10). They were recorded in triplicate from the approximate geometric center of the exposed LL muscle at the 13th rib, after 24 hours *pos mortem*, taking the readings of L*, a* and b* parameters, according to the Hunter system.

A portion of the LL was removed from the left side of carcasses, labeled, vacuum-packaged, and measured for shear force after 10 days of aging at 2 - 4 °C. The samples were cooked by immersion within a plastic bag in a water bath at an internal temperature of 70°C for 75 min. The internal temperature was monitored using type E thermocouples placed in the approximate geometric center of the sample. Six cores (2,54 cm in

diameter) parallel to the muscle fiber orientation were removed from each sample. A single peak WBSF measurement was obtained for each core using a WBSF machine (G-R Electric Manufacturing Co, Manhattan, KS). Individual-core peak shear force values were averaged to assign a mean peak WBSF value to each sample. Further procedures concerning measurements have been described in Montossi *et al.* (2003).

Statistics

The animal information was analyzed using the statistical package SAS (SAS, 2000), based on Split-Split-Plot design using 2 blocks, with the 4 forage species (*Lotus corniculatus* cv. INIA Draco, *Lotus pedunculatus* cv. Maku, *Lotus subbiflorus* cv. El Rincón and *Trifolium repens* cv. LE Zapicán), being the main plot arranged in a 2 x 2 factorial structure. Stocking rate (SR; 8 or 12 lambs/ha) was treated as the split-plot factor, while PEG (CT inactivated or activated) was used as the split-split-plot factor. All data were initially tested for normality and homogeneity of variance. Before the statistical analysis was performed, some variables (tenderness, temperature, pH, meat and fat color) were normalized by 3√, Ln or 1/Ln correction factors. Liveweight gain (LWG) was adjusted by covariance for initial live weight. Carcass fatness (estimated by GR point) was evaluated using hot carcass weight (HCW) as a co-variate.

Results and Discussion

Animal performance and carcass quality

Animal performance and carcass quality traits are presented in Table 1. Lambs grazing *Trifolium repens* cv. LE Zapicán (white clover; WC) reached the highest liveweight gain (LWG; g/d), intermediate values were found for *Lotus corniculatus* cv. INIA Draco (D) and *Lotus pedunculatus* cv. Maku (M) lambs, and the lowest value was for lambs grazing on *Lotus subbiflorus* cv. El Rincón (R) swards. These results of LWG between animals grazing different species caused differences in final liveweight (FLW), hot carcass weight (HCW), cold carcass weight (CCW) and fat cover (GR). Stocking rate (SR) affected animal performance and carcass traits, where animals of the lower SR obtained higher values than animals of higher SR. PEG supplementation did not affect these variables, probably caused by the high quantity and quality of the forage offered (Barry *et al.*, 2001).

Meat quality

It is desirable to decrease muscle temperature after slaughter in order to reduce the losses of proteins and to inhibit bacterial growth, but this reduction has to be slow to prevent muscle fibre shortening (cold shortening)(Brito, 2002). Table 2 shows the results of muscle temperature and pH at 1, 3 and 24 hours *post mortem*. Spp affected significantly temperature at 1 and 3 hours. Despite the differences found between SR in fat cover (GR), there was no effect of this factor on the reduction of the temperature *post mortem*, probably caused by the small differences shown. PEG supplementation did not affect temperature measurements. Muscular pH of alive animals is between 7.1 and 7.3, reducing itself down to 5.5-5.7 at 48 hours *post mortem* (Garrido and Bañón, 2000). In this study, the differences recorded in temperature at 1 and 3 hours between forage species did not cause *Longissimus lumborum* pH differences (1, 3 and 24 hours *post mortem*). SR and PEG supplementation did not affect pH measurements.

Consumer preferences are greatly affected by meat tenderness, being considered as the most important characteristic of meat quality and determinant of the repetition of purchasing (Brito *et al*., 2002). Tenderness results, obtained by shear force measurements (SF; kgF) of *Longissimus lumborum* muscle, were not affected by the effect of any of the evaluated factors (Table 3). These results could be due to the similar pH and temperature reduction shown by the different treatments (Brito *et al*., 2002). Anyway, the small differences found between treatments applied on tenderness, are strongly influenced by the experiment protocol used to determine the value of shear force, which includes 10 days of meat ageing. This process allows the tenderization of the muscular fibers, reducing existing differences caused by initial meat tenderness or some processes applied pre, during or after slaughter (Brito *et al*., 2002). Camesasca *et al*. (2002) did not find differences in meat tenderness despite the differences in temperature and pH. This suggests that the 10 days of ageing at 2-4 °C would explain these results, given the importance that this process has in reducing differences in meat tenderness (Brito *et al*., 2002; Koohmaraie *et al*., 1995, cited by Camesasca *et al*., 2002).

The findings on temperature, pH and tenderness (Tables 2 and 3), are similar to those obtained by Brito *et al*. (2002) for lamb carcasses (male and females) of different genotypes and less than 12 months old, reared with different nutritional regimes under grazing conditions. In the case of pH, the values are also similar to those obtained by Wheeler and Koohmaraie (1994). Both factors, in addition to the ageing process, and the high liveweight gains during the experiment, could be explained by the low values of SF obtained, which were very similar to those reported by Camesasca *et al*. (2002). Bickerstaffe (1996), cited by Brito *et al*. (2002), suggested that the values of lamb meat tenderness standardized by the meat industry of the United States and New Zealand, to maintain or access to new markets, has to be less than 5 kgF in terms of shear force.

According to the results obtained in the present experiment, these animals would be eligible to those important markets. Adams and Huffman (1972), cited by Osório and Sañudo (1996), reported that the meat color is one of the most important consumer attributes, and is the most relevant quality factor that the consumer considers at the time of purchase. Color of meat is affected by pre-slaughter (animal species, age, sex and feeding system, etc, Albertí, 2000), as well as post-slaughter factors (cooling conditions, pH reduction, etc.; Brito *et al*., 2002). Table 4 shows the results of the effect of Spp, SR and PEG on muscle and fat color. Spp and PEG did not have a significant effect on the parameters of lightness (L*), relative redness (a*) or yellowness (b*) of muscle. However, SR significantly affected muscle lightness (L*m), being higher in the SR of 12 lambs/ha, but did not affect the parameters a* and b*.
Channon and Leury (1992), comparing different diets (*Trifolium yannicum vs. Lolium rigidum*), did not find differences on muscle pH (*L. lumborum*) and lightness, but the treatments affected parameters a* and b*. In another work made by the same authors, animals fed at maintenance level and well fed later, did not show differences in meat color in comparison with animals without restrictions. Due to the lack of information gather from R treatment in fat color, the comparison is restricted to the remaining treatments. The parameters of fat a* and b* did not show differences of statistical significance between the evaluated factors. On the other hand, L* was affected significantly by forage species, but not by the remaining evaluated factors. WC achieved a higher value than M, and D did not have differences with both species. The values of muscle and fat L*, a* and b* are similar to the results reported by Brito *et al*. (2002) in Uruguayan national evaluations on lambs with different nutritional regimes.

Conclusions

For the conditions imposed in this study, under grazing conditions with adequate feeding levels and meat aging period of 10 days, lambs meat quality attributes were not substantially affected by the type of legume, feeding regimes and PEG supplementation used. The values of temperature, pH and tenderness found in this study, and those provided by Montossi *et al*. (2003) in a national sheep meat quality audit, suggest that the meat produced by these Uruguayan Corriedale lambs would be eligible to the most important external markets.

EFFECT OF HIGH PRESSURE TREATMENT AND SUBSEQUENT STORAGE ON THE COLOUR OF A BEEF PUREE

Bruce Moss, Donald E Johnston, William D Graham & Eileen M Stewart

Food Chemistry Branch, Agriculture, Food & Environmental Science Division, Department of Agriculture & Rural Development (DARD) for Northern Ireland, Newforge Lane Belfast BT9 5PX, UK.

Background

The effects of high pressure on meat have been reviewed by Cheftel and Culioli (1997) and include changes in muscle ultra structure, denaturation of proteins, inactivation of microorganisms and extension of shelf-life. The colour of meat depends on the amount and type of heme pigment, and the scattering properties of the meat (MacDougall 1983). High-pressure treatment of myoglobin solutions has been shown to result in partial denaturation with later renaturation (Defaye *et al* 1995). The effect of high-pressure treatment on myoglobin solutions depends on the temperature at which pressure treatment occurs. Zipp and Kauzmann (1973) did not observe denaturation of myoglobin below 225 MPa at 20°C, and Ooi (1994) did not observe denaturation until 500 MPa at 10°C. Carlez *et al* (1995) found increases in L* values and decreases in a* values when minced beef was pressure treated above 350 MPa at 10°C. High-pressure treatment is undertaken on vacuum packed meat and it is well established that when vacuum packs are opened the myoglobin oxygenates to oxymyoglobin. Thus given the partial denaturation reported by Defaye *et al* (1995) it is important to standardise colour measurement at a set time after opening of the vacuum pack of pressure treated meat.

Objectives

The purpose of this study was to compare the effects of high-pressure treatment at different temperatures followed by storage on the CIELAB colour values of vacuum packaged beef puree samples.

Materials and methods

Fresh minced beef was purchased from a local supplier in Belfast. The beef was mixed thoroughly to give a homogenous sample. A total 180 beef puree samples, each weighing approximately 100 g and formed into 5 cm sided cubes, were prepared after which each sample was placed in a sterile polyethylene/polyamide vacuum pouch, vacuum packed and stored overnight at 1ºC prior to high pressure treatment.

Samples were pressure treated in a Stansted Foodlab 900 high pressure isostat capable of operating at 900 MPa (Stansted Fluid Power Ltd., Stansted, UK). The pressure transmission fluid was a 10% vegetable oil in water emulsion. A submerged thermocouple was used to monitor the temperature of the pressurisation fluid during treatment. The pressure come-up time using this system was approximately 300 MPa per min and the pressure release time was 4.5 s per 100 MPa. The temperature increase due to adiabatic heating was approximately 2.5°C per 100 MPa. The puree samples were given pressure treatments of 100, 300 and 600 MPa or left untreated to serve as controls. Pressure treatment was carried out at temperatures of 5, 20 or 40ºC. Samples were treated at each pressure/temperature combination for 15 min. For each pressure treatment, 15 samples were treated at each temperature to give a total of 45 samples. Following treatment, colour measurements were carried out on three samples from each pressure/temperature combination. The reflectance spectra of the vacuum packs were measured immediately after opening and again at 45 min post-opening using a Monolight spectrophotometer and CIELAB values calculated (Moss *et al* 2000).

Results and discussion

High-pressure treatment had a statistically significant effect on all CIELAB colour parameters both on initial opening and after 45 min post-opening. In general, changes in CIELAB values were not observed until pressure treatment was applied at 300 MPa and above (Tables 1 & 2). These results are similar to those of Carlez *et al* (1995) who observed increases in L* from above 200 MPa and decreases in a* particularly above 400 MPa when minced beef was treated. Carlez *et al* (1995) observed little change in b* values with increasing pressure treatment, whereas in the present experiment b* values on initial opening increased with

pressure treatment above 300 MPa, whereas after 45 min opening only the b* values at 300 MPa were significantly different. Carlez *et al* (1995) undertook colour measurements 10 min post-opening with pressure treatment carried out at 10°C which could explain some of the differences observed, although in the current studies the temperature at which the meat was pressure treated had little effect on CIELAB unless at 40°C (Fig 1). O'Connor (2001) studied the effects of combination pressure/temperature treatments on both colour and microbiological shelf-life and showed that, in general, combination of high pressure with higher temperature resulted in greater inactivation of microorganisms.

The main effect of storage was an increase in L* values and decrease in a* values with storage time on both the initial opening and 45 min later. The major effect was seen between 0 and 2 weeks storage. The statistically significant interaction between pressure treatment and storage (Tables 1 and 2) shows that for a* values, in particular, the decrease between 0 and 2 weeks storage was greater for the 300 and 600 MPa treatments than for the control and 100 MPa treatments (Fig 1).

The effect of storage of beef in vacuum packs on colour values has been studied extensively. In the current studies the potential for the meat puree to oxygenate ('bloom') is evident at all storage times as indicated by the higher a* values in the packs 45 min post-opening (Fig 1). Studies on myoglobin solutions have shown denaturation occurs at 500 MPa at 10°C (Ooi 1994) and 350 MPa at 30°C (Taniguchi *et al* 1994). It has been suggested that the effect of pressure on myoglobin was similar to denaturation by heat, with spectral changes indicating the 6th co-ordination position (water for myoglobin) was replaced by imidazole group of histidine (Zipp & Kauzmann 1973).

In intact meat systems the contribution of the meat matrix to colour must be considered, particularly denaturation of myofibrillar proteins, sarcoplasmic proteins and consequently influences on enzyme activity (Govindarajan *et al* 1977). Studies on the effect of high-pressure individual proteins have shown a number of changes including aggregation of myosin (O'Shea *et al* 1976) and disaggregation of actomyosin (Ikkai and Ooi 1969). Changes in a number sarcoplasmic proteins and enzyme activity have also been observed (Cheftel and Culioli 1997). The paler appearance and higher L* values of PSE pork are due to an increase in the scattering coefficient (McDougall 1983).

In these studies the $^{k}/_{s}$ ratio at 730 nm decreased due to high-pressure treatment from 0.41 and 0.48 at 0 and 100 MPa to 0.15 at both 300 and 600 MPa. This decrease indicates general denaturation of the meat protein matrix and consequent increase in scattering coefficient, since at 730 nm absorption due to myoglobin is low (Millar *et al* 1996). The $^{k}/_{s}$ ratio at 525 nm shows a similar trend (3.2, 3.7, 1.4 and 1.4 at 0, 100, 300 and 600 MPa, respectively). Since 525 nm is generally considered to be the isobestic form of the myoglobin, oxymyoglobin and metmyoglobin (Millar *et al* 1996), any denaturation of myoglobin should have little effect on the absorption coefficient. Thus, the increased $^{k}/_{s}$ ratio at 525 nm is also indicative of a general increase in scattering coefficient. The colour of meat depends on oxygen penetration into the meat and the formation of oxymyoglobin in bloomed meat. The darker appearance of DFD meat and greater contribution of myoglobin to the observed colour is due in part to the lower scattering coefficient of high pH meat. Thus conversely, an increased scattering coefficient due to high pressure would result in a greater contribution of the outer surface to the observed appearance/measured surface reflectance. It might be expected that high pressure treated spectra show a more oxymyoglobin type spectra. Further detailed evaluation of the reflectance spectra at the meat surface and at depths through the meat is required to evaluate this.

Conclusions

High-pressure treatment of beef puree results in changes in CIELAB colour values. Increased L*, decreased a* were found at 300 MPa and above, but were not evident at 100 MPa. The results indicate that the myoglobin is not completely denatured and the beef puree has the potential to 'bloom' when the vacuum packs are exposed to air. The temperature at which high pressure treatment is undertaken also has an effect on CIELAB colour parameters with higher L* and lower a* values when pressure treated at 40°C. Decreases in a* values with storage are dependent on the pressure treatment used.

CONSUMER PREFERENCES OF PORK CHOPS: RESULTS OF AN INTERNATIONAL CROSS-CULTURAL COMPARISON.

Ngapo, T.M.[1], Martin, J.F. and Dransfield, E.

Propriétés Sensorielles et Préférences, Station de Recherches sur la Viande,
INRA, Theix, 63122 St-Genès-Champanelle, France.
[1]Current address: Agriculture and Agri-Food Canada, Food Research and Development Centre,
Saint-Hyacinthe, Quebec, J2S 8E3, Canada.

Background

The pork industry is competitive at both international and national levels and is responding to consumers' demands and expectations for safe, nutritious products, which conform to their life-styles. With increasing international trade, the industry needs to be aware of different consumer preferences for meat according to their different cultures and traditions. This will be increasingly important for the pork market.

Consumer preferences of pork are based on expectations of enjoyment within a given context. Expectations are perhaps different when the pork is for oneself, others or for a particular meal or event. These contextual differences play a role in the selection of pork and the type of pork to be bought. At the point of purchase, the choice is based on an expectation of good eating quality, an expectation that the pork will be tender and juicy. These expectations are based on information and previous experiences. Choice is therefore based on expectations, price and the appeal of the pork, where appeal is strongly expressed as a preference for the appearance characteristics.

Appearance characteristics of the pork are thought to be the main factors governing choice and comprise the main characteristics: colour, amount of fat cover, marbling and drip. Preferences for pork characteristics have been determined separately in different countries in several local studies but the practical limitations, imposed by the short display-life of meats, make it inevitable that the people in different localities have assessed different meats. The meats also will have differed simultaneously in several of those characteristics and the relative importance of those characteristics is uncertain. The conclusions from such studies are therefore limited when considering the cultural and international dimensions.

These limitations, particularly so when surveying large numbers of people in different countries, have been overcome by using photographs varying systematically in four appearance characteristics. This is the first time a large-scale systematic study has been conducted on meat appearance and consumer preference.

Objectives

- To identify the most important characteristics of fresh pork which determine preference
- To show any variations in preferences among people from different countries

Materials and methods

The methodology and chop characteristics are described in detail in Ngapo *et al.* (2004). Briefly, photographs of 16 pork chops were computer-modified to give two levels of each of the characteristics: fat cover, colour, marbling and drip. The pork chops were purchased at local supermarkets and butcher shops. The resulting 256 (2x2x2x2x16) images have been published as a book (Dransfield *et al.*, 2001), which can be used as a tool for analysing the importance of those factors in consumer choice. The book is comprised of 6 series of which series 1+2, 3+4, and 5+6 each contain all 256 images. A series constitutes 16 (A4) pages or 8 double-pages. Every double-page contains the 16 different chop shapes and each chop represents one of the combinations of the four characteristics studied. Therefore every double-page contains a complete set of all 16 combinations of the 2 levels of each of the four characteristics. Both the order of representation of the characteristics with respect to the chop shape and the position of the chops in a double-page are randomised. It is important to note that the chop shape was not a factor studied, but can be considered a distraction and a means to realistically present a range of characteristics to the consumer.

Consumers, older than fifteen years of age and who eat pork, were chosen at random and asked to select their preferred chop from each double-page. The selection was repeated 8 times completing one series. The consumers then completed a short questionnaire (translated by the research group undertaking the survey into the language of that country) asking basic socio-demographic and purchase- and eating-behaviour information (Table 1). Each new consumer was given a series in the order 1 to 6 so that all series were used approximately equally throughout a survey period. Consumers were surveyed at a range of sites, including agricultural shows, supermarkets and at their workplaces. The surveys were undertaken by 28 research groups in 26 countries and coordinated by the French group. These countries and the number of consumers surveyed in each were Argentina (505), Australia (498), Belgium (353), Brazil (710), Canada (Alberta and Quebec; 1053), China (544), Denmark (200), Estonia (248), Finland (305), France (573), Germany (143), Greece (412), Ireland (300), Japan (645), Korea (1014), Mexico (751), New Zealand (327), Poland (480), South Africa (562), Spain (358), Sweden (200), Taiwan (716), The Netherlands (873), United Kingdom (290), USA (Iowa and Texas; 732) and Yugoslavia (488).

Detailed analyses of the French results have been reported earlier (Ngapo *et al.*, 2002; Ngapo *et al.*, 2004) and, more briefly, the results of the Korean (Cho, *et al.*, 2003) and Brazilian (Cipolli *et al.*, 2003) surveys.

Results

The characteristics of the images of the pork chops used in these surveys are given in Table 1. Visual differences in colour were mainly due to average differences of 8.6 units in lightness (L*) and 5.4 units in redness (a*). Subcutaneous fat cover of the fat chops was, on average, twice that of the lean chops. Drip was either absent or represented almost 6% of the surface area in the samples modified to show drip. Bone and loin muscle area were similar across appearance variables.

Table 1. Mean composition of the 256 pork chop images.

	Light	Dark
Colour L*	64.3	55.7
Colour a*	18.3	23.7
Colour b*	20.8	18.8
(% chop surface area)	Fat	Lean
Cover fat	16.9	7.9
Drip	5.4	5.7
Bone	15.7	16.1
Loin muscle	39.2	43.9

From the results of the 8 replicates given by each person, the frequency of choice for the 4 main characteristics was calculated. For each of the 2 levels of each characteristic, the choice was classed as consistent when the same level was chosen at least 6 times from the 8 replicates, otherwise the choice was deemed inconsistent. Three classes were then produced for each characteristic: with the percentage of people choosing level 1 (for example for colour, light red), level 2 (dark red) and inconsistent (with <6 of the replicates the same choice) for each of the 26 countries.

This frequency of choice was then subjected to a correspondence analysis (SAS, 1999) to determine the relationships among countries of choice for each of the 12 classes (3 frequency classes for 4 appearance characteristics). The first 2 dimensions of the correspondence analysis accounted for 80% of the total variation and are shown graphically in Figure 1. The positions of the countries are given relative to 8 of the choice options (the 4 inconsistent options are not given for clarity, but are included in the analyses). Countries shown close to a given choice have a greater percentage of their people who chose consistently that characteristic as its preferred appearance. Conversely, large distances from a choice characteristic usually denote preference for the other option of the characteristic. Inconsistent choices tend to be found in the central region of Figure 1.

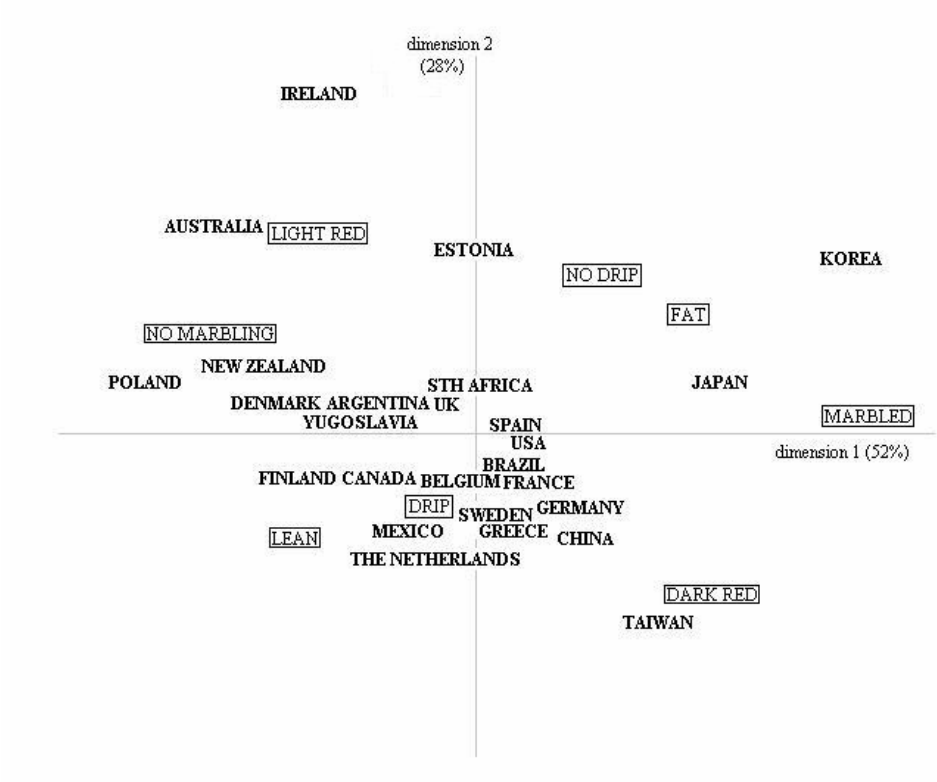

Figure 1. Preferences for 4 pork characteristics from surveys conducted in 26 countries.

Large differences in preferences were found between individuals, groups of people and between countries. Compared to the other consumers, more of the Polish, Australian and Irish consumers preferred non-marbled, light red pork, that is, they are positioned in the upper left quadrant. Those in Estonia preferred light red pork without drip. On the contrary, more people from Korea and Japan tended to prefer the fat and marbled options and are positioned in the upper right quadrant of Figure 1. More people in Taiwan preferred the dark red pork whilst the Dutch and Finnish preferred lean meat with little overall preference for colour. Most countries tended to group close to the 'centre' of Figure 1 showing that preferences for colour, marbling and drip were not strongly in favour of any one option but they were more consistent in their choice of the leaner option.

France, USA and Canada conducted surveys in different regions, and estimates can be made of the within and between country variation. In France, 3 regions were studied (Ngapo *et al.*, 2004), which showed differences in preferences between the regions composed of about 200 consumers each.

Discussion

This unique study of preferences for appearance characteristics, in which consumers in 26 countries viewed exactly the same appearance characteristics, has shown that choice of pork is influenced by its colour, fatness, marbling and drip and that preferences differed considerably between countries. The range of characteristics chosen for the study was not exceptional and can be found in the market within Europe.

Using replicate choices, the study was able to show those characteristics which were consistently chosen and those which were not. This is a unique consumer study conducted with replication, but without the consumers knowing it. Consistency is interpreted as a measure of importance to the individual, who presumably paid more attention to those characteristics to be able to give a consistent choice. So it was shown that, overall, colour and fatness were the most important appearance characteristics and marbling and drip were less important.

Using groups of people from different regions within the same country has also enabled the variation within country to be established which was found to be much less than that between countries.

Conclusions

- Significant differences were found for consumer choice of pork chops based on 4 appearance characteristics. The greatest differences were for external fat cover with preferences for both fat and lean chops differing among countries. The second criterion for selection was for colour where both dark and light red chops were preferred by different people.
- Differences in preference between regions within country were generally smaller than those between many of the countries surveyed.
- Significant market segmentation exists in preferences on a global scale.
- Pork producers should be aware and prepared to respond to such market opportunities.

FRENCH CONSUMER APPRECIATION OF A NOVEL POLISH-STYLE SAUSAGE

Ngapo, T.M.[1], Kubiak, M.S.[2], Batura, J.[2], and Dransfield, E[3].

Background

In Poland, product development of new meat products which are both healthy alternatives as well as novel competitors to the wide range of pork-based products already on the market is being undertaken. Poultry meat is being considered as an alternative using a new source derived from the soft separation of meat and fat from sinew, cartilage and bones, an application employed in the German poultry industry.
After removal of trade restrictions upon entry into an expanded EU, Ploand will likely look to increasing exportation of meat products into European markets. To achieve this successfully, any new meat products must meet the demands and tastes, not only of the consumers in Poland, but also of consumers in these potential new markets.
One such new product, that is a development of a typical Polish pork-based smoked sausage, is a poultry-based cheese-filled smoked sausage. Consumer acceptability of this product is currently being studied in Poland. Its acceptability in other markets which are unfamiliar to similar pork-based products is unknown.

Objectives

The objective of this study was to determine consumer acceptability of a novel Polish cheese-filled, smoked poultry sausage in France.

Materials and methods

Sausages were made in Olsztyn, Poland from a combination of turkey, goose and ostrich meats and transported to France in a chilled state. The turkey meat had been obtained using a Baader soft separator machine (Baader 1200-ST, Lubeck, Germany). The sausages that did not have any added fat, were formed with cubes of a low-fat cheddar-type cheese and smoked. For comparison, to be used for French consumers, 3 other types of sausages, of similar diameter, were bought from a French supermarket: a pork chipolata, a pork frankfurter and a poultry frankfurter with a cheese centre (containing a cheese was similar to sour cream).
A total of 72 consumers from the Clermont Ferrand region in Central France tasted the sausages (in April and May, 2003) after completing a questionnaire asking basic socio-demographic information. The consumers were told that some new sausage products were to be tasted and that two contained cheese. No information of the origin of the products, or their contents was given. The sausages were cooked on a plate grill with frequent turning and presented monadically to the consumer. The order of presentation was determined using Latin-square. Consumers were asked to score the acceptability of each product on a 12.5 cm scale from “I don’t like at all” to “I like a lot”, with a given midpoint. The consumers were encouraged to write comments.
The acceptability results were analysed by ANOVA and differences between sausage types compared using students t-test. A hierarchical cluster analysis was undertaken using the SAS CLUSTER procedure (SAS, 1996). Three clusters were evident considering the ‘distance’ between clusters and the profile of the resulting graph. A disjoint cluster analysis was carried out using the SAS FASTCLUS procedure (SAS, 1996) forcing the consumers into the 3 different clusters.

Results and discussion

Acceptability differed significantly (P<0.0001) among the products for the entire panel (Table 1). The cheese-filled smoked sausage was the least acceptable overall with an average score of 3.9 compared to the most acceptable product, the chipolata with an average score of 5.8.

Table 1. Acceptability scores of the sausages.

	Mean (maximum 10)	Standard deviation
Chipolata	5.83	2.38
Frankfurter	4.73	2.72
Cheese-filled frankfurter	4.58	2.67
Cheese-filled smoked sausage	3.90	2.92

Paired comparisons (Table 2) showed that the cheese-filled smoked sausage was less acceptable than the chipolata and the frankfurter (P<0.05), but equally as acceptable as the cheese-filled frankfurter.

Table 2. Differences in acceptability scores of the sausages.

	Pr > |t|
Chipolata vs frankfurter	0.0062
Chipolata vs cheese-filled frankfurter	0.0018
Chipolata vs cheese-filled smoked sausage	<0.0001
Frankfurter vs cheese-filled frankfurter	0.6939
Frankfurter vs cheese-filled smoked sausage	0.0360
Cheese-filled frankfurter vs cheese-filled smoked sausage	0.0876

Of the 72 consumers in total, 42 of them made 149 written comments which are summarised as negative comments, such as “horrible smoky flavour” or “too fatty”, or positive, including “interesting new idea” or “good level of fat” (Table 3). Although the sample size was relatively small and therefore extension of this work to the entire French population can only be undertaken with extreme caution, it was clear that most of the comments were negative (62%) with 34 consumers commenting negatively, and in particular, about the smoked nature (14) or the fatness (15) of the cheese-filled smoked sausages. No equivalent smoked sausage could be found in France and these comments may derive from its unfamiliarity. The sausage was made without added fat, but using a low-fat cheese which exuded a lot of oil upon cooking. The presence of the melted cheese could have contributed to the fatty perception of the sausage. Negative comments related to fatness also for the frankfurter (8) and the chipolata (10) and to a lack of taste for the cheese-filled frankfurter.

Table 3. Number of consumers giving comments about the sausages.

	Cheese-filled Smoked		Frankfurter		Chipolata		Cheese-filled Frankfurter	
Nature of comment	negative	positive	negative	positive	negative	positive	negative	positive
Consumers commenting	34	13	19	11	20	17	23	12
Fat	15	1	8	1	10	6	3	2
Taste	1	4	4	10	1	13	5	4
Texture	9		7	2	1	5	3	4
Colour	3		6	1	6	3	6	
Smoky	14		2				2	
No taste	1		2		4		9	
Smell	3		3	2		3	2	3
Salt	5		2	1	3	1	1	
Artificial	1		4		3		3	
Novel		8						3
Appearance	1			1	1	3	2	2
After-taste/acid	5							
Traditional/rustic		3				1		

The next step was to try to determine whether or not differences between the acceptability of products could be related to different consumers. For this, a cluster analysis was undertaken on the acceptability scores and three approximately equal sized clusters were retained (Table 4).

Table 4. Mean acceptability scores of the sausages (maximum 10) for each cluster with the significant differences within a cluster represented by different letters (P<0.05).

	Cheese-filled Smoked	Frankfurter	Chipolata	Cheese-filled Frankfurter
Cluster 1	5.8 [b]	5.8 [b]	7.4 [a]	6.1 [b]
Cluster 2	2.2 [b]	2.0 [b]	5.7 [a]	2.0 [b]
Cluster 3	2.9 [b]	5.6 [a]	3.5 [b]	4.8 [a]

Comparing acceptability scores within each cluster of consumers (Table 4), it can be concluded that:

- Cluster 1: 26 consumers (36%) who prefer chipolata, but like all four products
- Cluster 2: 23 consumers (32%) who prefer only the chipolata, (they do not like the other products)
- Cluster 3: 23 consumers (32%) who prefer the frankfurter products (both with and without cheese)

The socio-demographic questionnaire and responses are given in Table 5. The ages of the consumers were well distributed among the age group and 44% of the consumers were men. A large proportion of the consumers were in the lower income groups (<2300 Euros/month) and 63% were married.
To identify characteristics from the socio-demographic profiles relating to consumer acceptability, a chi-square test was applied to each response within each cluster of consumers. The results (degrees of freedom and probability) are given in Table 5 and show that the only socio-demographic characteristic significantly (P<0.025) linked with the consumer clusters was that of 'shopping for meat in the supermarket'. Cluster 1 consumers, who liked all the products, and in particular, the chipolata, did not shop for meat in the supermarket whereas a quarter of the consumers in the other two clusters did shop in supermarkets (Table 6). This result is in contrast to the traditional view that the novelty seekers buy their "trendy" foods at specialist stores or large supermarkets. Instead, the traditionalists who buy their meat at butchers are those that most liked the new smoked cheesy sausages.

Table 6. Relationship between shopping for meat in the supermarket and the clusters of sausage acceptability. Significant differences compared to the entire sample are shown in bold (P<0.05).

	Shop for meat in the supermarket	
	Yes	No
Cluster 1	**0**	100
Cluster 2	26	74
Cluster 3	23	77
Total	16	84

Conclusions

While the sample size was relatively small and therefore extension of this work to the entire French population can only be undertaken with extreme caution, this project has shown that the French consumers studied did not find the cheese–filled smoked sausage acceptable, in particular the smoky and fatty nature of the sausage were disliked. The poultry-based smoked sausage is similar to pork-based smoked sausages familiar to the Polish consumer. However, the added cheese is a novel concept in the Polish market and therefore the acceptability of these products is also being investigated in Poland.

MONITORING ACCELERATION (G-FORCE) DURING ANIMAL TRANSPORTS

Nøddegaard, F.[1] and Brusgaard, N.[2]

[1]Department of Pork and Beef Quality, Danish Meat Research Institute, Maglegårdsvej 2, DK-4000 Roskilde, Denmark
[2]Larsen and Brusgaard Aps, Mosevej 3, DK-4070 Kirke Hyllinge, Denmark

Background

Transport to the abattoir may stress animals (Bradshaw et al. 1996) and affect meat quality (Lehenska et al. 2002). One potential stressor is the motion of the truck. Vibration leads to increased heart rate (Perremans et al. 1998), increased plasma levels of cortisol (Perremans et al. 1995; Perremans et al. 2001), beta-endorphin (Perremans et al. 1995), and adrenocorticotropic hormone (Perremans et al. 2001). Vibration is also believed to be the reason why pigs develop motion sickness with vomiting (Randall and Bradshaw, 1998), whereas acceleration can cause animals to loose balance and receive injuries. The physical and physiological reactions of the animals during transport have a strong impact on the energy consumption within individual muscles, which in turn has strong implications for the quality of the final meat product (Rosenvold & Andersen, 2003).

Objectives

It is the objective to develop a monitoring system of G-force / vibration on animal transports fully integrating data on vehicle speed, road type, and balance of the animals on the truck. The system should be able to save data for evaluation and documentation. Also the system should be prepared for future modifications allowing the system to provide on-line alarms to the driver when certain pre-set G-force values are exceeded.

Materials and methods

Based on LabView software from National Instruments Corporation a programme ('G-force Viewer') was developed. 'G-force Viewer' integrates the information into a screen display that simultaneously shows data for G-force ('G-logger'), vehicle speed (GPS), animal balance (video camera), road type (video camera) and altitude ('G-logger').

A tri-axis G-force logger ('G-logger') was developed. The 'G-logger' constantly measures G-forces in all three axis and calculates the resultant G-force. It also measures barometric pressure that can be converted into altitude. The unit can store data up to 200 times per second.

Two units of the 'G-logger' were tested on a real pig transport on a fully air suspended three-axel truck (photo). The 'G-loggers' were set to log 100 times per second (100Hz). Each logger was placed on the rubber-coated floor and a 15 mm thick polyethylene foam was placed on top of the logger before a metal protective casing was firmly pressed down over it. The casing was fastened by four screws through the rubber layer and into the underlying aluminium floor. In this way it was believed that the 'G-logger' would fairly realistically record the vibrations / G-forces that the pigs are subjected to through their contact with the rubber floor. One 'G-logger' was mounted in the rear pen. This logger was placed 94 cm from the rear end; 151 cm aft of the rearmost axel and 274 cm aft of the central pivotal point of vertical movements. The central pivotal point was estimated to be half way from the fore axle to the centre point between the two rear axles (see photo). Another 'G-logger' was mounted in the pen located directly over the central pivotal point.

A video camera (Sony DCR-TRV10E) equipped with a wide-angle lens was mounted over the pigs in the rear pen in which the floor area per 100kg pig was 0.42 m^2. Another camera was mounted in the driver's cabin filming out the windscreen. A Global Positioning System receiver (Garmin eTrex Summit GPS) was used to record vehicle speed and location.

The test drive was intentionally made on secondary roads to get a picture of the worst scenario for transport conditions in Denmark. With very few exceptions the roads were paved.

Results and discussion

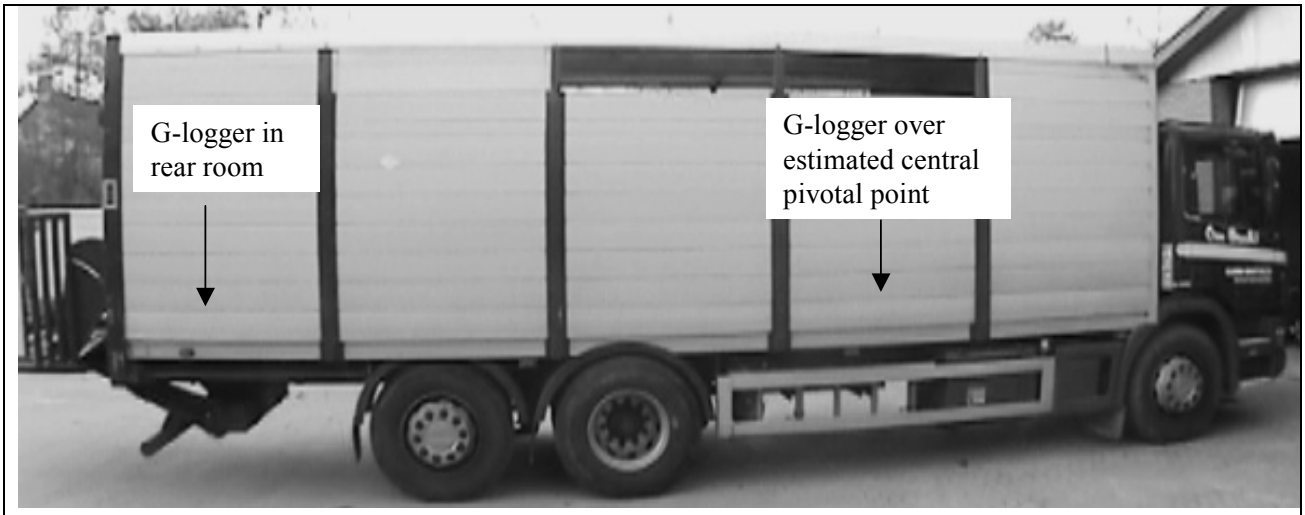

Photo. Truck used for the test of 'G-loggers'. Scania P94 6x2, OptiCruise automatic gear. Fully air suspended. The truck was loaded with approximately 5 tons of pigs.

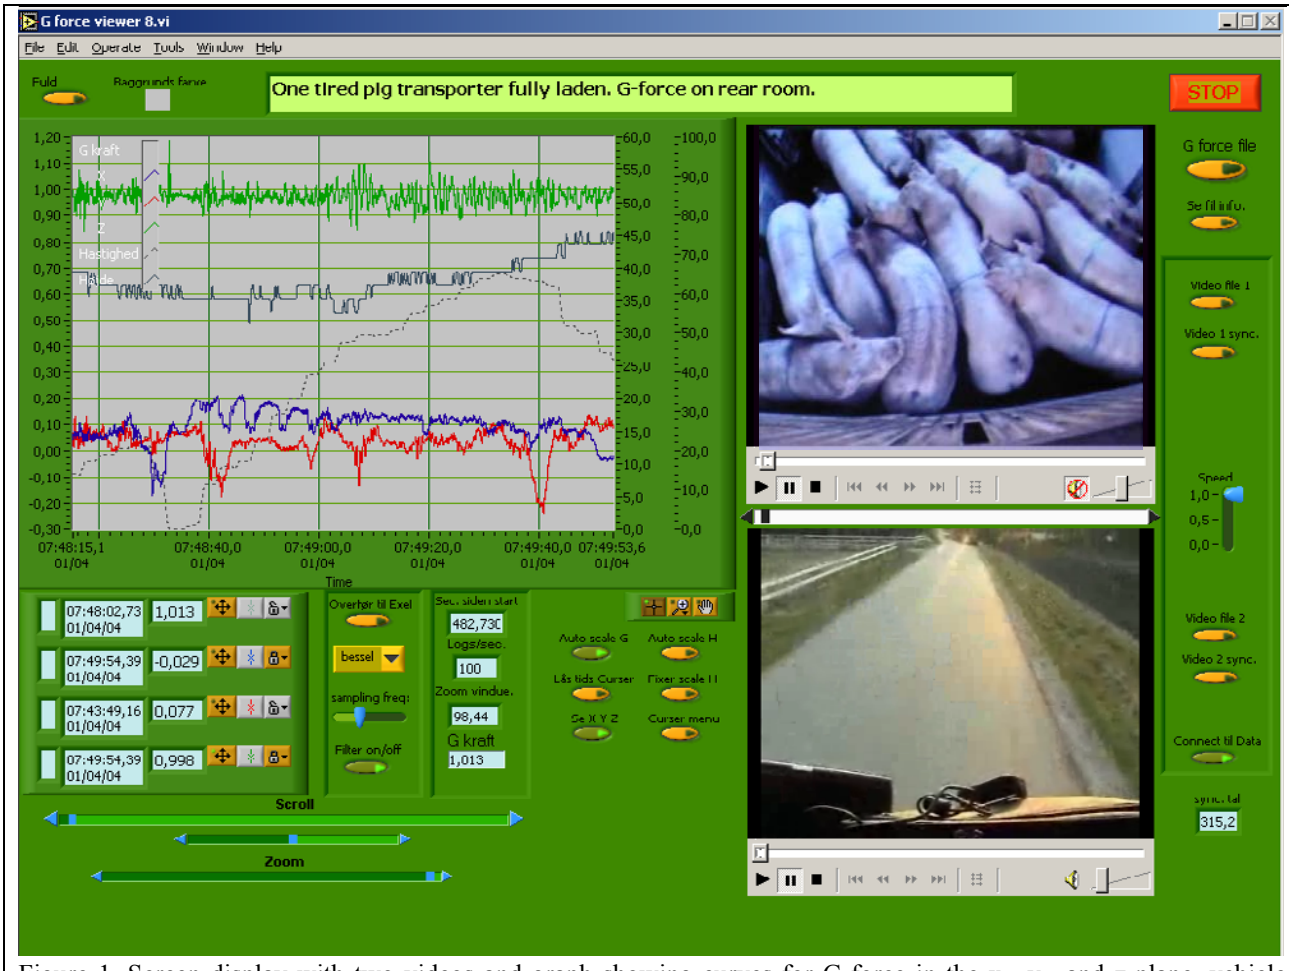

Figure 1. Screen display with two videos and graph showing curves for G-force in the x-, y-, and z-plane, vehicle speed, and altitude. The graph for the resultant force has been omitted for clarity. Data from rear pen. 1st order Bessel low pass filtered.

G-force measurements. Figure one is a screen display from the 'G-force Viewer' showing 1 minute:38 seconds of the test drive. Figure two shows another screen display from the same part of the test drive. Most imbalances of pigs seem to be caused by roundabouts as these caused repetitive shifts in direction of G-forces in two planes i.e. 0.4G laterally due to turns, and 0.3G for-aft due to acceleration and de-acceleration. When travelling at 70 km/h and maximum brake was applied - triggering the ABS anti-blockage system - the

G-force in the fore-aft direction (**X**) was 0.6g. With a loading density of 100 kg per 0.42m^2 this braking forced pigs forward in the pen and the ones not leaning against anything lost their balance - this happened again when the brake was released or when the truck came to a complete halt. Other loading densities would obviously have given different results. G-force in the vertical plane had negligible effects on balance.

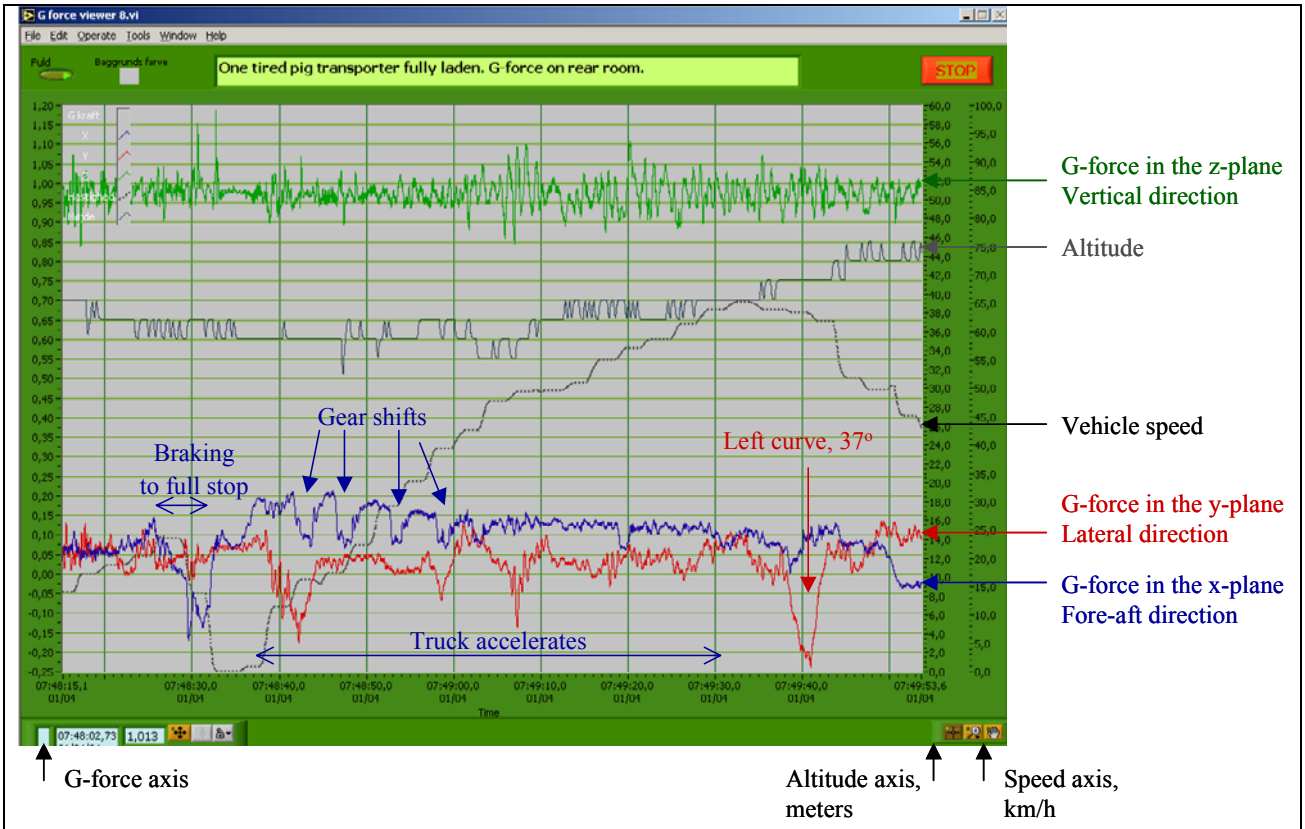

Figure 2. Screen display with only graphs. Data from rear pen. 1st order Bessel low pass filtered. The graph for the resultant force has been omitted for clarity.

Vibration measurements. The raw unfiltered G-force data (figure 3) reveals that in the vertical plane G-forces of ultra short duration (<3/100 second) of up to 3G occasionally occurred. However, this also happened occasionally when the fully laden truck was stationary leading to the conclusion that it was caused by the movements of the pigs. Probably when a pig stepped on the 'G-logger'. Ultra short peaks will probably have only minor effects on the pigs.

At a vehicle speed of 60 km/h the prevailing vibration frequency was 25-33 Hz with an amplitude of 0.05G in the lateral direction (**Y**); 25-33 Hz with an amplitude of 0.1G in the fore-aft direction (**X**); and 20-25 Hz with an amplitude of 0.2-0.4G in the vertical direction (**Z**). With reference to human vibration studies (Griffin, 1990; BSI, 1987), Randall et al (1995) speculated that pigs would feel less discomfort at these frequencies than at lower frequencies. With piglets Perremans et al (2001) found that - with regard to short durations (less than one hour) of vertical vibration - higher frequencies (18Hz) are less stressful than lower frequencies (2-8Hz). Since the prevailing vibration recorded in the current test was predominately of sinusoidal nature, the vertical amplitude of 0.2-0.4G can be estimated to correspond to 1.4-2.8 m/s^2 RMS (Griffin, 1990 p 468) and thus well below the maximum RMS value of 3 m/s^2 recommended by Perremans et al (1998). The effect on pigs from lateral vibration is unknown. With exception of the fore-aft direction (X) the vibration during driving conditions on the fully laden truck resembled the vibrations recorded on the stationary empty truck with the engine running. Thus the vibrations are caused by the engine. In the X-direction very little vibration occurred on the stationary empty truck with the engine running.

Conclusions

The 'G-logger' and the 'G-force viewer' provide easy to use tools for measurements of G-force and vibration on pig transporters. With minor modifications it can be used as an on-line alarm system educating the driver.

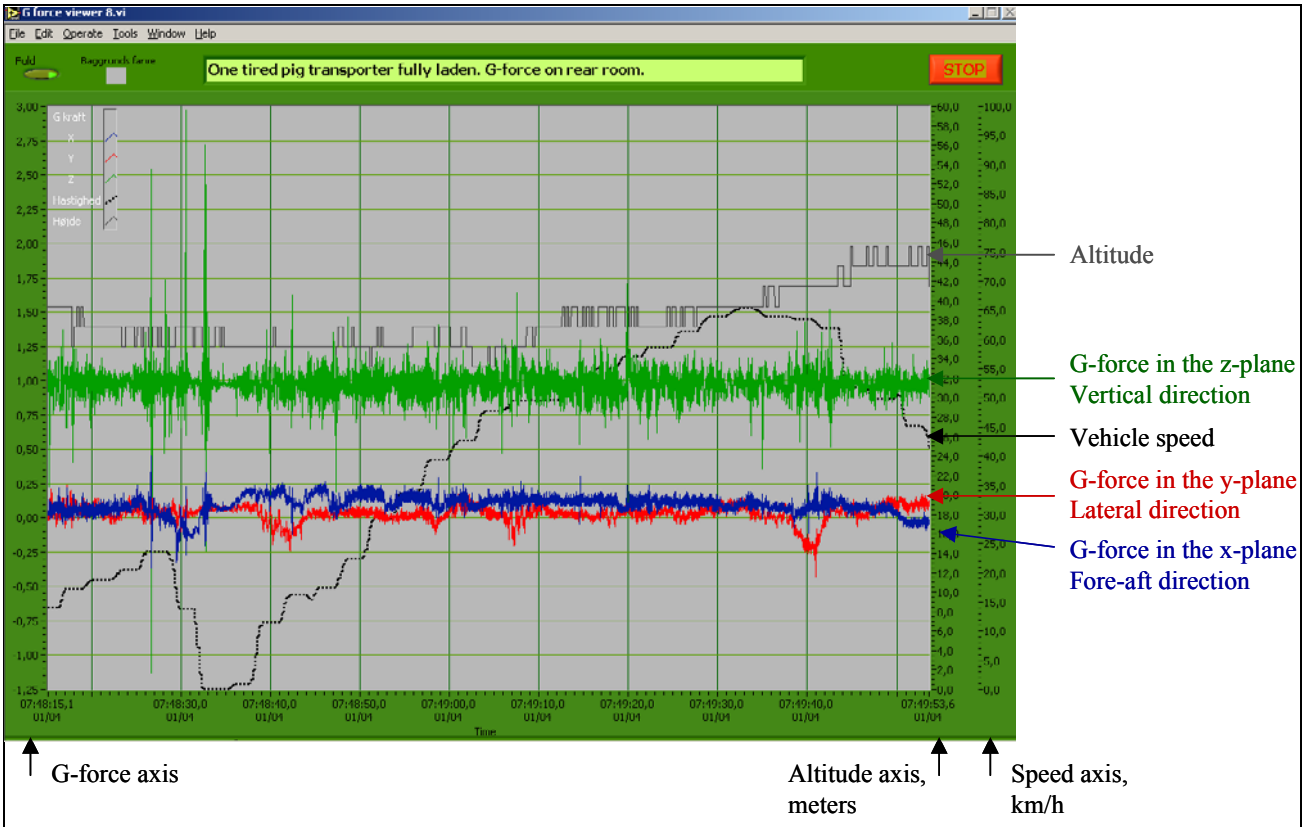

Figure 3. Screen display with only graphs. Data from rear pen. Raw data without filter. The graph for the resultant force has been omitted for clarity.

EFFECT OF LINSEED AND GRASS FEEDING ON THE FLAVOUR PROFILE AND TASTE-PANEL EVALUATIONS OF BEEF FROM BELGIAN BLUE DOUBLE-MUSCLED BULLS

Raes, K.[1], Claeys, E.[1], De Winne, A.[2], Dirinck, P.[2], Balcaen, A.[1] and De Smet, S.[1]

[1] Department of Animal Production, Faculty of Agricultural and Applied Biological Sciences, Ghent University, Proefhoevestraat 10, 9090 Melle, Belgium;
[2] Chemical and Biochemical Research Centre (CBOK), Department of Chemistry and Biochemistry, KaHo St-Lieven, Gebroeders Desmetstraat 1, 9000 Gent, Belgium

Background

Nowadays, a lot of research is performed aiming at increasing the n-3 polyunsaturated fatty acid content (PUFA) of meat to better meet human nutritional guidelines with respect to the P/S and n-6/n-3 ratios. Increasing the n-3 PUFA content of beef can be achieved by feeding fish oil/algae, linseed (oil) and/or grass or grass silage to cattle (see review Raes et al., 2004). However, it has been demonstrated that increasing the n-3 PUFA content may affect meat flavour. This effect seems to depend on the n-3 PUFA level in the meat and the feed source. Beef from grass-fed animals may elicit a typical grass-like flavour (Melton, 1990). Both C20:5n-3 and C22:6n-3 may cause an undesirable fishy flavour above certain levels, which is observed by consumers after heating the meat (Mottram, 1998). Also the heating method affects flavour profiles, however, most research on beef flavour has been done after moist cooking, and few references are available on flavour profiles of roasted or grilled beef (Elmore et al., 2004; Raes et al., 2003a).

Objectives

The aim of this study was to evaluate the flavour profile of meat from bulls fed a C18:3n-3 rich diet using linseed and/or grass or grass silage. The flavour profile as chemical components was measured by gas chromatography – mass spectrometry. Flavour was also evaluated by a semi-trained taste-panel.

Materials and methods

Experimental design

Thirty-one Belgian Blue double-muscled young bulls (mean (sd) live weight at start 339 (44.4) kg) were fed different feeds aiming at increasing the n-3 intramuscular fatty acid content (as fully described by Raes et al., 2003b), and studying the effects on oxidative stability and flavour of the meat. The animals were divided in 4 groups receiving different diets during three subsequent phases (last growing phase, prefattening phase and fattening phase). The diets differed according to the main fat source in the concentrate as well as in the type of roughage, as shown in Table 1. To increase the n-3 fatty acid content in the muscle tissue, linseed was added as the main C18:3n-3 source in the concentrates, and grass or grass silage as a C18:3n-3 roughage source. Animals were slaughtered at a mean (sd) live weight of 681 (26.3) kg. After cooling the carcasses for 24 h, the *longissimus thoracis* (LT) was sampled for flavour profile analysis, while the LT, *semitendinosus* (ST) and *triceps brachii* (TB) were sampled for taste-panel evaluations. The meat samples were vacuum packed and aged for 14 days at 2°C. After ageing, the samples were stored at –18°C until analysis.

Analyses

Taste-panel evaluations

Sensory characteristics ie., tenderness, juiciness, flavour intensity and flavour preference, were evaluated by a trained taste panel of ten members (22-55 years of age). In the first series of sessions, tenderness and juiciness were evaluated, while in the subsequent series of sessions flavour intensity and flavour preference were scored. All evaluations were performed for all three muscles with the exception that flavour preference of LT muscle was not ranked. Two servings were provided at a session. Each serving included one sample (from the same muscle) of each of the 4 feeding groups. As in Belgium, grilling is a very common heating method for beef steaks**,** samples (3x3x2 cm) were grilled for 2 minutes on a double-contact grill and served on pre-heated plates for sensory evaluation. The panellists were asked to assess tenderness and juiciness on

an 8-point scale. The values of 1 and 8 correspond with extremely tender or juicy and extremely tough or dry, respectively. Flavour intensity and flavour preference were evaluated using a ranking test. The values of 1 and 4 correspond to the lowest and the highest flavour intensity or flavour preference, respectively.

Flavour analysis

For each group, 3 samples of the LT were grilled and extracted using the Likens-Nickerson extraction. The aroma compounds were collected and analysed by gas chromatography-mass spectrometry (GC-MS) as described by Raes et al. (2003a). Semi-quantitative data of the flavour compounds were obtained by relating the peak intensities to the intensity of nonane, added to the dichloromethane phase as an internal standard.

Table 1. Composition of the diets for the different feeding phases depending on the feeding group

	Group C_1 (n = 7)	Group GC_2 (n = 8)	Group GC_3 (n = 8)	Group MC_4 (n = 8)
Last growing phase (70 d)				
Concentrate	----------	+ linseed	----------	– linseed
Roughage		Fresh grass		Maize silage
Prefattening phase (56-98 d)				
Concentrate	-------	+ linseed	-------	+ linseed	– linseed
Roughage		Whole triticale silage		Grass silage	Maize silage
Fattening phase (42-190 d)				
Concentrate	– linseed	+ linseed	+ linseed	+ linseed
Roughage	–	Grass silage	Grass silage	Maize silage
Concentrate/roughage ratio (on DM basis)	100/0	80/20	70/30	80/20

Statistical analysis

Data were subjected to analysis of variance (ANOVA), using Duncan as post-hoc test (SPSS 9.0). Principal component analysis (PCA) was carried out using data of the flavour profile analysis.

Results and discussion

In Figure 1, a PCA bi-plot of the flavour volatiles of the LT muscle and the average feeding group scores are shown. Group MC_4 is situated in an area where little volatiles were found, while group GC_2 show a strong association with derivatives of pyrrol and furan. Group C_1 and group GC_3 are situated in the areas characterised by pyrazines, branched and aromatic aldehydes, saturated aldehydes as well as sulphur containing compounds. In Table 2, the semi-quantitative analysis of the volatile categories is given per feeding treatment. Significant differences between feeding groups were only observed in pyrrol and furane derivatives, while no differences were found for the other volatiles. In grilled products, the pyrazines are important flavour compounds formed by Maillard reaction and Strecker degradation. No differences were observed between the feeding groups in the amount of these volatiles, which is in agreement with Elmore et al. (1999) who reported that the dietary fat source had no effect on the production of pyrazines. Overall, the amount of volatiles formed during heating of Belgian Blue beef is small, and lower compared to that originating from cattle with a higher degree of fat and/or different feeding regime (Raes et al., 2003a).

As it is known that flavour evaluations by a taste-panel can be influenced by differences in tenderness and juiciness, both these parameters were evaluated by the taste-panel. No differences in tenderness could be observed between the feeding groups (Table 3). For juiciness, however, the taste-panel evaluated the LT and TB samples from the groups GC_2 and GC_3 significantly juicier than those from the groups C_1 and MC_4. The analytical flavour profile corresponds to the results observed by the taste-panel (Table 3). Indeed, the taste-panel appointed the lowest flavour intensity to meat from animals of group MC_4, which is in agreement with the flavour profiling (Figure 1), the differences between the feeding groups being small, however.

A non-significantly higher amount of saturated aldehydes was found in the group MC_4 compared to the other groups, due to higher amounts of hexanal ($P = 0.076$) and 2,4-decadienal ($P = 0.128$). Both these volatiles originate from oxidation of n-6 PUFA. A significantly higher amount of 1-octen-3-ol ($P = 0.010$), formed during oxidation of C18:2n-6, was found in group MC_4 compared to the other groups. This corresponds with

the fatty acid analysis of the beef, where MC_4 showed a higher n-6 PUFA content than GC_2 and GC_3 (Raes et al., 2003b). Similarly, Elmore et al. (2004) found higher concentrations of hexanal and 1-octen-3-ol for concentrate fed animals compared to silage fed animals.

Concerning flavour preference, the taste-panel had the lowest appreciation for the steaks from group C_1 (Table 3). Thus, the flavour may have been positively affected by the linseed in the finishing diet.

[2] Evaluation using a 1 to 4 ranking test where 1 = lowest intensity or preference, and 4 = highest intensity or preference

Conclusions

Relatively small differences in the flavour profile were detected in grilled meat from Belgian Blue double-muscled young bulls fed rations differing in the presence of linseed in the concentrate and the use of grass or grass silage as roughage. However, the semi-trained taste-panel was able to observe flavour differences between the feeding groups.

EFFECT OF LAMB FEEDING WITH LINSEED MEAL ON SOME MEAT QUALITY TRAITS

Ragni, M., Di Turi, L., Melodia, L., Caputi Jambrenghi, A., Colonna, M.A. and Vonghia, G.
Department of Animal Production, Via G. Amendola 165/A – 70126 Bari, University of Bari, Italy

Background

The EC Regulation n. 1829/2003 sets at 0.9% the limit of genetically modified organisms (GMO) allowed in feeds for animals without any mention in the label. Such a limit dramatically stresses the need to identify raw materials free from genetically manipulated substances. Nowadays, about 63% of the soy cultivated all over the world is genetically modified, thus representing a serious problem for animal feeding since soybean is still considered as the main protein source. The possibility of using some traditional oilseeds can be a valid alternative to soy in order to obtain quality performances. Contrary of other seeds, normally rich in linoleic acid (LA), linseed is particularly rich in α-linolenic acid (approximately 350 g fat/kg fresh material, of which LNA accounts for about 50% of the total fatty acids). Omega-3 fatty acids, that may be only partially transferred to ruminant fat (Dufrasne *et al.*, 1991; Enser *et al.*, 1999; Choi *et al.*, 2000; Scollan *et al.*, 2001; Raes *et al.*, 2002; Raes *et al.*, 2004), are very important in the human diet, since they reduce the risk of cardiovascular diseases with their anti-thombogenic and anti-atherogenic effect. They inhibit tromboxane A2 synthesis, starting from the arachidonic acid in platelets, and the migration of monocytes in the atherosclerotic plaque (Condor, 1997). Several authors have used linseed meal in ruminant nutrition, especially for cattle, with positive results on digestibility (Khorasani *et al.*, 1994; Dufrasne *et al.*, 1991, Dixon *et al.*, 2003a; Dixon *et al.*, 2003b), productive performances (Dufrasne *et al.*, 1991; Berge *et al.*, 1993; Dumont *et al.*, 1997; Dixon *et al.*, 2003a; Dixon *et al.*, 2003b; Raes *et al.*, 2004) and meat quality traits (Dufrasne *et al.*, 1991; Berge *et al.*, 1993; Enser *et al.*, 1999; Choi *et al.*, 2000; Raes *et al.*, 2002; Scollan *et al.*, 2001; Raes *et al.*, 2004). There are, however, few reports in literature concerning the use of linseed meal in lamb production.

Objectives

The present study aimed to investigate some of the most important meat quality traits in lambs fed a linseed meal in comparison with a traditional diet based on soybean meal.

Materials and methods

The experiment was carried out on samples of *Longissimus lumborum* (Ll) and *Semimembranosus* (Sm) muscles isolated from Comisana male lambs (n. = 14). Lambs were fed *ad libitum* for 6 weeks from the age of 50 days on either a concentrate pelleted diet (Control group) or on a diet containing 20% linseed meal (LM). Diets were planned to contain approximately the same amount on dry matter of protein (16.5%), fat (5.0%) and crude fibre (10.5%). Following 24 hours of refrigeration at 4 °C, the lumbar region and the pelvic limb were excised from the right half carcass and dissected into their tissue components, i.e. lean, fat and bone. Ll and Sm muscles were assessed for pH using a glass electrode at slaughter (pH_1) and after 24 hours refrigeration at 4 °C (pH_2). Samples of both muscles were evaluated for colour and tenderness, while chemical analysis (ASPA, 1996) and the fatty acid profile were performed only on Ll samples. Lipids were extracted according to the 2:1 chloroform-methanol method described by Folch *et al.* (1957), whereas the acidic profile was assessed using a Chromopack CP 9000 gas chromatograph. Meat colour was estimated by the Hunter Lab system using a colorimeter (illuminant D 65), which measures the values of Lightness (L), Redness (a) and Yellowness (b) by making 5 readings for each meat sample, approximately 2.5 cm thick. Tenderness was measured using a Warner Bratzler shear device applied to an Instron 5544 and expressed as the shear force (kg/cm^2) required to cut perpendicularly to the direction of the fibres half an inch diameter cylinders of raw meat, taking three measurements for each muscle per subject. The atherogenicity and thrombogenicity indexes were calculated accordingly to Ulbricht and Southgate (1991). The PCL/PCE (plasma cholesterol lowering/plasma cholesterol elevating) ratio was also determined (Reiser and Shorland, 1990). Data were analysed for variance using the GLM procedure of SAS (1999/2000).

Results and discussion

By the end of the trial, the lambs had achieved similar live weights in both groups (23.67 *vs* 23.59 kg, respectively for the LM and control group), thus proving the productive efficiency of the linseed meal diet. As for pH values, no significant differences between groups were detected for Ll and Sm muscles at slaughter, nor after refrigeration (Figure 1). Dissecting data of the lumbar region and pelvic limb were not markedly different, although a higher incidence of lean was observed in the experimental group (Figure 2). The Sm meat colour parameters were quite similar between the two groups, while the yellowness of the Ll muscle was significantly lower ($P<0.01$) in the linseed meal diet (Figure 3). In both muscles, tenderness was slightly improved by LM feeding (Table 1). With regard to the chemical composition of meat, no statistical differences were assessed (Table 2). However, a slight increase of the protein content was found in the experimental group, corresponding to the greater amount of lean found at the dissection in the same group, in accordance with the results of Berge *et al.* (1993). Meat from lambs fed on the LM diet showed better dietetic properties, as evidenced by a markedly higher amount of unsaturated fatty acids and a lower one of saturated (Table 3), along with a lower percentage of C12:0 and C14:0 ($P<0.05$). As a consequence, lower indexes of atherogenicity and thrombogenicity and a higher PCL/PCE ratio were found in meat of the LM group ($P<0.05$). No significant differences were found in meat PUFA content of either group concerning the ω6 or the ω3 fractions. However, the LM diet significantly improved the ω6/ω3 ratio, as well as the UFA/SFA ($P<0.05$).

Conclusions

The results obtained in this research suggest that without altering the productive efficiency of lambs, the use of a linseed meal positively affected meat healthiness and dietetic properties, since a lower concentration of C12:0 and C14:0 fatty acids was found, corresponding to an increase in the total unsaturated fatty acids as well as the ratio of unsaturated to saturated fatty acids. Furthermore, this diet improved the atherogenicity and thrombogenicity indexes as well as the PCL/PCE ratio, with positive effects for human health. Finally, meat lean content and its tenderness were also better following linseed meal feeding.

Background

Beef produced from grazing cattle results in higher levels of unsaturated fatty acids (Miller, *et al.,* 1987 and García and Casal, 1992), lower n-6:n-3 fatty acids (Enser, *et al.* 2001) and higher levels of conjugated linoleic acid (CLA) in body fat (French, *et al.* 2000) as opposed to meat from animals fattened in high concentrate diets. However, short term supplementation with maize grain or soybean harvest by-products in the finishing stage did not affect fatty acid profile (Grigera Naón, *et al.*, 2000 and Grigera Naón, *et al.*, 2003).; longer supplementation periods may be necessary to overcome seasonal grass production , thus the widespread use of other supplements such as high moisture maize grain and maize silage (Abdelhadi, 2000), which in turn may affect meat quality. Frame size of animals can have decisive bearings on the length of the fattening stage (Di Marco, 1998) and on some aspects of quality such as tenderness and cooking loss (Muir *et al.*, 1998 and Camfield *et al.* 1999).

Objectives

The objective was to evaluate the effect of type of energy fall-winter supplementation with high moisture maize grain or whole plant maize silage on meat qualitiy of Aberdeen Angus steers with contrasting mature body weight.

Materials and methods

Over 177 days, covering autumn and winter, 32 male calves of six months of age, grazing pastures were assigned to the following treatments: LM, animals of low (L) mature body weight supplemented with high moisture maize grain (M); LS, animals of low (L) mature body weight supplemented with whole plant maize silage (S); HM , high (H) mature body weight animals supplemented with high moisture maize grain (M) and HS, high (H) mature body weight animals supplemented with whole plant maize silage (S). Individuals were weighed every 21 days and fat depth between ribs 12th and 13th was measured by ultrasound using a 3.5 MHz trasductor. At the end of the experiment, eight animals from each treatment were slaughtered. Colour was assessed on the *Longissimus* muscle exposed between the 12th and 13th rib, blooming time was 60 minutes (Wulf and Wise, 1999), readings were taken in L* a* b* colour space, using a Minolta CR-300 (Minolta Co. Ltd., Japan) colorimeter. A Testo 230 pH-meter with a puncture type combination electrode (Testo GmbH & Co., Germany) was used to measure muscle ultimate pH (pHu). Fatty acids were extracted according to Folch *et al.* (1957) and analyzed as methyl esters by gas cromatography. Tenderness was measured with an Instron 4442 Universal Testing Machine (Canton, MA, USA) with a Warner-Bratzler shearing attachment on samples cooked in a water bath at 70 °C for 50 minutes. Data were analyzed using GLM procedure SAS (SAS Inst. Inc., Cary N.C.).

Results and discussion

Animal performance data is shown in Table 1, H calves had higher ($P < 0.01$) initial liveweight as expected. Initial fat depth was the same accross treatments. At the end of the trial L steers had a deeper ($P< 0.01$)

subcutaneous fat layer, lower liveweight gain ($P < 0.01$) and were lighter ($P < 0.01$) than H reflecting that smaller animals were more mature. Steers on M gained more ($P < 0.01$) in autumn than those supplemented with S.

Among treatments , the proportion of ether extract (EE), saturated fatty acids (SFA), polyunsaturated fatty acids (PUFA), n-6 fatty acids, n-3 fatty acids and the ratio between the latter two (Table 2) in meat was similar ($P > 0.1$). The n-6: n:3 ratio was below 4:1, therefore considered healthy for human beings (Holman, 1995). Concentration of monounsaturated fatty acids (MUFA) was higher in L steers, in accordance to their higher degree of fatness. Animal size influenced the proportion of conjugated linoleic acid (CLA) for LS and LM was 1.08 g/100 g and 0.82 g/100 g respectively ($P< 0.05$), whereas for HS was 0.93 g/100 g and 1.06 g/100g for HM ($P > 0.10$). In smaller animals the effect of the different feeding regime became apparent, the rich forage diet enhanced CLA body fat levels as reported elesewhere (French *et al.,* 2000 and Grigera Naón *et al,*., 2003). In case of larger steers this difference was not detected, which can be associated with the fact that they were thinner animals. Ultimate pH (Table 3) was higher for H ($P < 0.05$) than for L and similar for both supplements. There was a significant ($P< 0.05$) interaction between animal size and diet for a* and b*, LM showed higher values in comparison to LS, both parameters were similar for large frame steers. Grigera Naón *et al*. (2001), reported that a* and b* were affected when maize grain was fed to grazing steers. Tenderness was not affected neither by type of animal nor by the supplement fed. However, there was a trend for those animals on S to produce somewhat more tender meat. Cooking loss was higher in H as compared to L ($P< 0.05$), Camfield *et al.* (1999), reported comparable results from three muscles of steers differing in frame size. Such higher cooking loss was recorded in spite of higher pHu in H ($P< 0.05$), but such value (pHu = 5.8) can seldom affect juiciness (Lawrie, 1998). Cooking losses were similar ($P> 0.1$), when comparisons were made between supplements, Geay *et al.* (2000) consider that juiciness cannot be modified by feeding regimes.

Conclusions

During the supplementation period, meat from large animals showed lower MUFA and higher pHu than meat from smaller animals; supplements had some effect on CLA concentration and colour parameters a* and b* in small frame steers.

Food Safety and Infection Biology, PO Box 8146 Dep., N-0033 Oslo, Norway.

Background

Nitrite ($NaNO_2$) and nitrate ($NaNO_3$), a precursor to nitrite, are widely used as additives in processed meat for enhancing colour and other properties of the products. Due to the risk of formation of carcinogenic compounds, finding alternative additives that can replace or reduce the addition of nitrite are highly desirable (Pegg and Shahidi, 2000). Carbon monoxide (CO) binds strongly to the muscle pigment myoglobin creating stable, bright red carboxymyoglobin. CO can be safely used in concentrations below 1 % in fresh meat packages, or in similar or higher concentrations for pretreatment of fresh meat (Sørheim *et al*., 1997). Carboxymyoglobin has a higher denaturation temperature than other forms of myoglobin, e.g. deoxymyoglobin (Hunt *et al*., 1999; Sørheim *et al*., 2001), thus having a potential use as a colourant in typical cooked meat products.

Objective

The main objective was to study the effect of replacing nitrite with CO on the colour of cooked meat batter systems.

Materials and methods

The study was a multifactoral design with a total of 44 batches including:
- colour processes (4): CO gas flushing directly to batter (CO-D), CO pretreatment of raw materials (CO-R), addition of nitrite to batter (N), no CO/nitrite as control (C)
- meat sources (2): semimembranosus muscles of pork or beef
- antioxidants for CO-D and CO-R (4): ascorbic acid, phosphate, ascorbic acid + phosphate, none
- sodium chloride level for CO-D and CO-R (3): 0, 1.4 and 2.8 %

The design was unbalanced with some factors considered more important than others. Significance testing was performed by univariate and multivariate (Langsrud, 2002) analysis of variance. Effects were illustrated by least square means adjusted for unbalance.

The basic batter receipe consisted of:
- 70.0 % meat
- 24.4 % water
- 1.4 % NaCl
- 3.5 % native potato starch (Hoff, Gjøvik, Norway)
- 0.7 % Na-caseinate (Tine, Oslo, Norway).

The following ingredients were added to some batches:
- 85 ppm $NaNO_2$
- 500 ppm ascorbic acid
- 0.3 % sodiumtripolyphosphate (A.B. Corneliussen, Oslo, Norway)

The raw batters contained on average 16.4 % protein, 1.4 % fat, 76.9 % water and 2.8 % carbohydrates. Total batter weight was 1.430 kg.

Fresh meat was ground twice through a 4 mm plate. Meat for the CO-R treatment was placed in polyamide pouches, compressed to < 5 mm, packaged in 1 % CO/ 99 % N_2 with < 0.2 % residual O_2 and stored at 3 °C

for 4 and 5 days for pork and beef, respectively. The meat pouch was turned at 2 days of storage to access gas from both sides. Batters were prepared in a Stefan UM5 chopper (A. Stephan u. Söhne, Hameln, Germany) with a lid and double bladed knives with a chopping time of 3 min and 20 sec. For CO-R, pretreated meat with CO was used without supply of CO in the chopper. Meat for CO-D was not pretreated with CO, but the batters were flushed with 1 % CO/ 99 % N_2 at 2 bars for the last 2 min of the chopping. All batters were filled in 50 ml polyethylene tube casings of 28 mm in diameter, centrifuged at 2000 rpm for 5 min, stored overnight at 3 °C, heated for 30 and 40 minutes in circulating water baths at 80 and 100 °C, respectively (the latter 8 batches only), chilled in ice water, and stored at 3 °C for 3 hours. Core temperature after cooking was measured with a 1 mm needle thermometer (Teck Instrument AS, Tranby, Norway). Casing was peeled off the cooked products, which were then sliced vertically in duplicate halves of 15 mm height for instrumental and visual colour analyses taking place at 0, 15 and 60 min of air exposure at 20 °C.

In a small additional experiment, two fermented batters of 1 kg each were prepared of beef *semimembranosus* muscle (94.5 %), dextrose (0.7 %), starter culture, NaCl (4.5 %), and ascorbic acid (500 ppm). In one batter, 180 ppm $NaNO_2$ was added, while the other batter was flushed with 1 % CO/ 99 % N_2 (see above for details). The batters were stored in 50 ml tubes for 6 days at 20 °C.

L*a*b* values (lightness, redness, yellowness) were measured with a Minolta Chroma Meter CR-300 (Minolta Camera Co., Osaka, Japan) with an 8 mm viewing port and a D_{65}-illuminator. Visual colour evaluation was performed by two trained assessors using a 5 point scale where 1 = very red/pink and 5 = extremely gray/brown. Denaturation of myoglobin was analysed by the method of Krzywicki (1979) (8 batches, each raw and at 80 °C). pH of the raw as well as the fermented batters was analysed with an Ingold Xerolyt gel electrode (Mettler-Toledo, Greifensee, Switzerland).

Results and discussion

Figs. 1 and 2 demonstrate a* values of pork and beef batters, respectively, heated into 80 °C, (actual core temperature was 79.5 °C), and exposed to air for 0, 15 or 60 min. Fig 3. shows the b* values for both pork and beef batters cooked to 80 °C. Fig. 4 demonstrates visual colour score of the batters at 80 °C. Immediately after slicing, the CO-D samples with CO gas flushing were more red with higher a* values than N samples on beef ($p<0.05$), but similar to the a* values on pork. However, after 15 and 60 min CO-D samples lost more redness than N in both species. The results of the visual colour evaluation corresponded to the a* values. Initial yellowness values (b*) were lower for CO-D than N beef samples ($p<0.05$), but were not different anymore at 15 and 60 minutes of O_2 exposure. CO-D samples were slightly lighter, expressing L* values of about a unit higher than the N samples at all measuring points (results not shown).

The CO-D gas flushing seemed to effectively replace O_2 with CO and bind to myoglobin in the final batters. The CO-R pretreatment was less efficient than direct flushing in producing a red colour of the samples, as shown in Figs. 1 - 4. Based on visual examination of the CO-R pretreated raw materials, 100 % of the pork and 80 – 90 % of the beef pigments were in the state of carboxymyoglobin. Despite the almost complete saturation of the meat pigment with CO, exchange of CO with O_2 during chopping was the likely cause for the less intense redness after cooking of CO-R samples. Although the red colour of CO-treated samples faded during air exposure, the colour could perhaps be maintained by keeping the samples in an anaerobic environment. The level of NaCl or the use of additives, either as ascorbic acid, phosphate or ascorbic acid + phosphate, did not much affect the colour of the final cooked batters of CO-D and CO-R (results not shown). The pH of the raw batters without additives was 5.51. Addition of phosphate increased the pH of the batter by 0.10 unit ($p<0.05$). Myoglobin denaturation at 80 °C was in the range 73 – 81 % for pork and 91 – 95 % for beef batters, respectively, with no apparent differences between CO-D, N and C samples. These results suggest that carboxymyoglobin denaturates to about the same extent as nitrosomyoglobin at 80 °C.

At 100 °C (actual core temperature was 98 °C), initial a* values of CO-D beef samples were slightly lower (about a unit) than at 80 °C, yet expressing a bright red colour (results not shown). However, pork CO-D samples gave approximately 2.5 units lower a* readings, and were clearly paler at 100 °C than the same samples at 80 °C.

In the fermented beef batters, pH was reduced from appr. 5.4 to 4.5 during fermentation. CO flushing produced a brighter red colour into the fermented samples than nitrite, but the colour of the CO sample faded away along with exposure to air (results not shown).

Conclusions

Direct flushing of pork and beef batters with 1 % CO produced an initial bright red colour into samples cooked into 80 °C. The internal colour of these samples immediately after slicing was equally or more intensely red than samples treated with nitrite. Pretreatment with 1% CO to raw materials that were later used for batter production, resulted in less efficient colour formation than the flushing of gas during chopping, probably due to exchange with O_2 during batter blending. Beef seemed to be more responsive than pork to colour improvement by CO flushing and pretreatment. The lack of colour stability of CO samples in O_2 exposure needs to be addressed further, perhaps with new processes or additives to counteract pigment oxidation.

Background

The use of dietary fats and oils to alter the fatty acid profile in meat animals to produce healthier and higher quality meat suitable for processing as well as consumption has been well documented, for example by Enser *et al*. (2000). In Ghana and other developing countries, local vegetable oils and agro-industrial by-products (AIBP) such as palm oil, palm kernel oil, palm kernel meal, coconut meal and cotton seed meal, are being used in animal feed, and recommended inclusion levels have been established (Okai, 1998). The economic incentive of using palm products is their relatively favourable cost compared to cereals and other oilseeds due to increasing global production (Shahidi, 1990). Furthermore, palm oil is cholesterol free, trans fatty acid free and fortified with carotenoids, tocopherols and tocotrienols (Sulaiman *et al*., 2001). There is, however, no information on the effect of Ghanaian AIBPs on the fatty acid profile of pork and pork fat. The processing characteristics of pork fat are influenced by its fatty acid composition. Poor slicing quality of floppy bacon is caused largely by soft fat (Morgan *et al*., 1994). High concentrations of saturated fatty acids (SFA) particularly stearic acid (18:0) as well as low concentrations of unsaturated fatty acids, mainly linoleic (18: 2), improve firmness/hardness of fatty tissues (Wood *et al*., 1985). The physical properties of fat also influence fat loss during cooking of comminuted meat products (Evans and Ranken, 1975; Teye *et al*., 2004).

Objectives

The objective of this study was to evaluate the effects of palm and palm kernel oils, and lysine level on the fatty acid composition of pork fat, fat firmness and the quality of belly bacon and frankfurter sausage.

Materials and methods

Sixty crossbred pigs (0.5 Duroc, 0.25 Large White, 0.25 Landrace) were used, with equal numbers of males and females. Each group of 10 were fed one of six diets in a 3x2 factorial design with 3 oil types (40 g/kg) and 2 lysine levels (HL-11 and LL-7 g/kg). Palm oil (PO) and palm kernel oil (PKO) were compared with soya bean oil (SBO). Pigs were housed in straw-based pens and fed *ad libitum*. Animals were reared from an initial mean live weight of 40 kg and slaughtered at an average live weight of 100 ± 10 kg. Measurements taken were cold carcass weight (CCW), pH_{45} min, pH_u (24h), drip loss, texture in *M. longissimus*, P2 backfat thickness and fat firmness at two positions (shoulder fat firmness SFF, loin fat firmness, LFF) at 2ºC with a custom-made digital penetrometer. Analysis of backfat fatty acid composition was by gas-liquid chromatography following extraction into chloroform. Slip point was determined by the open capillary method (BSI, 1985). Ten 4 mm thick slices from each cured belly were subjectively evaluated for slice integrity and classified as grade A, B or C. Bacon cohesion (BC) was assessed by a tensile test on cylindrical samples of 25 mm diameter. Pork frankfurter sausages, formulated with 5 kg lean and 2 kg fat from the shoulder and neck, were cooked individually in sealed vacuum-packed type polyethylene bags at 80ºC for 1h. Fat loss in the exudates was determined gravimetrically. Data were analysed by general linear model (Minitab 13). Correlations between fatty acids and fat firmness, bacon quality and fat loss from sausages were determined.

Results and discussion

Means for cold carcass weight, P2, pH45 and pHu, drip loss, texture of m. longissimus, backfat firmness and slip point are given in Table 1. Table 2 shows the means for fatty acid composition. The relationships between fatty acid concentration and fat firmness slip point, bacon and sausage qualities are given in Table 3. Oil type did not have a significant effect ($P > 0.05$) on carcass quality (Table 1), as also found by Okai (1998) and Rentfrow *et al*. (2003). PKO and PO significantly ($P \leq 0.001$) increased fat firmness and slip point,

relative to SBO (Table 1). The LL resulted in a significantly higher ($P<0.01$) shoulder fat firmness. PKO increased the concentrations of lauric (12:0), myristic (14:0), palmitic (16:0) and stearic (18:0) acids and decreased linoleic acid (18: 2). Valencia *et al*., (1993) found a similar result in poultry, consequently making the fat firmer (Wood *et al*., 2003). The LL diet increased the concentrations of 16:0 and 18:0 and decreased 18:2 and 18:3 concentrations (Table 2). PKO as well as the LL diet significantly ($P\leq 0.001$) reduced the P/S ratio (Table 2), apparently lowering the nutritional value of the fat. Fat firmness and slip point had moderate to strong positive relationships with SFA and 18:0/18:2 ratio, and strong negative relationships with PUFA (Table 3). Sausage fat loss was positively related to SFA and C18:0/C18:2, and negatively related to PUFA, as observed previously (Teye *et al*., 2004). There was no significant correlation between the grade A bacon slices and fatty acid concentrations (Table 3). Rentfrow *et al*. (2003) reported a similar finding, which is, however, contrary to what was observed by Teye *et al*. (2004) who found a positive correlation ($r=0.5^{**}$) existed between 18:0 and grade A bacon slices.

Conclusions

Fatty acid composition and backfat firmness were affected by dietary oil, with PKO and PO increasing fat firmness. PKO produced the most saturated fat and the lowest P/S ratio, which is considered having adverse implications to human health. The work suggests that PO could be used to improve pork fat firmness in lean pigs without adversely affecting its healthiness. The LL diet increased the concentration of saturated fatty acids and fat firmness. High concentrations of medium chain saturated fatty acids (12:0, 14:0 and 16:0) may not be suitable for frankfurter type sausage production due to high fat losses. Optimum inclusion levels of palm products for quality meat production need to be determined in all countries where these products are being used, such as in Ghana.

Background

The flavour of meat develops largely through the cooking process, however, raw meat contains several constituents that are non-volatile and contribute to its taste (MacLeod, 1986). Consequently, many of the constituents in raw meat undergo substantial changes during the cooking process and subsequently provide roasted, boiled, fatty and species-related flavours, as well as the characteristic meaty aromas associated with all cooked meats. Model experiments have suggested that the Maillard reaction between amino acids and reducing sugars is one of the main pathways for formation of many of the aroma compounds, which have been identified in cooked meat. The dominating reducing sugar in meat is the pentose, ribose, which originates from the degradation of ribonucleotides (Mottram, 1998). Moreover, nucleotides and related compounds, e.g. the 5´-ribonucleotides, adenosine monophosphate (AMP), inosine monophosphate (IMP) and guanosine monophosphate (GMP), are also important in relation to meat flavour, as they contribute with umami taste (Durnford, Shahidi, 1998; Spurvey et al, 1998). Umami taste has a characteristic savoury quality, first characterized for glutamate. Beside the characteristic umami taste, umami compounds have flavour enhancing properties, and are reported to enhance meaty, brothy, mouth filling, dry and astringent qualities and suppress sulphurous notes (Kuninaka, 1981). Finally, bitterness in meat may be derived from hypoxanthine, which is a degradation product of IMP, together with anserine, carnosine, other dipeptides and several free amino acids.

Considering that IMP, ribose and hypoxanthine all are considered important constituents in meat flavour formation and development, an understanding of the post mortem metabolism in muscle and the subsequent degradation of the adenosine triphosphate (ATP) metabolite, IMP, during aging and cooking, as schematically outlined below (Scheme 1), becomes crucial in the further exploitation of flavour development in meat.

Scheme 1

ATP ⇒ ADP ⇒ AMP ⇒ IMP ⇒ Inosine ⇒ Hypoxanthine + Ribose

ATP ≡ adenosine 5´-triphosphate
ADP ≡ adenosine 5´-diphosphate
AMP ≡ adenosine 5´-monophosphate
IMP ≡ inosine 5´-monophosphate

IMP has been found to be a desirable flavour enhancer and umami compound in meat and fish (Maga, 1987; Madruga M.S., 1997; Murata, Sakaguchi, 1989). As the dephosphorylation of IMP to inosine is a slow process, IMP has been reported to accumulate in beef and fresh fish muscle (Dannert and Pearson, 1967; Konosu, Yamaguchi, 1989). The IMP concentration has in fish been found to be highest within one to two days post mortem with a subsequent decrease resulting in a less acceptable flavour development (Fletcher and Statham, 1988). Formation of bitter taste through degradation of IMP to hypoxanthine might be an element in flavour deterioration of fish during prolonged storage, as nucleotide degradation is found to contribute to bitter taste in muscle foods (Bremner et al., 1988). Likewise, Cambero et al. (2000a) reported sour and astringent flavour of beef broth at higher cooking temperatures, which also may reflect severe nucleotide degradation.

Several studies have reported a heat-induced increase in ATP metabolites during cooking of different muscle foods, and a significant increase in inosine and hypoxanthine during cooking has been demonstrated in goat and sheep meat (Arya and Parihar, 1979). Moreover, increasing cooking temperatures have been found to

result in a significant rise in the concentration of creatinine, IMP, AMP in beef broth, with IMP showing the highest correlation to the sensory data of the broth (Cambero et al., 2000b). The stability of IMP is reported to be both temperature- and pH-dependent due to the presence of weak chemical bonds, e.g. glucoside and ester bonds (Matoba et al. 1988). Consequently, pH in the fresh meat must be expected to influence IMP degradation through aging and cooking.
Interestingly, the contaminant formation of ribose upon hydrolysis of inosine is not considered in the literature even though ribose, as mentioned above, is known as a major reactant in the Maillard reactions, which take place in meat.
Most flavour studies related to meat have been carried out in model systems or in spiking studies where potential flavour pre-cursors have been added to meat or meat broth with subsequent chemical or sensory analysis. The present study is a preliminary study to exploit the faith of inherent inosine monophosphate during aging and cooking of pork, which subsequently will be investigated in relation to the potential contribution of IMP, hypoxanthine and ribose to the formation of volatile flavour compounds and sensory characteristics, as a consequence of aging and cooking temperature.

Objectives

The objective of this study was to investigate the faith of IMP during aging and cooking of pork, by measuring IMP and its degradation products inosine and hypoxanthine.

Materials and methods

The *M. longissimus dorsi* from four pigs (cross-breeds of Duroc boar and Danish Landrace x Yorkshire dams) reared and slaughtered at The Danish Institute of Agricultural Sciences (DIAS), Foulum, Denmark was used in the experiment. Rectangular meat samples (3x3x2 cm), from which all visible fat and connective tissue were removed, were cut, vacuum-packed in pairs and stored at 4°C for 24, 72, 120 and 216 h after slaughter. From all meat samples, 400 mg sub samples were taken at different time of aging.
The meat with different time of aging was cooked in an oven at 150°C to an inner temperature of 70 and 90°C and then cooled to room temperature. From each cooked piece two samples from 1 mm outer layer and two samples from the inner part of the meat were cut, and extractions according to the procedure described below were carried out to determine inosine monophosphate, inosine and hypoxanthine.
Pork samples of 400 mg were mixed for 5 seconds in 24 ml of ice-cold 0.6 M perchloric acid (PCA) containing a pH indicator (bromthymolblue and phenolphthalein 0.004% of each) using Sarstedt 50 ml conical vials. The samples were left on ice-bath for 15 minutes before neutralization with 21.6 ml of ice-cold 0.8 M KOH and addition of 1 ml ice-cold KH_2PO_4 buffer. Subsequently the mixtures were mixed for 10 seconds using an IKA MS 2 Minishaker, and the pH was adjusted to 7-8 using either KOH or PCA. Finally, the mixtures were centrifuged using an Eppendorf Centrifuge 5417R (4000 rpm for 10 min at 4°C), and 1 ml supernatant (in triplicate) was transferred to an Eppendorf vial and frozen at -80°C until further analysis.
Analysis of inosine 5´-monophosphate, inosine and hypoxanthine was carried out by high-performance liquid chromatography (HPLC) on a Hewlett-Packard HPLC system series 1100 using UV detection (210 nm). The samples were thawed and centrifuged, and the supernatants were transferred to cold HPLC vials and placed in a thermostatted auto sampler (1-2°C). A 10 µl sample was injected on a Lichrospher 250 x 4 mm RP18 column from which the three compounds were separated by isocratic elution using a solvent based on a buffer containing 10 mM tetrabutylammonium hydrogensulfate and 215 mM KH_2PO_4, to which 7.5 ml methanol/l was added. The following flow gradient was used to obtain optimal separation: 0.5 ml/min for 5 min, increasing to 1.5 ml/min in 1 min and keeping this flow for 9 min before a final decrease to 0.5 ml/min in 0.5 min. Quantification was based on standard curves using external standards and calculations carried out in the included software (HP Chemstation).

Results and discussion

Figure 1 shows the concentrations of IMP, inosine and hypoxanthine in fresh pork during aging. The concentrations of IMP and hypoxanthine were constant throughout the first 72 h, while the concentration of inosine increased significantly from 24 to 72 h. From 72 h to 216 h the concentration of IMP decreased with a simultaneous increase in the concentrations of inosine and hypoxanthine hereby resembling the data reported previously by Kato and Nishimura (1987).

Significant correlations were found between the concentrations of IMP and inosine (R=-0.55, P=0.0012) and between [inosine] and [hypoxanthine] (R=0.46, P=0.0077) during aging, while no significant correlation was found between [IMP] and [hypoxanthine] during aging (R=-0.26, P=0.1522). This is in agreement with the expected difference in the rate constants of the dephosphorylation of IMP and the hydrolysis of inosine, as described by Dunford and Shahidi (1998).
The observed maximum in the concentration of IMP and its degradation products inosine and hypoxanthine at 72 h after slaughter is in agreement with the data by Lindahl et al. (2003), who found that the post mortem metabolism proceeded after 2 days post slaughter.
Figure 2 shows the concentrations of IMP, inosine and hypoxanthine at the surface (o) and the centre (i) of pork samples aged for different time intervals and heated to a centre temperature of 90°C. In general, cooking resulted in a decrease in [IMP] with a concomitant increase in [inosine] and [hypoxantine] independent of time of aging. The concentrations of IMP and inosine in the centre of the cooked samples decreased independently of time of aging while [IMP] and [inosine] at the surface increased independently of aging compared with the concentrations in the fresh meat. Even though not as drastically, the same pattern was seen when samples were heated to a centre temperature of 70°C (data not shown). The highly significant difference between concentrations in the centre and at the surface of the pork samples is most probably due to dehydration of the outer layer during cooking even though a thermally induced dephosphorylation of residual ATP/ADP and AMP might also be a possibility. This aspect needs to be investigated further.

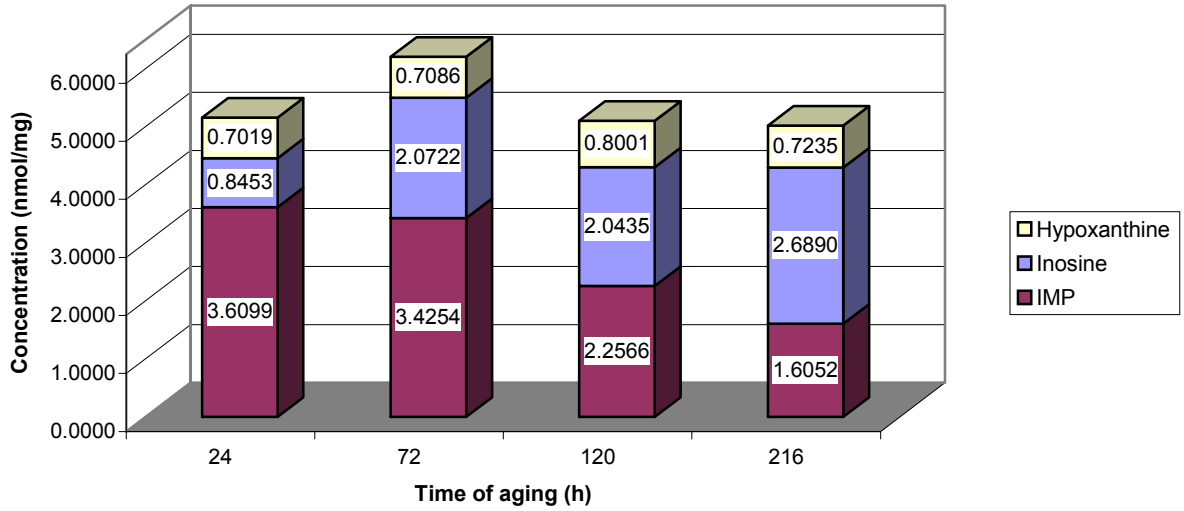

Figure 1. The concentration of IMP, inosine and hypoxanthine during aging of raw pork

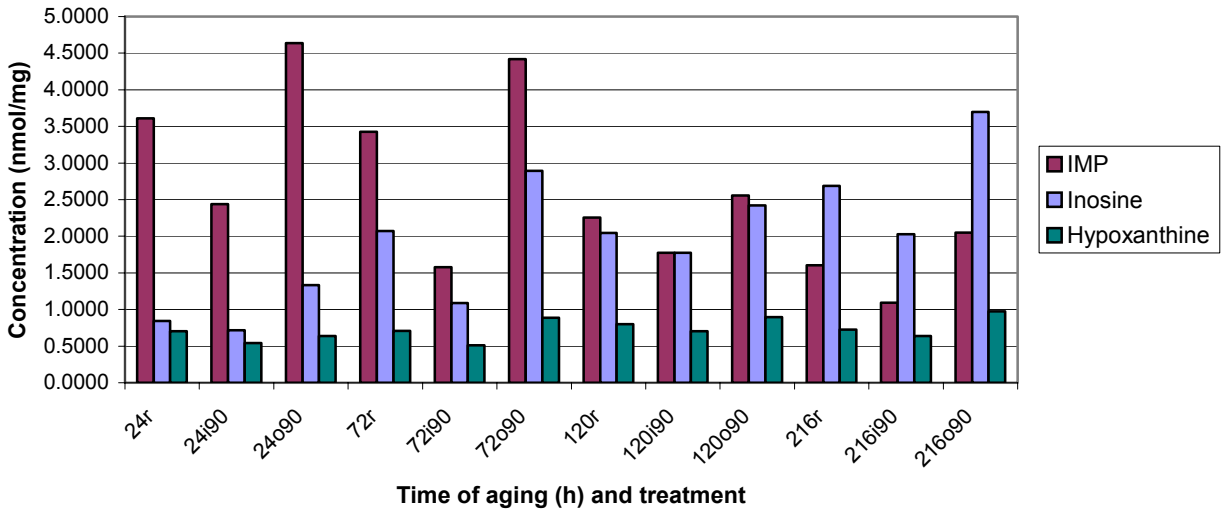

Figure 2. Influence of aging and heat treatment on the concentration of IMP, inosine and hypoxanthine. 24i90 means aging 24h, inside the meat at 90 ºC; r= fresh meat; o= outside layer; I= inside layer

Conclusions

This paper clearly demonstrates that aging and cooking are important for the development of essential meat aroma precursors. However, further studies including sensory analysis are needed to exploit the importance in relation to influence on sensory characteristics.

EFECT OF SLAUGHTER WEIGHT AND DIET COMPOSITION OF CALVES ON MEAT AND FAT QUALITY

Background

Many consumers in Spain and in other European countries prefer to consume meat from animals slaughtered at an early age, associating it with a healthy product, low amount of visible fat, high juiciness, high tenderness and a good smooth flavour. In fact, in the past, such meat was considered as the highest quality meat. In this sense, the use of local breeds, together with local production systems, could be a basis for establishing standards in order to improve local production and consumer confidence (Shackeldford *et al*., 2001; Dransfield *et al*., 2003).

However, in order to respond to consumer demands, it is essential to guarantee good quality meats, from a fundamental understanding of links between production factors and meat quality. Several factors, such as age, sex, breed and slaughter conditions, affect carcass and meat characteristics, but also diet is of importance. Most studies published about the effect of diet on calf performance, have been carried out using milk replacers (Beauchemin *et al*., 1990; Xiccato *et al*., 2002) and slaughtered at an early age or based on a relatively early weaning age (100-150 days), following an *ad libitum* diet of concentrate until slaughter (Hinks *et al*., 1999; Myers *et al*., 1999a, 1999b; Fluharty *et al*., 2000). However, the raising of calves on the basis of traditional systems, using whole milk, as unique feed or supplementing a concentrate diet may offer an alternative to the current systems as long as the quality of the final product could be guaranteed. On the other hand, this type of rearing system could also be used for other purpose, for example, in farms in which milk production is largely over the milk quota (Hornick *et al*., 1996). Owing to the peculiar digestive and metabolic characteristics of young calves, in which the effect of diet composition on body composition is of special importance, it may be assumed that the meat and fat from calves receiving a daily amount of milk until slaughter could show differential characteristics with respect to the meat from calves reared under intensive production systems. So, the aim of the present work was to study the effect of diet composition of calves might have on meat and fat quality.

Materials and methods

Animal Experiment

The animal experiment was conducted at the Agricultural Experimental Station of the Spanish Council for Scientific Research (CSIC) in León (Spain) while the analysis of meat quality characteristics were performed at the Meat Technological Station of Agronomic Institute (ITA) in Salamanca (Spain). Male Spanish Brown Swiss calves were used. Upon arrival, the calves were weighed and assigned to one of three groups, homogeneous in weight and age, according three experimental diets. Milk-fed (MF) calves were exclusively fed with whole milk, containing 13,8% powder milk served warm (39°C) twice daily (at 9 h and 19 h) in teat-feeder. These calves were slaughtered at 5 months of age. In the concentrate-fed (CF) treatment, after weaning at 100-kg body weight the calves received concentrate and barley straw, both available *ad libitum* until slaughter. The remaining calves, milk-concentrate group (MC), received 5 kg/d of whole milk made up the same way as for the MF group served individually once daily in buckets, and they were also fed with concentrate and barley straw, both available *ad libitum* until slaughter. The animals from last two groups were slaughtered at 7 months age. Individual weight was recorded before moving the calves to the slaughterhouse. Average slaughter weight for MF, MC and CF groups were 231.9, 346.0 and 345.5 kg respectively.

Analysis

pH was measured at 24 h post slaughter on *longissimus thoracis* muscle at 6th rib level by a penetration electrode. Dry matter, ether extract, crude protein and total collagen were determined according to official procedures (MAPA, 1979). Gross energy (GE) was determined by combustion in adiabatic calorimetric bomb. Concentration of haem pigments (mg mioglobin/g muscle) was measured by Hornsey method (1956). Labile collagen was analysed by Hill (1966) and collagen solubility was calculated as a percentage to total collagen. The fatty acid profile of subcutaneous, intermuscular and intramuscular fat from the 6th rib was obtained by gas chromatography (Perkin-Elmer Auto syst-X.L). Colorimetric parameters (L* a* b*) were obtained on *longissimus thoracis* muscle of the 6th rib, after the newly cut surface had been exposed to artificial light for 90 minutes at 10°C. Water holding capacity (WHC) was measured by four methods: drip loss (70 g aprox.) according to Honikel (1998), press loss by filter paper press method; thawing loss by thawing the sample during 4 hours in water at 18ºC (Ham, 1960) and cooking loss after cooking the sample in open polyethylene bags in water at 75°C, until the samples achieve 70ºC, measured with a thermocouple in the centre of the sample (Honikel, 1998). Water losses were expressed as a percentage of initial weight. Instrumental textural and sensory analyses were performed with the section between the 8th and 11th ribs aged through 7 days. Warner-Braztler test (Honikel, 1998) in heated meat was assessed using texture analyser TA-XT2. An eight-member trained sensory panel assessed the sensorial attributes, beef odour intensity, tenderness, juiciness; beef flavour intensity and general palatability, using a ten-point descriptive scale. Statistical analysis was performed using one-way analysis of variance (type of feeding) GLM procedure. However, in the case of fatty acid composition, in which the measurements were taken from several locations, two-way analysis of variance was used, considering the effect of diet, fat depot and the corresponding interaction. The statistical package used was SPSS 11.0.

Results and discussion

All calves shown pH values in normal range, and no differences between groups were found (5.5, 5.5 and 5.6 for MF, MC and CF respectively). The meat of calves whose diet was supplemented with milk until slaughter showed higher ether extract, lower crude protein and higher gross energy concentrations than exclusively milk-fed calves and concentrate-fed calves. Due the iron concentrate in milk and concentrate, myoglobin content was lower in exclusively milk-fed calves than in concentrate-fed calves, while calves received milk-concentrate diet provided an intermediate value (Table 1).

Table 1: Composition of *longissimus thoracis* muscle.

	Milk	Milk-Concentrate	Concentrate	P
Dry matter (%)	24.3 ± 0.78^{a}	25.7 ± 0.75^{b}	25.5 ± 0.75^{b}	*
Ether extract (% DM)	5.4 ± 2.23^{a}	8.2 ± 0.49^{c}	6.5 ± 1.53^{b}	*
Crude protein (%DM)	90.6 ± 1.33^{a}	88.0 ± 1.60^{b}	88.9 ± 2.46^{b}	***
Ash (%DM)	4.6 ± 0.25	4.3 ± 0.11	4.3 ± 0.18^{b}	ns
Gross energy (kcal/g)	5.4 ± 0.25^{a}	5.5 ± 0.07^{b}	5.5 ± 0.18^{b}	*
Myoglobin (mg/g)	2.1 ± 0.95^{a}	2.8 ± 1.04^{ab}	3.6 ± 0.62^{b}	*

a, b, c: values with different superscripts indicate significant differences between fat locations.
*** = p<0,001; ** = p<0,01; * = p<0,05; + = p<0,1; ns: p>0.1

The values of the colorimetric parameters obtained in *longissimus thoracis* muscle of the 6th rib are shown in table 2. As may be seen, statistically significant differences ($p<0.05$) were observed between the feeding strategies considered. Exclusively milk-fed calves provided the highest values of lightness and yellowness and the lowest value of redness. These results are probably related to the myoglobin content measured in *longissimus thoracis* muscle.

Whereas in the data concerning drip and thawing losses no statistically significant differences were observed between groups ($p>0.05$), solid feed supplemented with whole milk until slaughter led to a significant decrease ($p<0.05$) in press and cooking losses (table 2). This result is consistent with the findings of other authors who have observed a significant decrease in the percentage of liquid lost during cooking, parallel to the fat deposition (Gariépy *et al*., 1998; Scheeder *et al*., 1999).

Table 2: Colour, water holding capacity and Warner-Braztler for experimental groups.

	Milk	Milk-Concentrate	Concentrate	
Lightness (L*)	45.4 ±3.81 [a]	41.0 ± 1.84 [b]	40.9 ± 1.65 [b]	**
Redness (a*)	8.2 ± 2.78 [a]	12.6 ± 1.42 [b]	13.2 ± 0.64 [b]	***
Yellowness (b*)	10.6 ± 3.63 [a]	6.3 ± 0.71 [b]	7.3 ± 0.94 [c]	***
Drip loss (%)	3.0 ± 1.09	2.2 ± 0.52	2.5 ± 0.46	ns

W-B shear force (kg)	6.4 ± 1.34 [a]	5.4 ± 0.19 [b]	6.5 ± 0.75 [a]	*

a, b, c: values with different superscripts indicate significant differences between fat locations.
*** = p<0,001; ** = p<0,01; * = p<0,05; + = p<0,1; ns: p>0.1

The lower value found in Warner-Bratzler test in calves receiving concentrate and milk until slaughter could be partially explained by the greater intramuscular fat content. Nishimura *et al*. (1998) have reported the important role of the fat content in shear force of cooked meat, indicating that the development of adipose tissue weakens the perimysium and hence increases the tenderness.

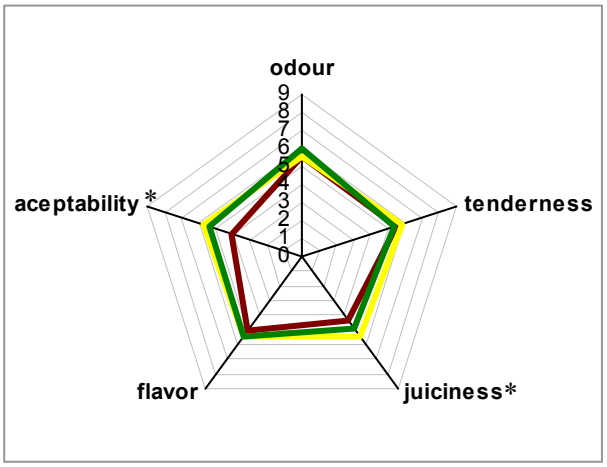

Figure 1: sensorial analysis for experimental groups

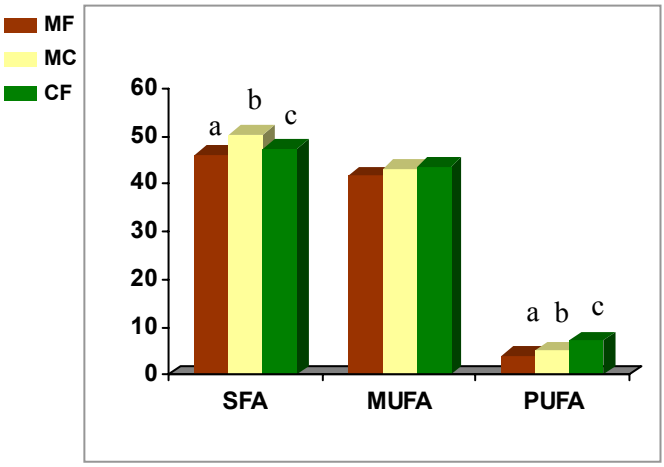

Figure 2: fatty acid composition as a function of type of feeding

The sensory analysis (figure 1) revealed statistically significant differences ($p<0.05$) for juiciness and acceptability, the lowest values corresponding to the calves received milk exclusively. These results are consistent with results obtained from water holding capacity and instrumental texture measurements.

Regarding fatty acid composition, due the absence of significant interaction between the location of fat depot and the type of feeding, both effects are described separately. The diet offered to both experimental groups provided a statistically significant effect on a large part of the fatty acids identified. Overall, the animals receiving a daily amount of whole milk until slaughter (MF and MC groups) showed a significantly higher percentage ($p<0.05$) of saturated fatty acids, which was particularly noteworthy in the case of short-chain fatty acids (figure 2).

Moreover, the calves from the CF group had a higher percentage of polyunsaturated fatty acids ($p<0.05$) and no significant differences ($p<0.05$) were found as regards the percentage of monounsaturated fatty acids. In relation with the saturation of the different fat depots, highly significant differences were found among them (date not shown). The highest proportion of polyunsaturated fatty acids corresponded to the intramuscular fat

and the highest percentage of monounsaturated fatty acids to the subcutaneous depot, being the intermuscular the most saturated fraction ($p<0.01$).

Conclusions

To sum up the results of the present work, we conclude that supplementing the concentrate diet with whole milk until slaughter may be an advantageous alternative to the traditional systems based in an early weaned and after fed only with concentrate and straw or based in exclusively milk fed. However, diets including whole milk changed the fatty acid profile in the carcasses by increasing the proportion of short- and medium-chain fatty acids and reducing their degree of unsaturation.

In either case, more studies are necessary to assess the economic costs involved in this process to achieve a compromise between production expenses and carcass, meat and fat quality.

PASTORAL-FLAVOUR DETECTION IN BEEF FAT USING SPME-GCMS

Watanabe,A., Ueda,Y. and Higuchi,M
Dept. of Animal Production and Grasslands Farming, Tohoku National Agricultural Resarch Center, 020-0198, JAPAN

Background

Some less desirable flavours have been reported in beef from forage-feeding, described as 'grassy' or 'gamey' (Larick et al., 1987). Maruri and Larick (1992) found six diterpenoids compounds in fat volatiles, phyt-1-ene, phytane, neophytadiene, phyt-2-ene, phytadiene and dihydrophytol, and showed these comprised 55.7% of the total volatiles from fat of pasture-fed steers. Bendall (2001) studied aroma compounds of milk, and showed phytol, phyt-1-ene and phyt-2-ene were more easily detected by panellists than neophytadiene and -diene compounds. The aroma of phyt-1-ene and phyt-2-ene were described as 'grassy', 'cardboard', or 'hay'. These volatiles as a component of pastoral flavour are important for consumer acceptance. However, their analysis requires a large amount of sample, and a costly module like purge-and-trap systems for concentrating volatiles.

Objectives

The solid phase micro extraction (SPME) fibre has been widely used because it is simple to use.. The aim of the present study was to establish the method for the sampling of head-space by SPME fibre and the analysis of pastoral-flavour by GCMS, and to clarify the kinetics of change in diterpenoids during a dry-lot period after grazing.

Materials and methods

Animals and sample preparation

Fourteen Japanese Shorthorn steers (14 months of age) were fed on pasture between May and September. After these five months, the steers were finished in a dry lot (concentrate diet 1.6 % of body weight/day, *ad libitum* access to rice straw), and serially slaughtered between 0 day to 154 days. Three steers which were fed on dry lot only were designated controls. Back fat samples were excised from carcasses two days after slaughter. The fat was minced and heated with an equal volume of distilled water at 100 ºC for 15min. This mixture was centrifuged at 3000 rpm for 5 minutes. An aliquot of rendered fat was removed into a glass vial and BHT was added as an internal standard and ant-oxidant (final concentration 0.5 mg/g of fat). Vials were purged with N_2 and stored with oxygen absorber in an aluminium bag at -80 ºC until analysed.

Flavour sampling and GCMS analysis

Fat samples were melted at 60 ºC, and 0.25g was placed in a glass crimp vial (10mL) with a glass fibre filter at the bottom. The vial was brought to 60 ºC for 5 min, after which the SPME fibre were inserted into the headspace and exposed for 30 minutes (static sampling). For selecting the right fibre, four types were purchased from Supelco (Bellefonte, PA), CAR/PDMS, DVB/CAR/PDMS, PDMS/DVB and CW/PDMS and were screened using the day 0 fat sample. The GC oven was held at –10 ºC for one minute after injection and rapidly increased to 40 ºC, held for one minute, and then increased to 290 ºC at 5 ºC /minute. Volatiles were analysed by MS at 70ev and a scanning range of m/z 29 to m/z 350.

Sensory evaluation

A trained sensory panel of 14 members was used. A triangle test was employed for the detection of the flavour difference between the fat from the pasture-fed animals at different dry lot periods, and the fat from the animals reared at the dry lot only.

Results and discussion

Optimization of the extraction by SPME

The day 0 fat sample was used to optimize the extraction of volatiles. The results of analyses are shown in figure 1 as chromatograms. Peaks were identified by mass spectrometry according to Maruri and Larick (1992). Phyt-1-ene, phytane, phytol, and phyt-2-ene were determined in all SPME-fibre extractions. The

CW/PDMS fibre showed the highst sensitivity for these volatile compounds, but lowest for the lower-boiling compounds. The CAR/PDMS fibre showed the higher sensitivity for lower and higher boiling compounds, but phytane was not clearly separated because of interfering peaks. The PDMS/DVB and the DVB/CAR/PDMS fibre were moderately useful for low and high boiling compounds. Although these data indicated that any SPME fibre could be used to study changes in phyt-1-ene, phytane, phytol, and phyt-2-ene, the DVB/CAR/PDMS fibre was selected for the present study.

Figure 2-a, for a DVB/CAR/PDMS fibre, shows the relationship between sampling temperature and extracted diterpenoids during the 20-minute exposure. Higher temperatures were more favourable. Figure 2-b shows the effect of holding time on diterpenoids extraction at 60 ºC, which indicates that the holding time of 40 minutes or more began to exceed the capacity of the absorption. Therefore, the sampling conditions were set to 30 minutes at 60 ºC with a DVB/CAR/PDMS fibre.

Changes of pastoral flavour and sensory analysis

Figure 3 shows the changes of pastoral flavour (phyt-1-ene, phytane, phytol and phyt-2-ene) during dry lot feeding after grazing. The headspace concentration of these compounds decreased with time of dry lot feeding. Among these compounds, phyt-1-ene was the most dominant in GC traces, and showed the highest negative correlation with time in the dry lot period, expressed by the equation of $Y= 12.455e^{-0.0135x}$ ($R^2= 0.90$). The concentration of phyt-1ene, relative value to BHT as internal standard, decreased from about 12 ppm to about one ppm during five months of dry lot feeding. The dry lot-only sample showed 0.10 ppm of phyt-1-ene.

Sensory evaluation revealed that the dry lot feeding over five months (154 days) completely eliminated the flavour. At that point, the concentration of phty-1-ene was below 0.98 ppm (Table 1). Young et al. (1999) reported that 4-methylphenol and indoles were among the compounds causing of pastoral odour and flavour in ruminant fat. These compounds were not detected with the present SPME method (Braggins et al. found already in 1999 that branch-chain fatty acids require dynamic SPME for detection). Phyt-1-ene, however, could be analysed quantitatively, and had a high negative correlation with the length of the dry lot period. These results indicate that phyt-1-ene may be used as a marker of pastoral flavour.

Conclusions

These results showed that SPME-GCMS technique is useful for rapid detection of pastoral flavour, for which phyt-1-ene could be used as a marker. The recognition of this kind of flavour is difficult if the concentration of phyt-1-ene is below one ppm (relative concentration to BHT in fat). Five months of dry lot feeding after grazing eliminated the flavour.

The authors wish to express their sincere appreciation to Dr. T. Braggins (Hill Laboratories, New Zealand) and Dr. O.Young (Auckland University of Technology, New Zealand) for their helpful comments.
