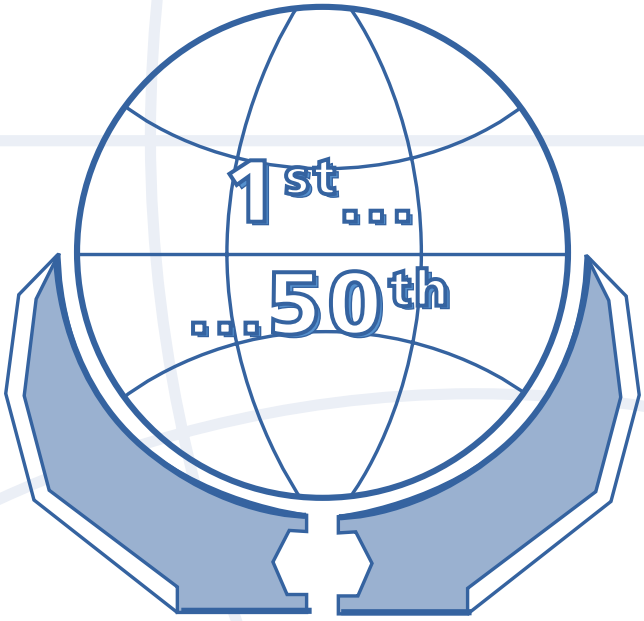
50th International Congress of Meat Science and Technology

August 8th – 13th 2004

Helsinki, Finland



Contents

Opening seremony

Session 1
Biochemistry and biology

SEMIQUANTITATIVE DETERMINATION OF GOAT TISSUE IN MEAT PRODUCTS BY MEANS OF PCR
Binke, R., Altmann, K., Honikel, K.O., and Schwägele, F.

PARAMETERS MEAT QUALITY OF BROILERS FROM DIFFERENT REARING SYSTEMS
Bogosavljevic-Boskovic, S., Gajic, Z., and Mitrovic, S.

STUDIES ON CHANGES OF SOME SELECTED PORK MEAT QUALITY TRAITS IN RELATION TO THE TIME AFTER SLAUGHTER
Borzuta K., Borys A., Grześkowiak E., Strzelecki J., Lisiak D.and Rogalski J.

THE EFFECT OF STORAGE ON THE OXYGEN CONSUMPTION RATE OF BOVINE *M. LONGISSIMUS DORSI* AND *M. PSOAS MAJOR*
Brandon, K., Butler, F. and Allen, P.

THE CORRELATION OF SLIGHT, MEDIUM AND EXTREME RIGOR MORTIS CARCASS TO HALOTHANE GENOTYPE, SARCOPLASMIC CALSIUM AND PROTEIN FUNCTIONAL CHARACTERISTICS IN ABATTOIR SLAUGHTERED PIGS
Chang K. C. , Wang S. C. , and Lin K. J.

EFFECT OF HCG STIMULATION ON ANDROSTENONE, SKATOLE AND INDOLE LEVELS IN ENTIRE MALE PIGS
Chen, G., Zamaratskaia, G. and Lundström, K.

EFFECT OF LACTOFERRIN LEVELS ON TBARS AND NONHEME IRON OF GROUND PORK
Chiu, C.H. and Kuo, C.C.

ASSOCIATION BETWEEN DNA MARKERS OF CANDIDATE GENES AND CARCASS COMPOSITION AND MEAT QUALITY IN KOREAN CATTLE
Chung, K.Y., Kim, W.T., Shin, S.C. and Chung, E.R.

ASSOCIATION OF NEW CALPASTATIN ALLELES WITH MEAT QUALITY TRAITS OF COMMERCIAL PIGS
Ciobanu, D.C., Lonergan, S.M., Bastiaansen, J.W.M., Mileham A., Miculinich, B., Schultz – Kaster, C., Sosnicki, A.A., Plastow, G.S. and Rothschild, M.F.

STUDY OF THE EFFECT OF THE SEXUAL CONDITION ON THE pH AND TEMPERATURE OF THE MEAT FROM CROSSBRED BRAHMAN TO THE 0 AND 24 HOURS POSTSLAUGHTER
Colmenarez, D., Pargas, H., Meléndez, S. and Ciria, J.

EFFECTS OF GROWTH RATE, SEX AND SLAUGHTER WEIGHT ON CARCASS COMPOSITION AND MEAT QUALITY IN COMMERCIAL PIGS
Correa, J. A., Laforest, J. P. , Marcoux, M. , Rivest, J. , Gariépy, C. and Faucitano, L.

ANALYSIS OF THE RELATIONSHIP BETWEEN DNA POLYMORPHISMS IN CANDIDATE GENES AND BEEF TENDERNESS
Costello, S., O'Doherty, E., Mullen, A.M., Kim, K.-S., Ernst, C.W. and Sweeney, T.

PROXIMATE COMPOSITION AND COLLAGEN CONTENT OF BEEF AND PORK MEAT CUTS
Della Torre, Jussara C. M. and Beraquet, N.J.

INFLUENCE OF SEASONS ON INCIDENCE OF DIFFERENT *M. SEMIMEMBRANOSUS* QUALITY OF PIG HALVES OF THREE-RACE HYBRIDS
Džinić, N., Petrović Lj., Tomović, V., Manojlović, D., Timanović, S., Trišić-Ilić, S. and Kurjakov N.

MECHANICAL STIMULATION OF C2C12 CELLS INCREASES M-CALPAIN EXPRESSION, FOCAL ADHESION PLAQUE PROTEIN DEGRADATION AND CELL DIFFERENTIATION
Grossi, A. and Lawson, M.A.

BEHAVIOR OF CHICKEN BREAST MUSCLE MYOSIN SOLUBILIZED IN NEUTRAL AND LOW IONIC STRENGTH SOLUTIONS
Hayakawa, T., Wakamatsu, J., Nishimura, T. and Hattori, A.

THE EFFECT OF SELECTION FOR GROWTH RATE ON SENSORY CHARACTERISTICS OF RABBIT MEAT
Hernández, P., Guerrero, L., Ramírez, J., Mekkawy, W. , Pla, M. , Ariño, B., Ibáñez, N. and Blasco, A.

EFFECT OF ORGANIC RAISING AND BREED CROSS ON CARCASS AND TECHNOLOGICAL MEAT QUALITY OF GROWING/FINISHING PIGS
Heyer, A., Andersson, K. and Lundström, K.

EFFECTS OF EXOGENOUS PROTEASE EFFECTORS ON CALPAINS ACTIVITY AND ULTRASTRUCTURAL CHANGES OF BEEF
Huang, M., Zhou, G.H. and Xu, X.L.

EFFECTS OF POSTMORTEM pH/TEMPERATURE DECLINE ON CHANGES IN FREE AMINO ACIDS DURING AGEING IN PIG LONGISSIMUS MUSCLE
Hwang, I.H., Park, B.Y., Kim, J.H., Cho, S.H., Kim, D.H. and Lee, J.M.

INHIBITON OF POST-MORTEM MUSCLE SOFTENING FOLLOWING *IN SITU* PERFUSION OF PROTEASE INHIBITORS IN FISH
Ishida, N., Yamashita, M., Terayama, M., Minami, T. and Sugita, T.

EFFECT OF FREEZE-THAW PROCESS ON MYOGLOBIN OXIDATION OF PORK LOIN DURING COLD STORAGE
Jeong, J-Y., Yang, H-S., Moon, S-H., Park, G-B. and Joo, S-T.

MECHANISM OF THE PRODUCTION OF TROPONIN T FRAGMENTS DURING POSTMORTEM AGING OF PORCINE MUSCLE
Kitamura, S., Muroya, S., Tanabe, S., Okumura, T., Chikuni, K. and Nishimura, T.

EFFECT OF RN^- AND CALPASTATIN (*CAST*) GENE AS RELATED TO MEAT QUALITY OF STRESS RESISTANT FATTENERS
Koćwin-Podsiadła, M., Krzęcio, E., Zybert, A., Antosik, K., Sieczkowska, H., Kurył, J., Pospiech, E. and Monin, G.

POST-MORTEM PROTEOLYSIS IN FRESH PORK: ROLE OF THE LYSOSOMAL ENZYME SYSTEM AND OF THE CALPAIN SYSTEM
Kristensen, L., Therkildsen, M., Oksbjerg N. and Ertbjerg, P.

THE INFLUENCE OF RYR1 AND CAST/MSPI GENES POLYMORPHISM AND THEIR INTERACTIONS ON SELECTED PORK MEAT QUALITY TRAITS
Krzęcio, E., Kurył, J., Koćwin-Podsiadła, M. and Monin, G.

PRESLAUGHTER HANDLING OF PIGS AND THE EFFECT ON HEART RATE, MEAT QUALITY, AND SR-Ca2+ TRANSPORT
Küchenmeister, U., Kuhn, G. and Ender, K.

DOES THE ACTIVITY OF GLYCOGEN DEBRANCHING ENZYME LIMIT THE RATE OF THE GLYCOLYSIS?
Kylä-Puhju, M., Ruusunen, M. and Puolanne, E.

EFFECTS OF DIETARY VITAMIN E AND VITAMIN C SUPPLEMENTATION ON LEVEL OF α – TOCOPHEROL AND L-ASCORBIC ACID IN MUSCLE AND ON THE ANTIOXIDATIVE STATUS AND MEAT QUALITY OF PIGS
Lahučký, R., Bahelka, I., Novotná, K. and Vašíčková, K.

PORK QUALITY AS RELATED TO HALOTHANE GENOTYPE AND SLAUGHTER CONDITIONS IN A BELGIAN STUDY
Leroy, B., Beduin, J.M., Etienne, G., China, B., Korsak, N., Daube, G. and Clinquart, A.

GIANT FIBRES IN BROILER CHICKENS
Mammoli, R., Branciari, R., Ranucci, D., Miraglia, D., Cioffi, A., Avellini, P. and Severini, M

HOW DOES LACTATE ENHANCEMENT IMPROVE BEEF COLOR STABILITY?
Mancini, R.A., Kim, Y.H., Hunt, M.C., and Lawrence, T.E.

EFFECT OF TRANSPORT TIME AND SEASON ON ASPECTS OF RABBIT MEAT QUALITY
María, G.A., Liste, G., Villarroel, M., Buil, T., Sañudo, C., Olleta, J.L. and López, M.

TRANSPORT RELATED BRUISING IN CATTLE
Midtveit, I., Johansen, J., Schwencke, H. and Alvseike, O.

DIFFERENCE IN DEGRADATION OF TROPONIN-T ISOFORMS AMONG BOVINE MUSCLES DURING POSTMORTEM AGING
Muroya, S., Nakajima, I. and Chikuni, K.

SPECIES-SPECIFIC DIFFERENCE IN INDUCING PIG ADIPOSE CONVERSION FROM THAT OF MOUSE
Nakajima, I., Muroya, S. and Chikuni K.

INTERMUSCULAR VARIATION IN DEGRADATION OF HIGH MOLECULAR WEIGHT PROTEINS IN BOVINE MUSCLES DURING POSTMORTEM AGING
Neath, K.E., Muroya, S., Nakajima, I., Kanai, Y. and Chikuni, K.

EFFECT OF TRANSPORT, LAIRAGE, AND PRESLAUGHTER STRESS ON PORK MEAT QUALITY
Newman, D.J., Hambrecht, E. and Berg, E.P.

MEAT TENDERIZATION BY ACIDIC LISOSOMAL PROTEINASES ASSOCIATED WITH GENOTYPE IN BEEF
Oliván, M., Coto-Montes, A., Caballero, B., Sierra, V., Aldai, N., Rodríguez-Colunga, M.J. and Osoro, K.

ANALYSIS OF POST MORTEM PRODUCTS OF PROTEOLYSIS IN PORCINE TCA SOLUBLE EXTRACTS AND THEIR ASSOCIATION WITH TENDERNESS
O'Reilly, K., Morzel, M., Bouchut, C., Troy, D. and Mullen, A.M.

SDS-PAGE ANALYSIS OF TCA SOLUBLE BOVINE MUSCLE EXTRACTS OVER THE POSTMORTEM AGEING PERIOD
O' Reilly, K., Troy, D.J., Lennon, A. and Mullen, A.M.

CHARACTERISTICS OF CARCASS COMPOSITION FOR HANWOO (COW, BULL, STEER) AND HOLSTAIN STEER
Park, B.Y., Cho, S.H., Kim, J.H., Chae, J.M., Kim, D.H., Yoon, Y.T. and Lee, J.M.

A METHOD FOR DETERMINING THE MUSCLE FIBRE LENGTH
Puolanne, E. and Räsänen, P.

GLYCOGEN, LACTIC ACID AND pH IN MEAT (META ANALYSIS)
Puolanne, E., Yli-Hemminki, M. and Kylä-Puhju, M.

ARE CATHEPSINS B AND D INVOLVED IN POST-MORTEM MYOFIBRILLAR DEGRADATION?
Reville, W.J., Motherway, M.M., Griffin, C. and Zeece, M.G.

MODELING CHANGES WITH AGEING IN THE MECHANICAL PROPERTIES OF BEEF CONNECTIVE TISSUE
Sandrin, A., Beakou, A., Favier, R. and Lepetit, J.

PROTEOMIC APPROACH TO CHARACTERIZE PALE AND DARK TURKEY BREAST MEAT SORTED BY IMAGE VIDEO
Santé-Lhoutellier, V., Le Pottier, G., Sayd, T. and Monin, G.

BLOCKING AGENTS FOR ELISA QUANTIFICATION OF CATHEPSIN L IN BOVINE AND PORCINE MUSCLE CRUDE EXTRACTS
Sentandreu, M.A., Aubry, L., Ouali, A. and Toldrá, F.

THE INDUCIBLE FORM OF HSP70 IN PORCINE SMALL INTESTINE, COLON AND SERUM
Sepponen, K. and Pösö, A.R.

FEEDING PROTEIN DEFICIENT DIETS DURING THE GROWER PHASE INCREASES INTRAMUSCULAR FAT DEPOSITION AND IMPROVES EATING QUALITY OF PORK
D'Souza, D.N., Dunshea, F.R., Pethick, D.W., Pluske, J.R. and Mullan, B.P.

EFFECT OF LAIRAGE TIME ON INCIDENCE OF DIFFERENT QUALITY OF *M. SEMIMEMBRANOSUS* FROM HALVES OF MULTI-RACE HYBRIDS
Tomović, V., Petrović Lj., Džinić, N., Manojlović, D., Timanović, S. and Vidarić D.

ZINC PROTOPORPHYRIN IX CONTRIBUTES TO THE BRIGHT RED COLOR IN PARMA HAM
Wakamatsu J., Nishimura T. and Hattori A.

MANIPULATION OF PRE-RIGOR GLYCOLYTIC BEHAVIORS TO PRODUCE CONSISTENT BEEF TENDERNESS
White A., O'Sullivan A., O'Neill E.E. and Troy D.J.

THE SIGNIFICANCE OF SARCOMERE LENGTH AND PROTEOLYSIS ON THE TENDERNESS OF BOVINE *M. LONGISSIMUS DORSI*
White A., O'Sullivan A., O'Neill E.E. and Troy D.J.

DIETARY CREATINE AFFECTS MEAT QUALITY OF PURE BREEDS OF DUROC AND LANDRACE DIFFERENTLY
Young, J.F., Bertram, H.C. and Oksbjerg, N.

Session 2
Meat quality

INTRAMUSCULAR CONNECTIVE TISSUE AND ITS ROLE IN MEAT QUALITY
Purslow, P.P.

THE CHILLING OF CARCASSES
Savell, J. W., Mueller, S.L. and Baird, B.E.

THE EFFECT OF INTRAMUSCULAR FAT ON EATING QUALITY OF PORK DEPENDNING ON END POINT TEMPERATURE
Aaslyng, M.D. and Støier, S.

COLOR STABILITY OF TRAY-PACKAGED FRESH PORK SAUSAGE LINKS IN LIGHTED DISPLAY
Acton, J.C., Grimes, L.W. and Skelley, G.C.

BEEF CHARACTERISTICS OF THREE MUSCLES FROM COW AND YOUNG BULL
Barge, M.T., Destefanis, G., Barge, P. and Brugiapaglia, A.

LIPID OXIDATION AND 2-ALKYLCYCLOBUTANONES IN IRRADIATED TRADITIONAL PORK PRODUCTS
Battaglia, A., Zanardi, E., Dazzi, G. and Chizzolini, R.

FAT CONTENT REDUCTION IN PIG-SKIN SHEETS BY EXTRACTION WITH SUPERCRITICAL CARBON DIOXIDE
Beltrán, S. and Vaquero, E.M.

QUALITY OF RABBIT MEAT UNDER MODIFIED ATMOSPHERES
Berruga, M.I., Vergara, H. and Linares, M.B.

THE EFFECT OF RIGOR-TEMPERATURE ON ISOMETRIC TENSION, SHORTENING, AND pH FOR OSTRICH *M. GASTROCNEMIUS*, PARS INTERNA
Botha, S.St.C., Hoffman, L.C., Britz, T.J., Nilsen, B.N. and Slinde, E.

PREDICTING AND SEGREGATING BEEF TENDERNESS AMONG URUGUAYAN STEER CARCASSES UNDER COMMERCIAL CONDITIONS USING *POSMORTEM* CARCASS TRAITS, pH, TEMPERATURE AND COLORIMETER READINGS
Brito, G., Pringle, D., San Julián, R. and Montossi, F.

PHYSICAL CHARACTERISTICS OF *LONGISSIMUS DORSI* MUSCLE IN BOVINES FROM DIFFERENT GENETIC TYPES REARED IN SICILY (ITALY)
Chiofalo, V., D'Alessandro, E., Cavallaro, M., Chiofalo, B., Vasi, S., Sanfilippo C., Simonella, S. and Liotta, L.

SENSORY EVALUATION OF BEEF LOIN STEAKS STORED IN DIFFERENT ATMOSPHERES
Clausen, I.

CONSUMER'S PERCEPTION OF BEEF TENDERNESS
Destefanis, G., Brugiapaglia, A., Barge, M.T., Barge, P. and Omento, E.

FACTORS AFFECTING THE WATER CHANGES IN MEAT DURING TENDERISATION
Devine, C.E., Wells, R.W. and Lowe, T.E.

PERFORMANCE DURING RETAIL DISPLAY OF BEEF AND BISON STEAKS AFTER STORAGE UNDER VACUUM AND MODIFIED ATMOSPHERE PACKAGING
Dhanda, J.S., Pietrasik, Z., Shand, P.J. and Pegg, R.B.

CONSUMER PREFERENCES FOR LEANNESS IN BEEF OVER THE PAST 50 YEARS - SMITHFIELD REVISITED -
Dransfield, E. and Ngapo, T.M.

TENDERNESS IN *M. LONGISSIMUS DORSI* FROM COWS – EFFECT OF PELVIC SUSPENSION AND AGEING TIME
Enfält, A.-C., Lundesjö Ahnström, M., Svensson, K., Hansson, I. and Lundström, K.

PHYSICAL QUALITY OF SEVERAL EUROPEAN BEEF BREEDS: PRELIMINARY RESULTS
Failla, S., Gigli, S., Gaddini, A., Signorelli, F., Sañudo, C., Panea, B., Olleta, J.L., Monsón. F., Hocquette, J.F., Jailler, R., Albertí, P., Ertbjerg, P.,Christiansen, M., Nute, G.R. and Williams J.L.

EFFECT OF CARCASS WEIGHT ON SENSORY QUALITY OF YOUNG HOLSTEIN BULLS
Farmer, L., Moss, B., Steen, R., Hagan, T., Majury, L., Kirkland, R., Patterson, D., Kilpatrick, D. and Dawson, S.

CHANGES IN IMMUNOELECTRON MICROSCOPIC LOCALIZATION OF CALPAIN IN MUSCLE INDUCED BY CONDITIONING AND HIGH-PRESSURE TREATMENT
Gerelt, B., Shuhei, Y., Toshie, S., Tadayuki, N. and Atsushi, S.

VOLATILE CHARACTERIZATION OF BLOOD SAUSAGE “MORCILLA” DE BURGOS
González, L., Diez, A. M., Collado, M., González-Sanjosé, M.L., Jaime, I., Ena, J. M. and Rovira, J.

CONSEQUENCES OF USING DENTAL CLASSIFICATION AS INDICATOR OF MATURITY AND BEEF TENDERNESS
Grigera Naón, J.J., Schor, A., Cossu, M. E. and von Bernard, H.

EFFECTS OF VARIOUS PRESLAUGHTER HANDLING TREATMENTS ON THE COLOUR OF DIFFERENT PORK MUSCLES
Hambrecht, E. and Eissen, J. J.

SENSORY AND INSTRUMENTAL ANALYSIS OF LONGITUDINAL AND TRANSVERSE TEXTURAL VARIATION IN PORK *LONGISSIMUS DORSI*
Hansen, S., Hansen, T., Dall Aaslyng M. and Byrne, D.V.

MODIFICATION OF VERY LONG CHAIN N-3 PUFA IN CHICKEN MEAT
Ivanković, S. and Kralik, G.

CHANGES IN PURGE LOSS, WATER HOLDING CAPACITY AND TENDERNESS DURING AGING OF DIFFERENT MUSCLES FROM PIG CARCASSES
Kim, J.H., Park, B.Y., Cho, S.H., Hwang, I.H., Lee, J.M., Sebranek, J.G. and Lonergan, S.M.

EFFECTS OF HOUSING SYSTEMS ON CARCASS CHARACTERISTICS OF FINISHING PIGS
Kralik, G., Romić, Z., Tolušić, Z. and Margeta V.

FACTORS AFFECTING CARCASS AND MEAT QUALITY OF THE HANWOO
Lee, J.M., Park, B.Y., Kim, J.H., Yoo, Y.M., Chae, H.S. and Choi, Y.I.

EFFECTS OF DIETARY *RHUS VERNICIFLUA* STOKES SUPPLEMENTATION ON MEAT QUALITY CHARACTERISTICS OF HANWOO (KOREAN CATTLE) STEERS DURING REFRIGERATED STORAGE
Lee, S. K., Kim, Y. S., Song, Y. H. and Liang, C. Y.

DYNAMICS OF MYOGLOBIN LAYER CHANGE DURING DISPLAY OF COLOR-STABLE AND COLOR-LABILE BEEF MUSCLES
Limsupavanich, R., Kropf, D.H., Hunt, M.C., Boyle, E.A.E., Boyle, D.L. and Loughin, T.M.

EFFECT OF BREED AND STRATEGIC FEEDING ON PORK TENDERNESS EVALUATED WITH INSTRUMENTAL AND SENSORY ANALYSES
Lindahl, G., Claudi-Magnussen, C., Heyer, A. and Lundström, K.

FACTORS AFFECTING BEEF LUMBAR VERTEBRAE DISCOLORATION
Mancini, R.A. and Hunt, M.C.

DIET AND AGEING EFFECT ON INSTRUMENTAL AND SENSORY CHARACTERISTICS OF MEAT FROM PODOLIAN YOUNG BULLS
Marino, R., Caroprese, M., Santillo, A., Pelosi, S., Pacelli, C. and Braghieri, A.

EFFECT OF CLASSING THE BULL CARCASSES WITHIN QUALITATIVE CLASSES (EUROP) ON CHEMICAL AND PHYSICAL-TECHNOLOGICAL PROPERTIES OF MEAT
Mojto, J., Zaujec, K., Lahučký, R., Novotná, K. and Pavlič, M.

CHEMICAL AND PHYSICAL CHARACTERISTICS OF FRESH SUBCUTANEOUS FAT FROM ALENTEJANO PIG BREED
Neves, J., Eusébio, I., Freitas, A., Martins, J. and Nunes, J.

PHYSICAL CHARACTERISTICS OF THE LONGISSIMUS TRAIT MUSCLE OF THE ITALIAN AND POLISH HORSE MEAT
Nicastro, F., Di Matteo, S., Pagone, A., Zezza, L. and Gallo, R.

EFFECTS OF POSTMORTEM DEBONING TIME ON PHYSICAL, CHEMICAL, MORPHOLOGICAL AND ORGANOLEPTIC PROPERTIES OF CHICKEN BREAST MEAT DURING POSTMORTEM AGING
Okumura, T., Morimatsu, F., Yamada, R. and Nishimura, T.

RELATIONSHIP BETWEEN ELECTRICAL IMPEDANCE SPECTROSCOPY AND SENSORY QUALITY OF BEEF
Oliván, M., García, P., Martínez, M.J., Mocha, M., Osoro, K., Elvira, J. and Oliver, M.A.

EFFECT OF PORK PIGMENT ADDITION ON THE COLOUR OF COOKED HAMS FROM EXUDATIVE MEAT
Oliver, M.A., Polo, J., Panella, N., Arnau, J., Gil, M., Contreras, M., Morera, S. and Ruiz, J.

EFFECT OF SUPPLEMENTATION WITH MAGNESIUM AND TRYPTOPHAN ON THE WELFARE AND MEAT QUALITY OF PIGS
Panella, N., Font i Furnols, M., Oliver, M.À., Rodríguez, P., Velarde, A., Tibau, J. and Gil, M.

MEAT QUALITY CHARACTERISTICS OF HIGHLTY MARBLED BEEF IMPORTED TO KOREA WITH REFERENCE TO HANWOO
Park, B.Y., Hwang, I.H., Cho, S.H., Kim, J.H. and Lee, J.M.

BENCHMARKING VALUE IN THE PORK SUPPLY CHAIN: PROCESSING CHARACTERISTICS AND CONSUMER EVALUATIONS OF PORK BELLIES OF DIFFERENT THICKNESSES WHEN MANUFACTURED INTO BACON
Person, R.C., Baird, B.E., Mueller, S.L., McKenna, D.R., Griffin, D.B., McKeith, F.K., Scanga, J.A., Belk, K.E. and Savell, J.W.

BENCHMARKING VALUE IN THE PORK SUPPLY CHAIN: PROCESSING CHARACTERISTICS OF HAMS MANUFACTURED FROM DIFFERENT QUALITY RAW MATERIALS
Person, R.C., Mueller, S.L., Baird, B.E., McKenna, D.R., Griffin, D.B., McKeith, F.K., Scanga, J.A., Belk, K.E. and Savell, J.W.

EFFECT OF GENETICS ON MEAT QUALITY AND SENSORY PROPERTIES OF PORK
Pommier, S.A., Murray, A., Robertson, W., Aalhus, J., Gibson, L., Sosnicki, A. and Klont, R.

REARING OF PARTLY OUTDOOR PIGS IN ESTONIA AND THE QUALITY OF THE PORK
Rei, M., Tammik, M., Vilks,V. and Raudsepp, A.

EFFECT OF FREE AND RUMINALLY-PROTECTED FISH OILS ON FATTY ACID COMPOSITION, SENSORY AND OXIDATIVE CHARACTERISTICS OF BEEF LOIN MUSCLE
Richardson, R.I., Hallett, K.G., Robinson, A.M., Nute, G.R., Enser, M., Wood, J.D. and Scollan, N.D.

INFLUENCE OF SEX, SEASON, WEIGHT AT SLAUGHTER AND MUSCLE TYPE ON BARROSÃ VEAL CHARACTERISTICS
Roseiro, L.C., Costa, P., Santos, C. and Alves, V.

IMPORTED AUSSIE BEEF QUALITY AND COMPARISON WITH US BEEF
Sakata, R. , Oshida T. , Okiura, T., Okumura, T. , Morimatsu, F. and Yamada, R.

EUROPEAN CONSUMER ACCEPTABILITY OF LAMB MEAT FROM DIFFERENT ORIGINS AND PRODUCTION SYSTEMS
San Julián, R., Sañudo, C., Campo, M.M., Olleta, J.L., Oliver, M., Font, M., Barluenga, I., Guerrero, L., Cañeque, V., Alvarez, I., Branscheid, W., Wicke, M , Nute, G.R. and Montossi, F.

THE EFFECT OF REFRIGERATION CONDITIONS IN THE QUALITY OF LAMB MEAT
Santos-Silva, J., Santos, R., Mendes, I., Prates, J., Fraqueza, M.J., Ferreira, C.M., Barreto, A.S. and Lemos, J.P.C.

CARCASS QUALITY OF SEVERAL EUROPEAN CATTLE BREEDS: PRELIMINARY RESULTS
Sañudo, C., Panea, B., Olleta, J.L., Monsón, F., Sierra, I., Albertí, P., Ertbjerg, P., Christiansen, M., Gigli, S., Failla, S., Gaddini, A., Hocquette, J.F., Jailler, R., Nute, G.R. and Williams, J.L

THE RELATIONSHIP BETWEEN CIE L* AND pH AT 1 DAY POSTMORTEM IN PORCINE SEMIMEMBRANOSUS MUSCLES HARVESTED FROM NATIONAL PORK DEVELOPMENT HOGS
Schilling, M.W., Marriott, N.G. and Wang, H.

THE EFFECTS OF RUMINALLY-PROTECTED DIETARY LIPID ON THE FATTY ACID COMPOSITION AND QUALITY OF BEEF MUSCLE
Scollan, N.D., Enser, M., Richardson, R.I., Gulati, S., Hallett, K.G., Nute, G.R. and Wood, J.D.

EFFECT OF VACUUM PACKAGE STORAGE ON PORK PURGE AND COLOR
Sebbana, S., Pommier, S.A., Murray, A.C., Gibson, L., Sosnicki, A. and Klont, R.

IMAGE ANALYSIS FOR CHARACTERIZATION OF THE INTRAMUSCULAR CONNECTIVE TISSUE IN MEAT
Sifre-Maunier, L., Taylor, R.G., Berge, P. and Bonny, J.M.

EFFECTS OF PELVIC SUSPENSION ON THE TENDERNESS OF MEAT FROM FALLOW DEER (*DAMA DAMA*)
Sims, K. L., Wiklund, E., Hutchison, C. L., Mulley, R. C. and Littlejohn, R. P.

EFFECTS OF HIGH OXYGEN PACKAGING ON TENDERNESS AND QUALITY CHARACTERISTICS OF BEEF *LONGISSIMUS* MUSCLES
Sørheim, O., Wahlgren, M., Narum Nilsen, B. and Lea, P.

HOW DIFFERENT OPERATING CONDITIONS OF FILTER PAPER PRESS METHOD AFFECT MEAT WATER HOLDING CAPACITY MEASUREMENT
Tassone, S., Barbera, S. and Battaglini L.M.

EFFECTS OF INTRAMUSCULAR FAT DEPOSITION ON THE BEEF TRAITS OF JAPANESE BLACK STEERS
Ueda, Y. , Watanabe, A. , Higuchi, M. , Shingu, H. , Kushibiki, S. and Shinoda, M.

EFFECT OF CARCASS SUSPENSION METHOD ON WATER HOLDING CAPACITY OF *M. LONGISSIMUS* FROM FALLOW DEER (*DAMA DAMA*) AND LAMB
Wiklund, E., Mulley, R. C., Hutchison, C. L. and Littlejohn, R. P.

Session 3
Microbiology and safety

THE SAFETY OF PASTEURISED IN-PACK CHILLED MEAT PRODUCTS WITH RESPECT TO THE FOODBORNE BOTULISM HAZARD
Peck, M.W. and Stringer, S.C.

MICROBIAL ECOLOGY OF MARINATED MEAT PRODUCTS
Björkroth, J.

EVALUATION OF PORK HYGIENE QUALITY USING BIODETECTING METHODS
Chen, M.T., Kuo, H.l., Lin, S.M., Lin, D. and Kuo, M.G.

INFLUENCE OF THE ONION VARIETY ON THE SHELF LIFE OF THE BLOOD SAUSAGE "MORCILLA DE BURGOS"
Diez, A. M., González, L., Ena, J. M., Jaime, I. and Rovira, J.

COMPARISON BETWEEN TRADITIONAL AND PCR TECHNIQUES IN THE IDENTIFICATION OF FOODBORNE PATHOGENS IN BLOOD SAUSAGE
Diez, A.M., González, L., Jaime, I., Llanos, A., Santos, J.A. and Rovira, J.

AN APPLICATION OF BLEND OF NATURAL ANTIOXIDANTS IN DRY-FERMENTED SAUSAGES
Dragoev, S. and Balev, D.

A TECHNOLOGYCAL STUDY ON THE LIPID PEROXIDATION IN GROUND MEAT AND PROLONGTION THE SHELF LIVE. CHEMICAL AND MICROBIOLOGICAL PROPERTIES
Dragoev, S., Balev, D. and Stoychev D.

METHODS FOR LISTERIA INOCULATION; VALIDATION OF A SURFACE AND A MIXING METHOD
Enthoven, P., Kaathoven, R., Geesink, G., Gerris, C. and Hemke, G.

EFFECT OF AR/CO2 MODIFIED ATMOSTHERE PAKAGING ON TURKEY MEAT CHARACTERISTICS
Fraqueza, M.J., Bessa, R.J.B., Pereira, M.S., Ferreira, M.C. and Barreto, A.S.

COMPARISON OF MICROFLORA OF TRADITIONAL FERMENTED SAUSAGES IDENTIFIED WITH TRADITIONAL AND MOLECULAR METHODS
Gasparik-Reichardt, J., Cocolin, L., Drosinos, E. and Gaitis, F.

EFFECT OF LACTIC ACID BACTERIA OR GLUCONODELTALACTONE ON TEXTURAL AND PHYSICOCHEMICAL PROPERTIES OF CALCIUM CHLORIDE MARINATED BOVINE BRACHIOCEPHALICUS MUSCLE
Gonzalez-Tenorio, R., Mateo-Oyagüe, J., Totosaus, A. and Pérez-Chabela, M.L.

COMPETITIVE INHIBITION OF MEAT SPOILAGE BACTERIA AND PATHOGENS
Greer, G.G. and Dilts, B.D.

THE EFFECT OF DISINFECTANTS ON *LISTERIA MONOCYTOGENES* ADHERENT TO MEAT BIOFILM
Gunvig, A.

MOLECULAR EPIDEMIOLOGY AND DISINFECTANT SUSCEPTIBILITY OF *LISTERIA MONOCYTOGENES* FROM MEAT PROCESSING PLANTS AND HUMAN INFECTIONS
Heir, E., Røtterud, O.-J., Lindstedt, B.-A., Vardund, T., Kapperud, G. and Nesbakken, T.

HYGIENIC CONDITIONS OF A MEXICAN LOCAL SLAUGHTERHOUSE
Hernandez, S., Zúñiga, A., Rovira, J., Jaime, I., Sanchez, I. and Santos E.M.

STUDY OF CONTAMINATION VARIATION LEVEL OF STAPHYLOCOCCUS AUREUS IN POULTRY SLAUGHTER PREMISES WITH HACCP SYSTEM
Javadi, A., Ranzavilar, V. and Jalali, M.

KINETICS OF COLOUR LOSS FOR SLICES OF FERMENTED SAUSAGE DISPLAYED IN LIGHT OF VARYING INTENSITY
Jydegaard, A-M., Nielsen, H.J.S., Dawson, P.L. and Acton, J.C.

QUANTITATIVE ASSESMENT OF ANTIBIOTIC AND ANABOLIC AGENTS IN BROILER MEAT CHICKEN
Kadim, I.T., Mahgoub, O., Al-Magbaly, R.S. and Annamali, K.

DNA-FINGERPRINTING OF *Campylobacter* spp. FROM POULTRY AND GENETIC RELATIONSHIP OF SELECTED STRAINS TO HUMAN ISOLATES
Klein, G., Beckmann, L., Luber, P. and Bartelt, E.

INFLUENCE OF FERMENTATION ON CREATINE AND LACTATE CONCENTRATIONS IN WHITE EFFLORESCENCES ON DRY FERMENTED SAUSAGE
Kröckel, L.

PHYSIOCHEMICAL PROPERTIES OF DRY-CURED HAMS FROM TAIWAN BLACK PIGS AND LYD HYBRID PIGS
Liu, D-C., Huang, P-C., Shiao, C-L., Chen, M-T., and Tan, F-J.

CHARACTERIZATION OF *STAPHYLOCOCCUS AUREUS* ISOLATED FROM A SLAUGHTERHOUSE FOR PIGEONS BY RAPD-PCR AND REA-PFGE
Losito, P., Blaiotta, G., Vergara, A., Villani F. and Ianieri, A.

COLONISATION OF PIGLETS BY GENOTYPES OF *CAMPYLOBACTER COLI*
Madden, R. H. and Soultos, N.

OPTIMISATION OF THE ISOLATION OF *CAMPYLOBACTER* SPP. FROM RETAIL PACKS OF RAW POULTRY
Madden, R. H., Moran, L. and Scates, P.

IDENTIFICATION OF IMPORTANT SPOILAGE BACTERIA AND FUNGI FROM TWO TYPES OF PORTUGUESE SMOKED DRY SAUSAGES AFTER SHELF-LIFE PERIOD IN MODIFIED ATMOSPHERE PACKAGE
Matos, T.J.S., Jensen, B.B., Barreto, A. and Hojberg, O.

INVESTIGATING OZONE TREATMENT AS A REMEDIAL ACTION FOR MICROBIAL SPOILAGE OF MEAT BY MEASURING VOLATILES USING PROTON-TRANSFER-REACTION MASS-SPECTROMETRY
Mayr, D., Mikoviny, T., Skalny, J.D., Hartungen, E., Mason, N.J. and Märk, T.D.

APPLICATION OF LACTATE AND DIACETATE TO IMPROVE THE SHELF-LIFE OF THE BLOOD SAUSAGE "MORCILLA DE BURGOS"
Molinero, C., Diez, A. M., González, L., Santos, E.M., Jaime, I. and Rovira, J.

EFFECTS OF HOT WATER AND LACTIC ACID TREATMENT OF PORK CARCASS PRIOR TO COOLING ON MICROBIAL AND ULTIMATE PORK QUALITY
Moon, S-H., Yang, H-S., Hwang, Y-H., Sung, N-J., Park,G-B. and Joo, S-T.

LETHAL EFFECTS OF NON-DEHEATED (HOT) MUSTARD FLOUR ON E. COLI O157:H7 IN REFRIGERATED NITROGEN PACKAGED GROUND BEEF
Muthukumarasamy, P., Han, J.H. and Holley, R.A.

SHELF LIFE OF MEAT FROM PODOLIAN YOUNG BULLS IN RELATION TO THE AGEING METHOD
Napolitano, F., Braghieri, A. , Pacelli, C., Cifuni, G.F., Riviezzi, A. M., Grasso, F. and Girolami, A.

OPTIMUM PROCESS CONDITIONS FOR SINGLE-SIDED PAN-FRYING OF HAMBURGERS FOR SAFETY
Ou, D. and Mittal, G.S.

MICROBIOLOGICAL, CHEMICAL AND PHYSICAL CHANGES IN ITALIAN "LONZA"
Paparella, Antonello, Chaves López, Clemencia , Pittia, Paola and Di Berardo, Luca

MICROBIOLOGICAL CONDITIONS OF SHEEP CARCASSES FROM HIGH-CAPACITY SLAUGHTERHOUSE: A PRELIMINARY STUDY
Pennisi, L., Colavita, G., Vergara, A. and De Castelli, L.

INFLUENCE OF INJECTION, PACKAGING AND STORAGE CONDITIONS ON THE MICROBIAL AND COLOUR STABILITY OF BEEF AND BISON STEAKS
Pietrasik, Z., Dhanda, J.S., Pegg, R.B. and Shand, P.J.

EFFECT OF MILD CHEMICAL AND PHYSICAL HURDLES ON THE SHELF LIFE OF VACUUM-PACKED PORTIONS OF ITALIAN MORTADELLA SAUSAGES
Pizza A., Pedrielli R., Quintavalla S., Bergamaschi M., Franceschini M., Barbieri G. and Larini A.

A PROPOSAL ON SETTING PERFORMANCE OBJECTIVES FOR CAMPYLOBACTER AND EHEC IN MEAT INDUSTRY
Rahkio, M. and Kärkkäinen, T.

QUANTITATIVE RISK ASSESSMENT OF PATHOGENIC *YERSINIA* AND *LISTERIA MONOCYTOGENES* CONTAMINATION PROCESS ALONG PRODUCTION STAGES OF ORGANIC AND TRADITIONAL PORK MEAT
Ranta, J., Siekkinen, K.-M., Laukkanen, R., Ortiz, P., Korkeala, H. and Maijala, R.

EFFECT OF MODIFIED ATMOSPHERES PACKAGING ON THE HYGIENIC AND ORGANOLEPTIC QUALITY OF "CECINA DE LEON" KEPT FOR EXTENDED STORAGE
Rubio, B., Molinero, C., Martínez, B., González-Fernández, C. and García-Cachán, M.D.

SENSORY AND MICROBIOLOGICAL PROPERTIES OF DRIED HAMS TREATED WITH HIGH HYDROSTATIC PRESSURE (HP)
Saccani, G., Parolari, G., Tanzi, E. and Barbuti, S.

MANUFACTURING PROCESS DEVELOPMENT ON A READY TO HEAT AND EAT PORTUGUESE TRADITIONAL PRODUCT: "MARANHOS"
Salavessa, J. J. and Barreto, A. S.

CHEMICAL CHANGES IN THE LIPID FRACTION OF TRADITIONAL DRY FERMENTED SAUSAGE "PAINHO DE PORTALEGRE" DURING RIPENING
Santos, C., Partidario, A. , Padilha, M. , Silva, L. , Roseiro, C. and Elias, M.

PREDICTING THE RISK OF HIDE CROSS-CONTAMINATION IN THE CATTLE LAIRAGE DURING HOLDING PRIOR TO SLAUGHTER
Small, A. and Buncic, S.

IDENTIFICATION OF PEDIOCIN PA-1 PRODUCING *PEDIOCOCCUS PENTOSACEUS* TISTR 536 ISOLATED FROM NHAM (THAI FERMENTED MEAT)
Swetwiwathana Adisorn, Zendo Takeshi, Lotong Napha, Nakayama Jiro, and Sonomoto Kenji

MICROBIOLOGICAL SAFETY IN SUCCEDANEUM ITALIAN SALAMI
Terra, N. N., Fries, L. L. M., Terra, A., Peña, C. V. M., Terra, L. M. and Milani, L.

ENRICHMENT OF THE ITALIAN SALAMI WITH INSOLUBLE WHEAT FIBER
Terra, N.N., Terra, A. M., Peña, C. V. M., Terra, L. M., Milani, L. and Fries, L. L. M.

MICROBIOLOGICAL QUALITY OF FRESH MEAT PRODUCTS STORED UNDER MODIFIED ATMOSPHERES
Tremonte, P., Sorrentino, E., Succi, M., Di Renzo, T., Reale, A., Maiorano, G. and Coppola, R.

RESULTS OF PHYSICOCHEMICAL AND SENSORIAL INVESTIGATION OF DIFFERENT TYPE OF FERMENTED SAUSAGES DURING FERMENTATION AND RIPENING PROCESS
Turubatović, L., Hadžiosmanović, M., Čaklovica, F., and Gaitis, F.

COMPARISON OF SENSORY AND ANALYTICAL PROPERTIES OF DRY SAUSAGE PRODUCED WITH DIFFERENT PROCESSING PROCEDURES
Ulmer, K. and Fischer, A.

MICROBIOLOGICAL CONTAMINATION OF LAMB CARCASSES: EFFECT OF ABATTOIR SIZE, SAMPLING SITE AND TIME OF STORAGE
Vergara, H., Berruga, M.I., Linares, M.B. and Gallego, L.

A MECHANISTIC SIMULATION MODEL TO STUDY THE EFFECTIVENESS OF INTERVENTIONS AGAINST *E.COLI* O157 IN A CATTLE SLAUGHTERHOUSE
Vosough Ahmadi, B., Velthuis, A.G.J., Hogeveen, H. and Huirne, R.B.M.

THE EFFECTS OF NITRITE AND TRADITIONAL COOKING PROCESS ON THE SURVIVAL OF *CLOSTRIDIUM SPOROGENES* AND AUTOXIDATION IN KAVURMA, A TRADITIONAL TURKISH FRIED MEAT PRODUCT
Yetim, H., Kayacier, A., Gungor, Z. and Ockerman, H.W.

Session 4
Meat technology

RECENT CONCERNS ABOUT STUNNING AND SLAUGHTER
Gregory, N.G.

EFFECTS OF HEAT ON MEAT PROTEINS–IMPLICATIONS ON STRUCTURE AND QUALITY OF MEAT PRODUCTS
Tornberg, E.

PHYSICOCHEMICAL PROPERTIES OF MEAT BATTERS WITH ADDED WALNUT: EFFECT OF SALT LEVELS
Ayo, M. J., Jiménez Colmenero, F., Carballo, J. and Ruiz-Capillas, C.

EFFECT OF ADDING TUMERIC AND LEMON GRASS DURING MARINATION ON THE QUALITY OF ROAST CHICKEN
Babji, A.S., Hui Vern, N., Ch'ng, S.E. and Siaw, C. L.

EFFECTS OF COOKING ON CAROTENE AND FREE FATTY ACID CONTENTS OF CHICKEN BURGER INCORPORATED WITH PALM FATS
Babji, A.S., Nor Aishah, M.S ., Alina, A.R ., Wan Rosli, W.I. and Ch'ng S.E.

STUDY ON SALT-INDUCED CHEMICAL CHANGES IN PORK MUSCLE BY FT-IR IMAGING
Böcker, U., Ofstad, R., Egelandsdal, B. and Kohler, A.

pH, WATER ACTIVITY, AND PROXIMATE COMPOSITION OF MORCILLA DE LEÓN, A TRADITIONAL EUROPEAN BLOOD SAUSAGE
Cabeza, E., Zumalacárregui, J.M. , Antiduelo, A. and Mateo, J.

LOW VOLTAGE ELECTRICAL STIMULATION, HOT BONING AND HIGH TEMPERATURE CONDITIONING OF *LONGISSIMUS LUMBORUM* MUSCLE FROM *BOS INDICUS*: DRIP AND COOKING LOSS, WATER HOLDING CAPACITY AND COLOUR
Cardoso, S., Beraquet, N.J. and Pinto Neto, M.

EFFECT OF PHOSPHATE, ASCORBIC ACID AND ALPHA-TOCOPHEROL WITH CONTINUOUS NON-VACUUM OR VACUUM TUMBLING PROCESS ON LIPID OXIDATION OF PRECOOKED ROAST BEEF
Cheng, J-H. and Ockerman, H.W.

FACTORS AFFECTING ACCEPTABILITY OF DRY-CURED HAM THROUGOUT EXTENDED RIPENING UNDER "BODEGA" CONDITIONS
Cilla, I., Martínez, L.A., Beltrán, J.A. and Roncalés, P.

EFFECT OF WALNUT, MICROBIAL TRANSGLUTAMINASE AND STORAGE TIME ON THE WATER AND FAT BINDING CAPACITY OF SALT-FREE BEEF BATTERS
Cofrades, S., Serrano, A., Ayo, J., Carballo, J., Ruiz-Capillas, C. and Jiménez Colmenero, F.

ADDITION OF WHEY PROTEIN CONCENTRATE AND SODIUM CHLORIDE TO BEEF MUSCLES: EFFECTS OF TUMBLING PROCEDURES AND SOUS VIDE COOKING TREATMENT ON TECHNOLOGICAL PARAMETERS, PHYSICAL PROPERTIES AND SENSORY QUALITY
Corrales, D.D., Gonzalez, C. B., Szerman, N., Sancho, A. M., Carduza, F., Sanchez, G., Irurueta, M. and Vaudagna, S.R.

OPTIMISING THE MEASURING OF MEAT FLAVOURS BY MEANS OF AN ELECTRONIC NOSE VIA SENSOR SELECTION
Dederer, I.

SENSORIAL AND RHEOLOGICAL PROPERTIES OF "PAINHO DE PORTALEGRE". THE INFLUENCE OF MEAT AND FAT SIZE PORTIONS AND NACL CONCENTRATION
Elias, M., Santos, A. C., Palma, V., Santos, C. and Roseiro, L.C.

EFFECT OF THE ADDITION OF SAGE AND ROSEMARY EXTRACTS ON THE OXIDATIVE STABILITY OF DIFFERENT TYPES OF LIVER PATES
Estevez, M., Morcuende, D.,Ventanas, J. and Cava, R.

LIPID OXIDATION DURING REFRIGERATED STORAGE OF LIVER PATES FROM EXTENSIVELY REARED IBERIAN PIGS AND INTENSIVELY REARED WHITE PIGS
Estevez, M., Ventanas, S., Ramrez, R. and Cava, R.

CALCIUM CHLORIDE MARINATION OF BOVINE BRACHIOCEPHALICUS MUSCLE: EFFECT OF TUMBLING ON TEXTURAL PROPERTIES
Gonzalez-Tenorio, R., Mateo-Oyagüe, J., Totosaus, A. and Pérez-Chabela, M.L.

DISTRIBUTION OF RELATIVE HUMIDITY IN DEPENDENCE OF THE INLET AIRFLOW DIRECTION IN DRY SAUSAGE RIPENING CHAMBERS
Hermle, M., Jesinger, T., Gschwind, P., Kottke, V. and Fischer, A.

PROTEOMIC CHARACTERISATION OF NORMAL AND PASTY SPANISH DRY-CURED HAMS
Hortos, M., Santé-Lhoutellier, V., Arnau, J. and Monin, G.

EFFECTS OF COOKING TEMPERATURE AND TIME ON GEL FORMATION ABILITY AND COLOR OF SURIMI-LIKE PORK
Hwang, Y-H., Kang, G-H., Sung, N-J., Park, G-B. and Joo, S-T.

EFFECTS OF HIGH-PRESSURE TREATMENT ON INTRAMUSCULAR COLLAGEN MOLECULE
Ichinoseki, S., Nishiumi, T., Sakata, R. and Suzuki, A.

GEL PROPERTY OF SURIMI-LIKE MATERIAL FROM PRE- OR POST-RIGOR PORCINE MUSCLE
Kang, G-H., Yang, H-S., Hur, S-J., Joo, S-T. and Park, G-B.

THE EFFECT OF SODIUM CHLORIDE, SOYBEAN PROTEIN AND STARCH ON GEL PROPERTIES AND COLOR OF BEEF SURIMI
Kong Baohua, Chi Yujie, Li Boxun and Jin Zhong

METHOD AND DEGREE OF MECHANICAL TENDERISATION OF BEEF MUSCLES FOR USE IN RE-FORMED JOINTS MADE WITH A COLD-SET BINDER
Lennon, A.M., Moon, S.S., Kenny, T.A. and Ward, P.

HEAT-INDUCED CHANGES IN THE MECHANICAL PROPERTIES OF PERIMYSIAL CONNECTIVE TISSUE FROM TWO BEEF BREEDS
Lepetit, J., Damez, J.L., Favier, R. and Listrat, A.

DEVELOPMENT OF TECHNOLOGY FOR PRODUCTION OF MEAT-PLANT EXTRUDATES
Lisitsyn, A.B., Krylova, V.B., Oleinikov, V.V.

EFFECT OF DIFFERENT CONCENTRATIONS OF NATURAL COLORANTS ON THE COLOUR OF FRESH PORK SAUSAGES PACKAGED IN MODIFIED ATMOSPHERE
Martínez, L., Cilla, I., Beltrán, J. A. and Roncalés, Pedro.

RESIDUAL LEVELS OF THREE PRESERVATIVES AND ECONOMICAL VIABILITY OF SURFACE TREATMENTS APPLIED IN PORTUGUESE SMOKED DRY SAUSAGES
Matos, T.J.S., Barreto, A. and Bernardo, F.

THE INFLUENCE OF WINE COMPONENTS ON THE TENDERNESS AND HISTOLOGICAL STRUCTURE OF COOKED MEAT
Mega, A., Mitsuhashi, T. and Tajima, M.

INFLUENCE OF ANATOMICAL ORIGIN OF RAW MEAT ON THE SENSORY AND CHEMICAL CHARACTERISTIC OF DRIED BEEF "CECINA DE LEON"
Molinero, C., Rubio, B., González-Fernández, C., Martínez, B. and García-Cachán, M.D.

DEVELOPMENT OF BEEF BURGER MEAT PATTIES ENRICHED IN CLA
Murray, B.E., Sarries, V., Dalton, D., Maloney, A.P., and Troy, D.J.

EFFECTS OF *POLYGONUM HYDROPIPER* L. EXTRACTS ON THE QUALITY OF CHILLED BEEF STEAK
Noriham, A., Babji, A.S. and Nulkirah, M.

EFFECT OF ANTIOXIDANTS ON COLOR CHANGE AND LIPID OXIDATION OF SLICED ROAST BEEF
Okayama, T., Iwanaga, S., Kamisoyama, H., Numata, M., Sakata,R. and Muguruma, M.

IMPROVEMENT OF PROPERTIES OF PRODUCTS MADE FROM PSE MEAT BY ADDITION OF SODIUM CASEINATE AND MTGASE
Olkiewicz, M., Pospiech, E., Grześ, B. and Kłossowska, B.

COLOUR PHOTOGRAPHS TO ESTIMATE HETEROCYCLIC AMINE INTAKE FROM PORK OF DIFFERENT RN GENOTYPES
Olsson, V., Skog, K., Lundström, K. and Jägerstad, M.

SOUS VIDE COOKED BEEF MUSCLE. EFFECT OF SALT ADDITION ON BIOCHEMICAL PARAMETERS
Pazos, A.A., Guidi, S., Vaudagna, S.R., Sancho, A., Carp, D., Toledo, A.E., Langman, L.E., Sanchez, G. and Gonzalez, C.B.

ANALYSIS OF UNIQUE FLAVOR OF CHINESE TRADITIONAL XUANWEI HAM
Qiao, F., Ma, C., and WU, X.

INDONESIAN BAKSO MEATBALL PROPERTIES WITH POSTMORTEM MEAT TIME AND TAPIOCA STARCH CONCENTRATIONS
Rahardiyan, D. and McMillin, K.W.

WATER LOSS FROM PORK DURING COOKING – DOES pH DURING COOKING HAVE AN IMPACT?
Rosenvold, K., Baltzer, M., Aaslyng, M.D. and Støier, S.

DESCRIPTIVE EMPIRICAL MODEL OF INSTRUMENTAL HARDNESS CHANGES IN DRY-CURED *SEMIMEMBRANOSUS* AND *BICEPS FEMORIS* MUSCLES AS A FUNCTION OF WATER CONTENT, NaCl AND pH
Ruiz-Ramírez, J., Arnau, J., Guerrero, L. and Gou, P.

ANTIOXIDANT ACTIVITY OF BORAGE (*BORAGO OFFICINALIS*) IN FRESH AND COOKED BEEF PATTIES
Sánchez-Escalante, A., Dávila, J.L., Torrescano, G., Valenzuela, M. and Roncalés, P.

QUALITY OF LOW-FAT MEATBALLS CONTAINING LEGUME FLOURS AS EXTENDERS
Serdaroglu Meltem, Yildiz-Turp Gülen and Abdoimov Kiyalbek

TEXTURE PROPERTIES OF SAUSAGE EMULSIONS ANALYSED BY EXTRUSION METHODS AS PREDICTION INDEX OF SAUSAGE TEXTURE
Severiano Pérez P. , Rovira J. , González-Sanjosé M.L. and Jaime, I.

PREDICTION OF INTER-MUSCULAR FAT IN THE FRESH PORK LEG
Stetzer, A.J., Klont, R.E., Sosnicki, A.A. and McKeith, F.K

THE INFLUENCE OF PHYSICAL AND CHEMICAL PROPERTIES OF PORK FAT ON THE QUALITY OF HEAT TREATED MEAT PRODUCTS
Svenstrup, G., Kristensen, L., Risbo, J. and Skibsted, L.H.

PHYSICAL AND SENSORY CHARACTERISTICS OF MARINATED CHICKEN DRUMSTICKS TREATED WITH THE LACTOPEROXIDASE SYSTEM AND THERMAL TREATMENT
Tan, F-J. and Ockerman, H.W.

PHYSICAL PROPERTIES AND FOLDING TEST OF COMMERCIAL MEAT BALLS IN THAILAND
Taprap R., Surapunpisid Y., Fungladda E., and Jiatrakul, P.

VISIBLE-NIR SPECTROSCOPY: A NON-DESTRUCTIVE RAPID TECHNIQUE TO ASSESS END-POINT TEMPERATURE OF KAMABOKO GEL
Uddin, M., Okazaki, E., Uddin, Ahmad, M. U., Fukuda, Y. and Tanaka, M.

EFFECTS OF BLENDING CHICKEN BY-PRODUCTS WITH PALM FAT OXIDATION AND SENSORY PROPERTIES OF CHICKEN BOLOGNA DURING FROZEN STORAGE (-18ºC)
Wolyna, P. and Babji, A.S.

EFFECTS OF PROTEIN CONCENTRATION, pH, IONIC STRENGTH ON HEAT-INDUCED GELATION PROPERTIES OF MYOSIN FROM RABBIT SKELETAL MUSCLES
Xu, X.L., Zhou, G.H. and Huang, H.B.

TEXTURAL AND SENSORY PROPERTIES OF OATMEAL ADDED LOW FAT SAUSAGE WITH DIFFERENT TYPES OF MEATS
Yang, H-S., Chol, S-G., Lee, J-I., Kang, G-H., Joo, S-T. and Park, G-B.

Session 5
Meat in nutrition and health

MEAT AS A COMPONENT OF A HEALTHY DIET – ARE THERE ANY RISKS OR BENEFITS IF MEAT IS AVOIDED IN THE DIET
Biesalski, H-K.

MEAT FATS IN NUTRITION
Valsta, L., Tapanainen, H. and Männistö, S.

SODIUM IN MEAT PRODUCTS
Ruusunen, M. and Puolanne, E.

BREED AND FEEDING EFFECT ON FATTY ACID COMPOSITION OF INTRAMUSCULAR FAT IN YEARLING BULLS
Aldai, N., Murray, B.E., Troy, D.J., Oliván, M., Martínez, A., Nájera, A.I. and Osoro, K.

CONJUGATED OCTADECADIENOIC ACID ISOMERS (CLA) IN PORTUGUESE VEAL FROM AROUQUESA AND BARROSÃ AUTOCHTHONOUS BREED CALVES SLAUGHTERED IN EARLY AUTUMN
Alfaia, C.M., Quaresma, M.A., Portugal, A.P., Bessa, R.J., Castro, M.L. and Prates, J.A.

ANTIHYPERTENSIVE ACTIVITIES GENERATED FROM PORCINE SKELETAL MUSCLE PROTEINS BY LACTIC ACID BACTERIA
Arihara, K., Nakashima, Y., Ishikawa, S. and Itoh, M.

FATTY ACID CONTENT AND COMPOSITION OF MUSCLE LIPIDS OF GOAT KIDS FED SUNFLOWER OIL SUPPLEMENTED DIET
Banskalieva, V., Marinova, P., Renerre, M. and Tzvetkova, V.

ABOUT SOME REGULAR FEATURES OF CHANGE OF BEEF FAT FRACTIONAL COMPOSITION DURING FERMENTATIVE GLYCEROLYSIS
Berdutina A.V., Nikitina E.S., Mitaleva S.I., Karpo B.S. and Trubnikova O.N.

ASSESMENT OF EFFICIENCY OF CHICK-PEA USE FOR SELENIUM ENRICHMENT OF STEER BEEF AND POULTRY MEAT
Chernukha I.M., Belyakina N.E.and Gorlov N.F.

COMMON DIETS: NUTRITION AND OBESITY
Chikere, K.R.

EFFECT OF BREED ON MEAT QUALITY AND FATTY ACID COMPOSITION OF KOREAN NATIVE BLACK PIGS, LANDRACE AND YORKSHIRE
Cho, S-H., Park, B-Y., Kim, J-H., Hwang, I-H., Kim, M-J., Kim, Y-J. and Lee, J-M.

FIBER TYPE PROFILE AND CHEMICAL COMPOSITION OF THREE MARONESA VEAL MUSCLES
Costa, P., Roseiro, L.C., Oliveira, D., Gonçalves, H., Alves, V. and Santos, C.

HORSEMEAT AS A PROMISING RAW MATERIAL FOR PRODUCTION OF CANNED MEAT FOR CHILDREN
Cretov M.A., Ustinova A.V. and Belyakina N.E.

FATTY ACID COMPOSITION OF LAMB MEAT FROM SPAIN, BRITAIN, GERMANY AND URUGUAY
Díaz, M.T., Álvarez, I., De la Fuente, J., Sañudo, C., Campo, M.M., Oliver, M.A., Font i Furnols, M., Montossi, F., San Julián, R., Branscheid, W., Nute, G. R. and Cañeque, V.

EFFECT OF A LINSEED OIL SUPPLEMENTATION ON TOTAL FATTY ACIDS OF MUSCLES AND ON COLOUR STABILITY AND LIPID OXIDATION OF BOVINE MEAT
Gatellier, P., Bauchart, D., Durand, and Renerre, M.

EFFECT OF ROSEMARY EXTRACT ON THE FORMATION OF HETEROCYCLIC AROMATIC AMINES IN FRIED BEEF PATTIES
Gibis, M., Jautz, U. and Fischer, A.

THE EFFECT OF GENDER ON THE MEAT QUALITY CHARACTERISTICS OF KUDU (*TRAGELAPHUS STREPSICEROS*)
Hoffman, L.C.

COMPARISON OF IMPORTED VS. DOMESTIC BEEF CUTS FOR RESTAURANT USE IN VENEZUELA. I. COOKERY TRAITS, CONSUMER IMPRESSIONS AND SHEAR FORCE
Huerta-Sánchez, D., Huerta-Leidenz, N. and Rodas-González, A.

COMPARISON OF IMPORTED VS. DOMESTIC BEEF CUTS FOR RESTAURANT USE IN VENEZUELA. II. MARBLING LEVELS, PROXIMATE AND MINERAL COMPOSITION
Huerta-Sánchez, D., Villa, V., Arenas de Moreno, L., Huerta-Leidenz, N., Guiffrida de Mendoza, M.and Rodas-González, A.

BIOLOGICAL ACTIVITIES OF ACE INHIBITORY PEPTIDES DERIVED FROM BEEF HYDROLYSATES
Jang, A., Lee, M., Lim, D.G., and Kang, K-S.

A NEW METHOD FOR QUANTIFICATION OF APOLAR HETEROCYCLIC AROMATIC AMINES WITH PLANAR CHROMATOGRAPHY
Jautz, U., Morlock, G., Gibis, M., Schwack, W. and Fischer, A.

HEME IRON AND B VITAMINS AS QUALITY MARKERS IN COOKED MEATS
Lanzi S., D'Evoli L., Salvatore P., Aguzzi A., Nicoli S., Marletta L. and Lombardi-Boccia G.

EFFECT OF SUPRANUTRITIONAL AND ORGANICALLY-BOUND DIETARY SELENIUM ON THE NUTRITIVE VALUE AND CASE LONGEVITY OF BEEF
Lawler, T.L., Marchello, M.J., Taylor, J.B. and Caton, J.S.

UP-TO-DATE KNOWLEDGE ON THE NUTRITIONAL COMPOSITION OF POULTRY MEAT
Lesiów, T. and Xiong Y.L.

INTRODUCTION INTO FOODS COMBINATORICS
Lipatov, N.N., Bashkirov, O.I. and Gevorgyan A.L.

NON-TRADITIONAL IDEAS ABOUT ECOLOGICAL SAFETY AND NUTRITIONAL ADEQUACY OF FOODSTUFFS (including meat-based ones)
Lipatov, N.N., Bashkirov, O.I. and Gevorgyan, A.L.

ROLE OF THE CHOSEN DIETARY FIBRE PREPARATIONS IN SHAPING OF STRUCTURE AND QUALITY OF MODEL MEAT PRODUCT
Makała H. and Olkiewicz M.

EFFECT OF ADDITION OF TEA CATECHINS AND VITAMIN C ON SENSORY EVALUATION, COLOUR AND LIPID STABILITY IN COOKED OR RAW BEEF AND CHICKEN PATTIES
Mitsumoto M., O'Grady M. N. , Kerry J. P. and Buckley D. J.

THE COMPOSITION AND OXIDATIVE STABILITY OF LIPIDS IN LONGISSIMUS MUSCLE FROM GRAZING CATTLE SUPPLEMENTED WITH SUNFLOWER OIL OR LINSEED OIL
Moloney, A. P., Noci, F., Monahan, F.J., O'Grady, M.N. and Kerry, J.P.

ISOLATION AND PURIFICATION OF ACE INHIBITORY PEPTIDE DERIVED FROM CHICKEN BONE EXTRACT
Nakade, K., Muguruma, M., Inoue, Y., Kawahara, S., Yamauchi, K., Nakayama, T., Maruyama, M., Okayama, T. and Numata, M.

IDENTIFICATION OF SOURNESS-SUPPRESSING PEPTIDES IN COOKED PORK LOINS
Nishimura, T., Okumura, T., Morimatsu, F. and Yamada, R.

EFFECT OF MILK-REPLACER REARING VS NATURAL REARING ON FATTY ACID COMPOSITION OF SUCKLING LAMB LIVER
Osorio, M. T., Bermejo, B., López, O. A., Zumalacárregui, J.M. and Mateo, J.

MEAT PROTEIN-TANNIN INTERACTIONS: OBSERVED ANTIOXIDANT ACTIVITY AND POTENTIAL HEALTH BENEFITS
Pegg, R.B. and Amarowicz, R.

SUCKLING LAMB FATTY ACIDS AS AFFECTED BY EWES FEEDING SYSTEM
Priolo, A., Bella, M., Biondi, L., Fasone, V., Galofaro, V., Scerra, M., Valvo, M.A.and Lanza, M.

COMPARISON OF TOTAL CONTENT OF LIPID AND CHOLESTEROL IN PORTUGUESE BOVINE MEATS-PDO FROM FOUR DIFFERENT AUTOCHTHONOUS BREEDS (BARROSÃ, AROUQUESA, ALENTEJANA AND MERTOLENGA)
Quaresma, M.A.G., Alfaia, C.M.M., Castro, M.L.F., Bessa, R.J.B. and Prates, J.A.M.

EFFECTS OF MODIFICATION OF FATTY ACID COMPOSITION OF ANIMAL PRODUCTS ON ADOLESCENT FATTY ACID INTAKE IN BELGIUM
De Smet, S., Matthys, C., Bilau, M., Van Camp, J., Warnants, N., Raes, K., Sturtewagen, G. and De Henauw, S.

EFFECT OF HIGH PRESSURE TREATMENT ON THE ALLERGENICITY OF BOVINE SERUM ALBUMIN EVALUATED BY HISTAMINE RELEASE ASSAY USING SERA FROM ALLERGIC PATIENTS AND HUMAN BASOPHILIC KU812F CELLS
Suzuki, A., Hara, T., Koyama, H., Nogami, N., Han, G.D., Odani, S., Matsuno, M., Joh, T. and Nishiumi, T.

PHYSICO-CHEMICAL CHARACTERISTICS OF RAW AND CANNED OSTRICH MEAT
Torrescano, G., Jiménez, R., Sánchez-Escalante, A., Estrada, M., González, N., Valenzuela, M., Cumplido, G. and Dávila, J.L.

PIG HOUSING AFFECTS THE FATTY ACID COMPOSITION OF PORK FAT
Trezona, M., Pluske, J.R., Mullan, B.P. and D'Souza, D.N.

BULL PRODUCTION FACTORS AFFECTING PROXIMATE AND MINERAL COMPOSITION OF COOKED *LONGISSIMUS* STEAKS
Uzcátegui Bracho, S., Arenas de Moreno, L., Jerez-Timaure, N., Huerta-Leidenz, N. and Byers, F. M.

FATTY ACID COMPOSITION OF INTRAMUSCULAR LIPIDS IN VARIOUS BEEF BREEDS AND GENOTYPES
Wagenhoffer, Zs. and Szabo, F.

THE CHEMICAL COMPOSITION OF THE MEAT TYPE DRAKES MUSCLES FROM BREEDING STRAINS
Woloszyn, J., Ksiazkiewicz, J., Skrabka–Blotnicka T., Biernat, J., Kisiel, T. and Orkusz, A.

SALIVA INCORPORATION DURING MEAT BOLI FORMATION IN RELATION TO CHEWING EFFICIENCY
Yven, C. and Mioche, L.

CONJUGATED LINOLEIC ACID AND THE RATIO OF ω6:ω3 FATTY ACIDS ON THE OXIDATIVE STABILITY OF CHICKEN MEAT
Zanini, S.F., Colnago, G.L., Fernandes, G.S., Bastos, M.R., Pessotti, B.M.S., Casagrande, F.P. and Lima, V.R.

CONJUGATED LINOLEIC ACID AND THE RATIO OF ω6:ω3 FATTY ACIDS ON THE LIPID METABOLISM OF BROILER CHICKENS
Zanini, S.F.[1], Colnago, G.L., [2] Pessotti, B.M.S.[1], Bastos, M.R.[1], Casagrande, F.P.[1], and VR Lima[1]

LIPID COMPOSITION OF LAMB MEAT, AFFECTED BY GENOTYPE AND SEX
Žlender, B., Rajar, A., Polak, T., Gašperlin, L., and Čepin, S.

Session 6
Hot topics in meat science

FEEDING AND MEAT QUALITY
Andersen, H.J., Oksbjerg, N., Young, J.F. and Therkildsen, M.

THE FUTURE OF BSE FROM THE GLOBAL PERSPECTIVE
Heim, D. and Mumford, L.

PRELIMINARY RAMAN SPECTROSCOPIC INVESTIGATION OF THE CHANGES IN BEEF STERNOMANDIBULARIS MUSCLE DURING THE THAWING OF MUSCLE STRIPS FROZEN PRE-RIGOR
Beattie J.R , Bell, S.J. and Moss, B.W.

EFFECT OF OUTDOOR REARING SYSTEM ON FAT DEPOSITION AND EATING QUALITY IN ORGANIC HEAVY PIGS
Bondesan, V., Sartori, A. and Danesi, P.

QUANTITATIVE EVALUATION OF CHLORAMPHENICOL CONTENT IN CHICKEN MEAT PRODUCED BY DOMESTIC PRODUCERS WITH ELISA - TEST
Brdarić, N., Zahirović, L., Hajrić, D. and Bećar, E.

FLAVOUR PERCEPTION OF OXIDATION IN BEEF
Campo, M.M., Nute, G.R., Hughes, S.I. , Enser, M., Wood, J.D. and Richardson, R.I.

EFFECTS OF DIETARY LINSEED OIL ON FATTY ACID COMPOSITION OF LAMB MEAT
Caputi Jambrenghi, A., Giannico, F., Sanapo, S., Bozzo, F., Colonna, M.A., Vicenti, A. and Vonghia, G.

PREPARATION AND PROPERTIES OF HAEMOSTATIC POWDER AND FILM
Chen, M.T., Tseng,T-F. and Tsai, T-M.

EFFECTS OF KID FEEDING WITH A DE-STONED OLIVE POMACE ON THE QUALITY OF RAW AND COOKED MEAT
Colonna, M.A., Vicenti, A., Toteda, F., Facciolongo, A.M., Pennisi, P. and Cocca, C.

USING DENSITY TO MEASURE MYOFIBRILLAR DENATURATION
Dobbie, P.M., Falconer, S.J., Simmons, N.J. and Daly, C.C.

SHIFTING SENSORY THRESHOLDS OF PRE-COOKED ENTIRE MALE MEAT USING THE MARINATING TECHNOLOGY
Egelandsdal, B., Løvlund, E., Choinsky, J., Koller, A. and Mielnik, M.

PERFORMANCES AND MEAT QALITY OF LEPRINO VITERBESE BREED RABBIT, BRED WITH THREE DIFFERENT HOUSING SYSTEM.
Failla, S., Contò, M. , Ballico, S. , Concetti, S. and Negretti, P.

LEVEL OF GAMMA RADIATION IN SOME MEAT PRODUCTS MARKETED IN UPPER EGYPT
Fathi, Sh. , Ismail, M. , Nassar, A. and Afaf Mahmoud

EFFECT OF CURRENT, VOLTAGE, FREQUENCY AND CARCASS TEMPERATURE ON IMPEDANCE MEASUREMENTS OF LAMB CARCASSES
Forsyth, S., Cosgrave, P., Allen, P. and Butler, F.

THE AUTOFOM AND CVT-2 FOR PREDICTING SALABLE MEAT YIELD IN PORK CARCASSES
Fortin, A., Tong, A.K.W. and Robertson, W.M.

REGULATION OF TASTE-ACTIVE COMPONENTS OF MEAT BY DIETARY PROTEIN LEVELS
Fujimura, S., Eguchi A., Kobayashi, T., Sakai, F. and Kadowaki, M.

REGULATION OF TASTE-ACTIVE COMPONENTS OF MEAT BY DIETARY BRANCHED-CHAIN AMINO ACIDS
Imanari, M., Kadowaki, M. and Fujimura, S.

VACUUM COOLING OF COOKED MEATS
Jin, T.X., Zhu, H.M., Feng, H.D. and Xu, L.

CHEMICAL PROPERTIES OF THE MEAT AND BLUBBER OF THE CAPE FUR SEAL (*ARCTOCEPHALUS PUSILLUS PUSILLUS*)
Koep, K.S.C., Hoffman, L.C., Slinde, E. and Dicks, L.

METABOLIC MECHANISM OF COMPENSATORY GROWTH IN PIGS
Lametsch, R., Kristensen, L., Therkilsen, M., Oksbjerg, N., Larsen, MR. and Ertbjerg, P.

MEAT QUALITY OF HEIFERS AS INFLUENCED BY GRAZING, FINISHING FEEDING AND CARCASS SUSPENSION METHOD
Lundesjö Ahnström, M., Enfält, A-C., Hessle, A. Johansson, L. and Lundström, K.

QUALITY CHARACTERISTICS OF MEAT FROM PODOLICA AND CROSSBRED CALVES REARED ON FEED CONTAINING GRAPE SKINS
Marsico, G., Dimatteo, S., Ragni, M., Rasulo, A., Di Turi, L. and Vicenti, A.

DECOCTIONS OF NORWEGIAN HERBS STABILISE MARINATED TURKEY THIGHS
Mielnik, M.B., Sem, S., Egelandsdal, B. and Skrede, G.

EFFECT OF FORAGE LEGUME, STOCKING RATE AND CONDENSED TANNINS ON CORRIEDALE LAMB MEAT QUALITY IN URUGUAY
Montossi, F., San Julián, R., Brito, G., De Barbieri, I., Dighiero, A., Iglesias, M., Ramos, N., Nolla, M. and Risso, D.F.

EFFECT OF HIGH PRESSURE TREATMENT AND SUBSEQUENT STORAGE ON THE COLOUR OF A BEEF PUREE
Moss, B., Johnston, D.E, Graham, W.D. and Stewart, E.M.

FRENCH CONSUMER APPRECIATION OF A NOVEL POLISH-STYLE SAUSAGE
Ngapo, T.M., Kubiak, M.S., Batura, J., and Dransfield, E.

CONSUMER PREFERENCE OF PORK CHOPS: RESULTS OF AN INTERNATIONAL CROSS-CULTURAL COMPARISON
Ngapo, T.M., Martin, J.F. and Dransfield, E.

MONITORING ACCELERATION (G-FORCE) DURING ANIMAL TRANSPORTS
Nøddegaard, F. and Brusgaard, N.

EFFECT OF LINSEED AND GRASS FEEDING ON THE FLAVOUR PROFILE AND TASTE-PANEL EVALUATIONS OF BEEF FROM BELGIAN BLUE DOUBLE-MUSCLED BULLS
Raes, K., Claeys, E., De Winne, A., Dirinck, P., Balcaen, A. and De Smet, S.

EFFECT OF LAMB FEEDING WITH LINSEED MEAL ON SOME MEAT QUALITY TRAITS
Ragni, M., Di Turi, L., Melodia, L., Caputi Jambrenghi, A., Colonna, M.A. and Vonghia, G.

QUALITY OF MEAT FROM STEERS OF TWO DIFFERENT FRAME SIZES GRAZING HIGH QUALITY PASTURES SUPPLEMENTED WITH HIGH MOISTURE MAIZE GRAIN OR WHOLE PLANT MAIZE SILAGE
Santini, F.J., Villarreal, E., Grigera Naón, J.J. , Cossu, M. E., Grigera, J. M., Pavan, E. and Schor, A.

CARBON MONOXIDE AS A SUBSTITUTE FOR NITRITE IN MEAT BATTER SYSTEMS
Sørheim, O., Johannessen, T. Chr., Cornforth, D., Langsrud, Ø., Berg, P. and Nesbakken, T.

EARLY PREDICTION OF CARCASS YIELD GRADE BY ULTRASOUND IN HANWOO (KOREAN CATTLE)
Song, Y. H., Kim, J. Y., Rhee, Y. J. and Lee, S. K.

EFFECT OF DIETARY OIL AND PROTEIN LEVEL ON CARCASS AND FAT QUALITIES AND PROCESSING CHARACTERISTICS IN PIGS

FROM EMMRW TO ICoMST - SOME FEATURES OF THE BIRTH AND DEVELOPMENT OF INTERNATIONAL COOPERATION

Professor emeritus F.P. Niinivaara, Finland.

The organizing committee has asked me as promoter of the cooperation and as the organizer of the first congress 1955 to tell you about the birth and development of this congress.

The first congress was held in Hämeenlinna in August 1955. It was attended by a group of 22 meat researchers from seven European countries. As this 50th congress is being held again in Finland, it could be said that, the congress has returned to its roots.

This congress was first called "The European Meeting of Meat Research Workers", EMMRW.
It soon expanded, as participants from other continents attended it, too. In 1987 the name was changed to "International Congress of Meat Science and Technology", ICoMST. We, the "founding fathers", could not even imagine that a small group of European meat researchers would grow into a large international congress.

Meat is connecting people over the world.

I am very happy to have the opportunity to tell the prominence of the meat scientists of the world about some memories of the birth of the first meeting.

My own career as meat researcher started after the World War II in 1946. European cities had been bombed to ruins. Finland had its share of bombs. Helsinki was badly ruined. The main building of this University was burned. This festival hall we are sitting now looked like a black ghostly skeleton after the fire. After spending five years in grisly war, I could continue my studies. We did not win the war, but we reached our goal: Finland kept her freedom and was never occupied.

The University was rebuilt, opened its doors again, and I was able to continue my studies of biochemistry. As a mentor and teacher I had the famous biochemist Professor Virtanen, who just had received the Nobel-prize in chemistry. This acknowledgment – a Nobel-prize to a Finnish scientist- was like a shot of stimulant to the depressed people of a ruined country. I had been participating in the research work which he presented in his Nobel-speech in Stockholm.

When I passed my final examinations in December 1946, Profesor Virtanen came to me and asked if I would be interested in starting to work as head of a meat research institute. He said: "I have been asked for a suitable person, and I consider you suitable for this mission". And he continued and said unforgettable words:" I think meat research is an important task. Valuable research has been done with dairy science, which I also have taken part in. Meat is economically and nutritionally just as important as milk. That is why I wish that you would take on this task and start developing meat science in our country."

This was the testament of the Nobel laureate to a young biochemist. I promised to take on this task and I think I have fulfilled it. Meat research and teaching meat technology has become my life work. For this task I have given my best years. It has been 57 years since I took on this task, and here I stand – still lecturing about meat. When I started in 1947, I was perplexed. Meat science. What ever is it? Dairy science and professor Virtanen were well known, but what would meat science be like?

I decided to leave for an excursion abroad in hope for finding ideas from the world. In 1952 I visited Sweden, Norway and Denmark without finding any research work being done on meat. In Germany, I found

one very modest meat research institute. It was founded in Berlin, but was destroyed in the bombings. The rest of it had evacuated to a small South-German town called Kulmbach. With this institute I had many years of cooperation. As an acknowledgment for this, I was first foreigner to receive the Rievel-medal, which is given by this institute to scientists for outstanding work in meat research.

Next year, in 1953, I had the opportunity to visit the American Meat Institute Foundation in Chicago. This Institute had somewhat more capacity. A discussion with Dr. Niven gave me the idea of studying useful bacteria in fermented sausages. After returning I concentrated in this research and in 1955 was able to publish my thesis about this subject. This was the foundation both for the research of Starter cultures and their use in producing dry sausage.

During my excursions I met many distinguished and sympathetic meat scientists. We discussed the possible cooperation between research institutes and scientists. I noticed that the scientists did not know each other personally, but were only reading the publications of one another. It would be very much more useful if information about the work and goals of the institutes would be better available. It also would be more economic and efficient.

Everybody seemed very interested in developing cooperation. It was suggested that all of us scientists should meet to discuss how to start and how to carry out the cooperation. I promised to organize the meeting if it were held in Finland. Everybody was ready for this. So in the spring of 1955 I sent invitations to institutes and persons I knew would be interested in this meeting. This was to be the first meeting of the "European Meeting of Meat Research Workers". There were representatives from seven countries attending this meeting.

They were:

Prof. Reinhold Grau, Germany, Dipl. ing. Mogens Jul, Denmark Dr. Hans Baretta, Holland
Dr. Olle Dahl, Scans laboratorium, Sweden, Spice manufacturer and butcher J.-P. Daul, France Dr. Hans Wyttenbach, Switzerland Director Hermann Herzer, Switzerland
Dipl.ing. Martti Knuuttila, congress secretary, Finland
Dr. F.P. Niinivaara, congress chairman, Finland

The congress was also attended by a number of representatives of the Finnish food industry, Altogether, 22 persons were attending the meeting. This committee worked out the guidelines, which have been followed for 50 years. The most important issue of the first congress was how to create the cooperation. These individuals created the main lines and the content of the future conferences.

The program of this first meeting consisted of the same topics, which have for half a century remained as part of the meeting. So, in addition to being an occasion for discussing the scope of cooperation, the meeting was also the first congress of meat researchers. There were eight lectures: Professor Grau talked about the meaning of chemistry in meat research; Mogens Jul talked about gas stunning of pigs, Martti Knuuttila talked about microwave heating in meat industry, Hans Baretta about the importance of education; I talked about using starter cultures in producing dry sausage; Olle Dahl about the influence of the race on quality of beef. Eino Niemistö talked about a modern solution in handling slaughter by-products, and Eini Laakkonen talked about the meat products in domestic economy. J.P. Daul suggested an alternative solution for the cooperation in form of a subcommittee in the Council of Europe. This solution was considered inefficient and complicated.

The congresses have been held fifty times without a fixed secretariat. It has only had to be cancelled once. This was in the year 1968 in Czechoslovakia. The "Proceedings of the Congress" was already printed, but instead of congress participants the country the country was occupied. Part of the congress participants had already arrived and were caught in the middle of a riot. This would have been the end of the congress series, as the next host country was not elected yet. An emergency meeting was held in Vienna, and it was settled that I should host the 15th congress in Finland. There was only eight months time for the organization, but the congress series was saved. The spirit of meat was stronger than the tanks.

This congress series is a miracle. From a small European beginning it has grown into a world congress, which today is held for the 50th time and with 330 participants. It has always acted on a voluntarily basis, without an elected board or fixed secretariat. In 1955, with high border walls between countries and obligatory visas, we could not as far as imagine this amount of popularity. East and West were divided by the iron curtain, Europe was in ruin, and above these ruins political storms were raging. In these conditions we were building up a co-operation between the meat researchers of different countries. The whole thing seemed utopic. But we made it.

Kenneth Johnson writes that the driving power has been the "spirit of meat" -which he thinks was born in the finish sauna. *Meat is tender, but the spirit of meat is always strong.* I hope the spirit of meat will be the driving force for Meat Congresses in the future, too.

R. B. Sleeth said in the 41st congress in Texas:
"Friendships that last a lifetime are one of the greatest conference benefits."

I wish to all of you pleasant days in Finland, in the birth country of ICoMST.

50th International Congress of Meat Science and Technology

August 8th – 13th 2004

Helsinki, Finland

Abstract

Functional genomics, including analysis of the transcriptome and proteome, provides new opportunities for understanding the molecular processes in muscle and how these influence its conversion to meat. The Quality Pork Genes project was established to identify genes associated with variation in different aspects of raw material (muscle) quality and to then develop genetic tools that could be utilized to improve this quality. DNA polymorphisms identified in the porcine *PRKAG3* and *CAST* genes illustrate the impact that such tools can have in improving meat quality. The resources developed in Quality Pork Genes provide the basis for identifying more of these tools.

Introduction

Pig breeding companies are now paying more attention to meat quality and are including quality traits as an integral part of selection programmes. This has been in part driven by consolidation and integration in the meat processing industry and the retail sector together with an increasing consumer awareness of food quality. In addition, the development of the field of genomics has also stimulated interest in breeding for meat quality as this "trait" constitutes the classic case where DNA marker based selection is at its most efficient: where the trait cannot be measured on the selection candidate and can only be measured at high costs on its relatives post-mortem. Once a DNA marker (a polymorphism, see below) has been shown to be associated with variation in the target trait, then it can be used to genetically type young animals for pre-selection before performance testing. This is a distinct advantage over sib slaughter schemes which are increasingly difficult and expensive to implement (see Knap, Sosnicki, Klont, & Lacoste, 2002). Even so sib slaughter schemes will continue to play a role, both for the identification of new markers and for monitoring breeding lines in order to optimize the breeding direction. The advantage of incorporating markers into selection programmes can be sustained when new markers are identified to replace older markers that begin to reach fixation. The database builds up over time to provide a very useful resource for this purpose or further validation of DNA markers identified in experimental populations or to test candidate genes.

In the last decade DNA tests have been developed that allow much more effective eradication of undesirable alleles of the major genes negatively impacting pork quality, such as the *Hal* gene (HAL–1843™, as licensed from the Innovations Foundation, Toronto, Canada, owner of the trademark. Fujii *et al*., 1991) and the *RN* gene (Milan *et al*., 2000) which are associated with pale, soft and exudative meat and processed ham yield respectively.

Breed differences in meat quality traits are large (Sellier, 1998) and commercially relevant. Duroc, Hampshire and Berkshire lines are commonly marketed as "meat quality lines" and several industry lines have been based on these breeds. However, significant variation in meat quality related traits is also present within breeds (e.g. Gil *et al.*, 2003). The discovery of the *Hal* and *RN* genes also encouraged researchers to consider single gene effects as an alternative to breed effects. As indicated above, once DNA markers for meat quality are identified they can be used in a wide range of breeds by changing allele frequencies through selection and/or introgression.

Recent examples of these marker effects include polymorphism in the genes for calpastatin (*CAST*) and *PRKAG3* that are associated with quantitative variation in tenderness (*CAST*) and pH and colour (*PRKAG3*) (Ciobanu et al., 2001, 2002, 2004). Future success for the industry will require the production of consistent and predictable high product quality to ensure customer satisfaction. The target should be to combine efficient growth with the best possible meat quality or alternatively the aim can be described as optimizing meat quality with the lowest cost production.

To date DNA markers have been identified using two basic approaches: quantitative trait loci (QTL) mapping or the "candidate gene approach". The first utilizes specific genetic designs (for example three generation families based on divergent breed crosses such as Chinese Meishan or Wild Boar and Large White) to find the location of QTL on the genetic map. Several QTL studies have addressed pork quality traits (summarized in Bidanel and Rothschild 2002) and they provide the starting point for the identification of individual genes (or markers) influencing these traits (the positional candidate gene approach). Indeed, the RN^- mutation, identified initially by a mapping approach was then elucidated using positional cloning and a "BAC contig" constructed for that region of the genome (a physical representation of the DNA sequence from the QTL region) (Milan et al 2000).

It is now possible to add functional genomics to the range of options available for understanding the molecular basis of pork quality. The objective of this study was to develop the resources required to do undertake this approach. The QualityPorkGENES project (http://www.qualityporkgenes.com) was initiated in order to create a unique phenotypic resource that could be exploited through the application of new

functional genomics tools that determine differences in the transcriptome and proteome of muscle and relate this to the different aspects of meat quality. This approach has the potential advantage of generating information, in parallel, on multiple genes and gene products which, in turn provides the opportunity to identify pathways and interacting genes (see Maltin & Plastow, 2004). In this way the efficiency of marker detection is increased as well as providing insight into epistatic effects that can further the understanding of the genetic component of meat quality.

Materials and Methods

Animals and samples
Five closed populations (breeding lines) were chosen for the project. These were based on Large White, Landrace, Duroc, Piétrain and Meishan breeds (although in the latter case a Meishan/Large White crossbred line was used) in order to represent a significant proportion of European pig production. The Piétrain line was normal for the "Halothane" gene. In addition, initial characterization of lines (at IRTA Monells, Spain) indicated that these lines would provide significant variation both within and between populations. Animals were reared under the same environment and production regime in a breeding nucleus farm in France. Data was collected on farm for growth, ultrasonic backfat and basal stress hormone levels. At approximately 140 days of age the animals were transported in batches of around 25 to overnight lairage at a research abbatoir in Spain (IRTA Monells). Animals were harvested after CO2 stunning and carcass, meat quality, biochemical and sensory data were collected for 100 animals per line (in 22 batches). Urine samples were taken after transport on arrival at lairage and the next morning before they were moved to the CO2 chamber. Immediately after harvest loin (*Longissimus thoracis*) and ham (*Semimembranosus* - SM) muscles were collected and samples prepared for fibre type and proteome analysis (after mounting and freezing in liquid nitrogen) and RNA isolation (RNAlater).

Phenotypic traits
Measurements of fat depths at 45 minutes postmortem (p.m.) were made using the Fat-O-Meat'er equipment at 60mm from the mid-line at the level of the last rib (LRFOM). At 24 hours p.m., the surface area of the eye of the *Longissimus thoracis* (AREALT) was measured between the 3rd and 4th last rib level. This was done by making a transversal cut at this point and taking a digital image. This image was used to calculate the AREALT using a specific program. Each left half carcass was cut and dissected following the method of Walstra and Merkus (1995). In order to have more commercial cuts some parts were jointed as hind hand plus leg (ham), loin minus subcutaneous fat of the loin (loin) and belly plus to ventral part of the belly (belly). Estimated carcass lean content (PLEAN) was calculated using the Spanish official equation (Gispert and Diestre, 1994).

The left side of each carcass was used to assess meat quality. Muscle pH was measured using a Crison portable meter equipped with a xerolyt electrode in the *Longissimus thoracis* muscle (LT) at 45 min. (pH_{45}LT) and 24 h. (pH_u LT) p.m. Colour measurements were taken 24 h. p.m. on the exposed cut surface of the LT at the last rib level, using a Spectrophotometer Minolta C2002 in the CIELAB space (CIE, 1976). Drip loss was determined in the muscle LT according to the method of Honikel (1998).

The metabolic traits of the muscle were determined by measuring the lactate dehydrogenase (LDH) activity according to Ansay (1974) and the isocitrate dehydrogenase (ICDH) activity according to Briand, Talmant, Briand, Monin and Durand (1981). Enzyme activities are expressed as µmol NADH per minute per g of muscle (LDH) and as nmol NADPH per minute per g of muscle (ICDH). The percentage of slow myosin heavy chain (MHC-I) in the muscle was determined with a specific MHC-I monoclonal antibody by the ELISA technique (Picard et al., 1994).

Cathepsin B activity was assayed with N-CBZ-L-arginyl-L-arginine 7-amido-4-methylcoumarin (Z-Arg-Arg-NHMec) (Etherington and Wardale, 1982). One unit of activity was defined as the amount of enzyme hydrolysing 1 nmol of substrate per min at 37°C. Activities were given in enzyme units per mg of extracted protein. The protein concentration of the enzyme extracts was measured according to Lowry, Rosebrough, Farr and Randall (1951), using bovine serum albumin as standard.

Intramuscular fat (IMF) content was determined by a NIT (Near Infrared Transmittance) apparatus. Fat was extracted by the method of Folch, Lees and Stanley (1957) and aliquots of the extracts were collected to perform the analysis of fatty acids and triglycerides. Fatty acids were determined by GC-FID as methyl esters (FAMES) by the method described by AOCS. A capillary column coated with cyanopropylpolysiloxane was used (SGE, BPX-70) 30 m x 250 µm, width film 0.25 µm. Triglycerides were determined by HPLC with RI detector.

Sensory characterization of the samples was performed through a Qualitative Descriptive Analysis (QDA) using 6 selected trained assessors including texture descriptors in cooked meat. Samples of LT (1.5 cm thick) were stored at 4 ºC during 24 h and afterwards frozen. Twenty-four hours before the evaluation, the samples were thawed at 4 ºC. They were cooked in an electric oven at 110 ºC until reaching an internal temperature of 65 ºC and then cut and evaluated. The samples were quantified for hardness and juiciness using a 10 point scoring scale where 0 means 'absence or minimum intensity' and 10 means 'very strong or maximum intensity'

Texture Profile Analysis (TPA) was undertaken in sample cubes of 1.5 cm x 2 cm x 2 cm obtained from an adjacent slice of that used for sensory analysis. Samples were cooked as described in sensory analysis. All the measurements were carried out using a Texture Analyser TA.TX2 (Stable Micro systems Ltd) with a 25 kg load cell and using a crosshead speed of 5 mm/second.

The statistical analysis of the phenotypic traits was performed using the GLM procedure of SAS (1999). The effect of the genetic type was included in the model as a fixed effect. The slaughter day was included as a block effect and the carcass weight as a covariable if they were significant. Family relationships were not accounted for as the dataset contains too few offspring within both full- or half-sib families. Significant differences ($P<0.05$) between means were obtained with the Tukey test. For the sensory analysis, GLM procedure was also used. Genetic line and session were in the model as fixed effects. Significant differences between means were obtained with the Tukey test.

Proteomics

Loin muscle samples from each animal for the five breeds were subjected to two dimensional gel electrophoresis (2DGE) over the p*I* range of 3 to 10 and molecular weight range of 10 to 200 kDa, enabling the separation of more than 750 spots per gel. Image analysis (Phoretix Evolution) was used to generate a master proteome map representing the proteomes of the five divergent porcine breeds. Areas of saturation and poor resolution were removed digitally prior to analysis.

Preparation of cDNA libraries and Real-time PCR

Total RNA and mRNA were prepared from muscle samples preserved in RNAlater (Ambion Inc.). RNA was analysed for quality by Northern blot analysis and visualization using the Agilent BioAnalyser. The RNA was then used for the construction of suppression subtractive hybridisation (SSH) porcine muscle cDNA libraries from animals within and between divergent genotypes and for the construction of a full-length representative pig muscle cDNA library.

Suppression subtractive hybridisation was performed using the PCR-select cDNA Subtraction kit (BD Biosciences Clontech UK). Eight SSH libraries were constructed based on specific contrasts available in the project (breed, muscle type, meat quality and stress). A standard full-length pig muscle cDNA library was prepared to facilitate the isolation of full-length cDNA for candidate genes to be identified from the SSH libraries, microarray screening and proteomics analysis. The full-length cDNA library was constructed using the λ Zap Express cDNA synthesis/Gigapack cloning kit (Stratagene Cloning Systems) using 5 µg of mRNA pooled from LT and SM muscle from all five pig lines, and different slaughter days. The quality of this library was assessed by titration of library size and cDNA fragment length analysis using PCR with the M13 forward and reverse primers.

The expression pattern of the candidate gene *PRKAG3* was analysed by quantitative real-time polymerase chain reaction (PCR) using either the lightcycler system (Roche) or the MX3000P 96 well real-time PCR

System (Stratagene), and the Quantitect SYBR green one-step RT-PCR kit (Qiagen). A PCR fragment of 118bp was generated using primers located at 310-428bp in the gene sequence (Genbank AF214520),

sense: PRKAG3LCF2: (5')CAGTCCAGGCCAGTTGCTGAGTC
antisense: PRKAG3LCR2: (5')GCTCTGTTGGGGGGTTGTCCAC

Total RNAs were selected from LT and SM muscle from Landrace and Meishan animals that had been selected as showing variation in meat quality on the basis of pH_u and LMinolta colour values. A typical experiment analysed expression of *PRKAG3* in RNA from at least eight different animals (up to 14). Samples were analysed in triplicate and each experiment was repeated on two or three separate occasions. Expression level was inferred from the cycle threshold (Ct) value, or Ct values were converted to copy number per µl using a standard curve of cRNA standards *in vitro* transcribed from cloned cDNA products. Results were analysed statistically using ANOVA with Tukey post hoc analysis.

Microarray construction
Microarrays have been constructed using purified PCR products generated from cDNA clones. These clones were derived from the SSH libraries plus additional muscle expressed candidate genes. All PCRs were prepared in a sodium phosphate/ SDS spotting buffer using a 384 well format prior to printing. The products were spotted onto Corning GAPS 2™ slides along with Cy3 and Cy5 orientation spots and control elements, using a 48 x 100 µm pin tool and a BioRobotics Microspot 2500 microarrayer. For the prototype array every element was spotted in duplicate using a 17 x 18 subarray, giving a total of 14688 elements per slide. The second generation slides have been spotted in triplicate using a 21 x 21 subarray allowing a total of 21168 elements per slide.

Post spotting, slides were baked for 2 hrs at 80°C. They were then blocked in 1% BSA (Molecular Biology grade, Sigma Aldrich B 2518), 0.1% SDS in 3x SSC at 55 °C for 1 hour. This was immediately followed by denaturation in a 95 °C water bath for 2 min, rinsing in isopropanol, spinning dry, and storage in dark, dry conditions at RT prior to hybridization.

Microarray hybridization
20 µg of each RNA sample selected for hybridization to the slides was labelled with either Cy3 or Cy5 using an indirect method. RT-PCR (SuperScript II, Invitrogen) with a polyT primer was used to generate complex cDNA in the presence of aminoallyl dUTP (Sigma). The reaction was followed by a post-PCR coupling to the reactive CyDye (Amersham Pharmacia) in the presence of sodium bicarbonate/ hydroxylamine buffer. Samples were then purified using a Qiagen PCR Purification Kit column prior to precipitation in the presence of 10 µg of pig genomic DNA plus 500 ng of cloned pig SINE repeat element. The resulting pellet was resuspended in 100 µl of formamide hybridization buffer (Sigma) along with 1 µl of yeast tRNA (Sigma) and 1 µl of poly dA (Amersham Pharmacia Biotech). Hybridization mixes were applied to the slides, and incubated at 42 °C for 18 hours before washing in an SSC series to a final concentration of 0.1 X. Slides were scanned on an Axon 4100 scanner, at 10 µm resolution, and images captured with the GenePix software.

Image analysis
All images were analysed for the pixel intensities in each of the two channels (Cy 3 and Cy5) using BlueFuse (BlueGnome Ltd.). Background signal was removed from the spot signals, and replicate data fused to produce single values, with a high confidence probability, for each clone represented on the array.

Microarray experimental design and analysis
Animals for the first experiments (investigating water holding capacity and intramuscular fat content) were selected on the basis of a factor analysis, where the first four factors were descriptive of (1) fatness versus leanness (2) water holding capacity (pH, LMinolta, driploss) (3) intramuscular fat and (4) percentage loin. The lines with the greatest variance for each factor were identified: the Meishan – factor (1), Large White and Piétrain – factor (2), Duroc and Meishan – factor (3) and Landrace – factor (4). Animals were ranked on their individual factor scores and the top ten and bottom ten animals for each factor were selected within the lines of interest. Outliers, animals with residual values more than three standard deviations from their respective within-line means, were removed.

For each factor comparison, cDNA samples prepared from animals with high or low scores from at least two different breeds were hybridized to the prototype array using a loop design. At each point within the loop one high scoring sample is compared against one low. Each sample occurs twice within the loop with an intrinsic dye swap. (Figure 1a, Page 14) (Kerr and Churchill, 2001a, 2001b).

A second experiment will be undertaken to enable the relationship between gene expression and tenderness and sensorial traits to be established. One hundred individual animals, twenty animals from each line, will be arrayed. Samples will be compared against a common pooled control sample (reference design: Figure 1b, Page 14) for this second expression experiment.

For both microarray experiments the data will be analysed using microarray ANOVA (Kerr, Martin and Churchill, 2000). ANOVA methods can be used to normalize the microarray data, for example by taking account of variation between slides, and also to provide estimates of changes in gene expression that are corrected for potential confounding effects, such as slaughter batch.

3. Results and Discussion

Carcass, biochemical and meat quality traits
More than 150,000 datapoints have been collected to describe the phenotypic characteristics of the animals in this study. These can be assigned to 358 measured and 62 derived traits for the following groups; performance (7), carcass (20), cutting (84), meat quality (20), biochemical (e.g. enzyme activity) (16) endocrine (18), sensory (13), texture (12), fatty acid content (198) and fibre type (32).

Table 1 (Page 19) shows the mean values and standard deviation of the parameters of carcass quality and also the differences between and within line. The Meishan based line showed lowest value for carcass weight and the Duroc based line the highest value, although not significantly different from the Landrace and Large White based lines. It is important to note that the variation within line (STD) is relatively large and similar in all the lines. In relation to the carcass quality, the Piétrain line had the leanest carcass, showing – with significant differences - the least fat depth and, accordingly, the highest muscular area (57.4 cm^2) and lean content in the carcass (60.3%). The fattest line was the Meishan line, showing 20.9 mm of LRFOM and 48.8% of lean content. The other lines were intermediate. These results were in accordance with Gil *et al.* (2003).

Meat quality parameters are shown in Table 2 (Page 19). It can be seen that the Landrace based line presented the lowest pH_{45} and the highest L* value, indicating lighter meat. None of the lines presented PSE meat. Ultimate pH was significantly higher in the Large White, Duroc and Piétrain lines. Drip losses were always lower than 3% with the exception of the Landrace line (3.3%).

The activities of the enzymes LDH and ICDH and the glycolytic ratio LDH/ICDH were determined to assess the metabolic traits of the muscles (Table 3, Page 20). The within line variability for the LDH was between 19.1 and 25.5%. This variable showed no significant differences between the five lines studied. The within line variability for ICDH activity and for the ratio LDH/ICDH were in the range 26.3 – 39.5%. ICDH differed significantly between lines: The Duroc and Piétrain lines presented higher activity than the other lines. In accordance with this, the glycolytic ratio for the Meishan line was higher than for the Duroc and Piétrain lines, with the Landrace and Large White lines having intermediate values. The percentage of MHCI differed between lines and the Duroc line had the highest value (8.65%) whereas the Meishan line had the lowest (6.96 %). The other three lines presented intermediate values. The within line variability of this variable was between 32.9% and 41.3 %. The values obtained for these variables were similar to those reported before for different porcine genetic lines or crosses (Henckel et al., 1997; Petersen Henckel, Oksbjerg and Sorensen, 1998, Gil et al., 2003). Cathepsin B activity also showed a high variability in all the lines (between 40.9 % in the Large White line and 48.1% in the Piétrain line). The Duroc based line had higher proteolytic activity than the Meishan line, and the other lines showed values in between. Hernández, Zomeño, Ariño and Blasco (2004) also report differences in cathepsin B activity between different porcine lines.

Table 4 (Pade20) shows the means and standard deviations for IMF, fatty acids and triglycerides in LT muscle. IMF showed a high within line variability. The highest values of IMF were found in the Duroc and Meishan lines. The other lines showed similar values, with the Piétrain line having a higher marbling content than the other two lines. Regarding the fatty acids, the percentage of stearic was higher in the Duroc line – that also presented a high IMF content – than in the other four lines. The Meishan line although having a high percentage of IMF, did not show a percentage of stearic acid as high as the Duroc line. It is interesting to note that the within line variability for this acid was quite low (5.8-7.7%). The percentage of linoleic acid was significantly higher in the Landrace, Large White and Piétrain lines than in the Duroc and Meishan lines. These data, together with the values of stearic acid, would suggest that the metabolism for the C18 acids was different between lines, which could be related with the genetics and, thus, with specific genes directly or indirectly associated with lipid metabolism. With respect to the minority triglycerides, dioleyl-steaoryl-glycerol (SOO) and disteaoryl-oleyl-glycerol (SSO), that are important because they are related with the consistency of the fat, the Duroc and Piétrain lines showed higher values for SOO than the other lines; the lowest percentage was for the Large White line, which contained high linoleic acid % but not a very high stearic acid %. For the SSO, no significant differences between lines were observed - possibly due to the high within line variability - but the Landrace and Duroc lines showed the highest percentages. This result could be related to the higher fat firmness in these two lines.

Table 5 (Page 21)shows the least square means and the significant differences per genetic line for hardness and juiciness sensory attributes. Hardness was lower in Meishan, Duroc and Piétrain lines and higher in Landrace and Large White lines. Regarding juiciness it seems that the lean lines were those with the lowest score for juiciness.

Table 6 (Page 21) shows the average values (means) and the significant differences per genetic line (Tukey test) for hardness from instrumental texture analysis (TPA test). Regarding this parameter obtained from the TPA curve, it seemed that the Piétrain line was different from the rest with the exception of the Meishan line. Hardness was evaluated differently by the instrumental test than by the sensory panel. The conditions in the mouth during chewing possibly could explain the different assessment of the sensorial hardness compared with the instrumental evaluation. Further analysis is needed regarding relations or correlations with other variables in order to interpret these results.

Stress hormone analysis

Urine was sampled when spontaneously voided in the farm (basal conditions), when the animals arrived in the lairage area (after approximately 10 hours of transportation in a lorry) and the next morning before slaughter. Levels of cortisol and catecholamines (adrenaline and noradrenaline) were measured in these urine samples as described (Hay and Mormède, 1997a&b). Blood was sampled during exsanguination, and creatine kinase activity, cortisol, glucose, lactate and free fatty acid (FFA) levels were measured in serum. A strong relationship between the urinary concentrations of cortisol in basal conditions and after transportation stress, were found indicating that genetic factors primarily influence the intrinsic activity / reactivity of the corticotropic axis. Across genetic types, concentrations of cortisol in urine were also correlated with carcass fat content, except for Piétrain pigs that combine a very low adiposity together with high urinary cortisol levels. This result confirms previous data demonstrating the genetic linkage between the hypothalamic-pituitary adrenal axis activity and fat accumulation, with *Cbg*, encoding corticosteroid-binding globulin, the carrier of cortisol in plasma, as a strong candidate gene (Désautés et al., 2002; Ousova et al., 2004). A correlation between cortisol levels measured in urine collected after slaughter and adiposity was also demonstrated in a segregating F2 intercross between Large White and Duroc pigs (Foury et al., 2002). Since urinary cortisol levels are directly related to cortisol secretion by the adrenal gland, the present data, together with available literature, suggest that adrenal secretory activity is another candidate for genetic polymorphism that could influence carcass composition. It will be interesting to see if this pathway is identified in the transcriptome analysis to be undertaken in the next stage of the project.

Secretion of catabolic hormones (cortisol and catecholamines) was the lowest in Large White pigs that also showed the lowest levels of energy mobilisation under slaughter stress (low levels of plasma lactate and FFA). Low levels of plasma glucose in Meishan and Duroc pigs suggest that their metabolism is more oriented towards energy storage, in accordance with the higher carcass fat content. Altogether these measures also showed that in the present experiments animals experienced very low levels of stress before and at the time of slaughter, so that the phenotypic and molecular data can be considered as representing 'basal' values with a minimal influence of pre-slaughter stress, that is a main component of meat quality, in interaction with genetic factors (Sellier and Monin, 1994, Mormède et al., 2004).

Longissimus thoracis *proteome*

Proteomics technology is becoming increasingly popular in the identification of gene products to aid in determining meat quality. Recent studies have utilised two dimensional gel electrophoresis (2DGE) to investigate changes in the *Longissimus thoracis* (LT) muscle proteome over 72 hours post-mortem in relation to meat quality (Lametsch and Bendixen, 2001, Lametsch, Roepstorff and Bendixen, 2002 and Lametsch *et al.*, 2003; Morzel *et al.*, 2004). The degradation of specific structural and metabolic proteins was demonstrated that varied significantly with aging time. In contrast, the current study presents the first major investigation comparing the proteome of the LT muscle for five divergent porcine breeds at the time of slaughter. This will enable us to detect breed differences in perimortem muscle metabolism in relation with organoleptic characteristics and phenotype.

A master proteome map was constructed for conditions yielding nearly 800 spots (a typical gel is shown in Figure 2, Page 15). The identity of a number of key muscle proteins was confirmed after excision and analysis by MALDI-TOF mass spectrometry and their expression is comparable with previous studies (Lametsch and Bendixen, 2001, Lametsch, Roepstorff and Bendixen, 2002, Yan *et al.*, 2001). Initial comparison of the proteome of the five breeds has identified 21 spots that significantly differ ($p<0.01$; data not shown). These proteins are now being identified using MALDI-TOF mass spectrometry. Any novel proteins will be characterised by Electrospray mass spectrometry and comparison with translated sequences from the cDNA libraries generated within the project.

cDNA libraries

One of the main aims of the project is the analysis of the transcriptome of muscle at the time of slaughter and to relate this to differences observed in the phenotypic characteristics of the muscle. In order to do this, specific cDNA libraries were prepared from both loin and ham muscle to provide the basis for the construction of microarray tools that could be used for this analysis. The quality of the SSH cDNA libraries was assessed by careful analysis of each step during the subtraction process and by hybridisation of subtracted cDNAs to known housekeeping genes that should decrease in representation during the subtraction process (see Figure 3 for examples, Page 16). Furthermore approx 500 clones from each of the eight SSH libraries have now been sequenced using the M13 reverse primer, and this analysis has revealed a low-level of sequence redundancy, another indicator of the quality of the SSH libraries. This analysis also suggests that these libraries may prove a useful resource for the isolation and characterization of candidate genes associated with meat quality as each library forms a unique population of cDNAs. A standard full-length pig muscle cDNA library was prepared to facilitate the isolation of full-length cDNA for candidate genes to be identified from the SSH libraries, microarray screening and proteomics analysis. The quality of this library was assessed by titration of library size and cDNA fragment length analysis. The results obtained showed that the size of the cDNA library (4.8×10^5 pfu) was above the bench-mark figure of 10^5 cDNA clones required to have a good probability that all rare mRNA transcripts would be represented in the library. Analysis of the size of cDNA inserts from random clones showed the largest cDNA insert to be 3.3 kb in length, with the majority of clones > 0.7 kb and an average insert size of approximately 1.4 kb. The quality of the libraries has also been investigated

by DNA sequence analysis. Using contig assembly followed by BLAST to NR and EST databases to assign tentative gene identities to the SSH library clones, over 900 separate genes are detected, with many genes represented by different non-overlapping sequences.

Microarray development

The SSH libraries have formed the basis of the first microarrays constructed for initial transcriptional profiling using muscle mRNA from animals selected on the basis of variation in key aspects of quality such as pH and colour, drip loss, loin area or marbling. The rationale behind using these clones is that they have already been taken through a pre-selection process, and therefore should be enriched for those transcripts with differential expression profiles at the extremities of commercially important phenotypic traits. Additional clones for candidate genes were selected from the literature or from prior knowledge, and genes defined as muscle specific or muscle variant (based on the human HUGe index analysis of skeletal muscle: Hsiao *et al.*, 2001) were also included on the array. Every element occurs more than once within the microarray grid design.

This prototype array has been verified by hybridization with samples from pooled LT against pooled SM (Figure 4, Page 17). Genes that showed up or down regulation in LT were verified from the known characteristics of the muscle types. In addition, genes enriched in LT by SSH were up-regulated in LT on the array, giving greater confidence that the SSH libraries will provide a valuable resource of potential candidate genes for the phenotypes compared in the subtraction process. This will be particularly important where changes at the transcriptional level are more subtle than can be detected with an array-based approach. The first large-scale microarray experiments are now being undertaken using this array focusing on the relationship between variation in gene expression and the water holding capacity of meat (measured by drip loss, pH and colour) and its intramuscular fat content.

The second-generation microarray now under construction will contain fewer individual elements, with some of the redundancy removed from the gene set, but additional clones from the most unique SSH libraries and further candidates supplementing it, giving approximately 7000 different elements. The reduction in clone number will allow a triplicate printing of all the elements: this means that the internal validation of data by comparison of pixel values from replicate elements on a slide will not be compromised by loss of information from one replicate. This can occur owing to background or hybridization anomalies, and with a duplicate system, singleton data is often discarded owing to lack of confirmation of the intensity ratios.

This second-generation array will be used to assess the correlation of gene expression results with phenotypic measurements of tenderness and sensorial traits, together with other detailed measurements such as fatty acid composition. The five batches of animals selected for this experiment have detailed phenotypic measurements and also proteomics results. One hundred individual animals, twenty animals from each line, will be arrayed and compared against a common pooled control sample in a reference design (Figure 1b, Page14). By using a common reference, data from each animal can be compared against any other animal in the experiment. In addition, some samples from the first series of loop designs occur within the second experiment. As both arrays contain a core common set of elements, these animals are potentially useful for the comparison of data between the experimental designs. In the first experiment genes which show significant differential expression between high and low scoring animals will be identified. In the second experiment the objective will be to find significant correlations between phenotypic trait values and the normalized residual gene expression values, after correction for dye, array and batch effects.

New tools for understanding variation in muscle phenotype

The project was established in order to exploit new technology developments that allow parallel analysis of gene expression (the transcriptome and proteome). The ultimate aim being to identify variation in the genes which contribute to variation in meat quality. The assumption was that some of these genes will be expressed in muscle at the time of slaughter and that variation in expression levels would be associated with variation in quality parameters of meat derived from this muscle. When these genes are identified the resources developed in the project (e.g. cDNA libraries) will enable further analysis of them and also the search for

variation in the sequence of the genes. Once sequence polymorphism is identified this can then be tested for association with variation in the traits of interest. The project database allows for simultaneous analysis of effects on related or secondary traits including aspects of performance and also the yield of some cuts.

This approach is illustrated by the results obtained for the "RN" gene, *PRKAG3* (see Milan *et al.*, 2000, Ciobanu *et al*., 2001), and the protease inhibitor calpastatin, *CAST* (see Ciobanu *et al*., 2002, 2004). Variation in the gene sequence has been identified that explains significant variation in the pH and colour or the tenderness of meat. Simple DNA screening tests can then be developed to select for animals having the preferred genotype. One interesting observation made with respect to the effect of variation in *PRKAG3* was that the impact on pH and colour seemed to be more pronounced in ham than loin (Ciobanu *et al*., 2001). One explanation may be that this difference relates to a difference in the levels of expression in these two muscles. The resources developed in this project allowed this hypothesis to be tested. Initial real time PCR analysis of samples from Landrace and Meishan lines revealed a significant line difference in the expression level of *PRKAG3*, with expression been higher in Landrace (results not shown). Furthermore the expression level of *PRKAG3* in LT muscle was greater than SM ($p = 0.06$)) and this disparity was more evident in the Meishan line than the Landrace line. In a second analysis RNA was selected from LT and SM muscle from randomly chosen Piétrain animals. The expression level of *PRKAG3* in this line was again greater in loin samples than in ham (mean LT versus SM copy number $p=0.041$) although there was also substantial individual variation in expression of this gene (Figure 5, Page 18). The next step will be to see if *PRKAG3* genotype can explain some of this individual variation. The expression results suggest that the *PRKAG3* gene may be expressed differentially between muscles and this may play a role in the variation of metabolism (and ultimately meat quality) between muscles.

Conclusions

DNA markers for meat quality traits have already been identified and are being used by pig breeding companies as part of genetic improvement programmes (see Knap *et al*., 2002). The Quality Pork Genes project has established a phenotypic database and collection of RNA/DNA samples that will enable the search for new genes responsible for variation in pork meat quality, including the interaction with stress. It is anticipated that this unique resource will result in the identification of markers (which may be metabolic, biochemical, and neuroendocrine as well as genetic markers) associated with variation in quality. These markers will then be delivered for further research and/or validation of their utility in breeding and selection or screening, in order to provide the basis for the development of new tools to improve raw material quality.

The project database and samples together with the new research tools (e.g. muscle specific cDNA microarrays), represent important resources that can be used to advance research in muscle physiology and meat quality. Ultimately, these tools will play a role in delivering consistently better product quality to the consumer.

CARBOHYDRATE METABOLISM IN MEAT ANIMALS

Pösö, A.R.[1] and Puolanne, E.[2]

Viikki EE, P.O. Box 66, FIN - 00014 Helsinki, Finland

Introduction

This review deals with the perimortem oxidative/glycolytic capacity of meat animals, especially in muscle tissue. We discuss carbohydrate metabolism focusing on the relationships between the pre-mortem and post-mortem phenomena. The nutritional and hormonal regulation of energy metabolism in skeletal muscles of meat animals has recently been thoroughly reviewed e.g. by Hocquette, Ortigues-Marty, Pethick, Herpin & Fernanadez (1998) and will not be treated here. The subject discussed here has also been presented by the authors of the current review also elsewhere, at Reciprocal Meat Conference (Puolanne, Pösö, Ruusunen, Sepponen & Kylä-Puhju, 2002)

Carbohydrates are essential in the conversion of muscle to high quality meat, but in live animals they are stored in the muscles to provide the animal with a rapidly available source of energy. In "fight-or-flight" situations the muscles have to produce energy at the highest possible rate and even in animals with high aerobic capacity part of this energy production will involve anaerobic pathways and accumulation lactic acid, which is the end product of anaerobic glycogen breakdown. Within the animal kingdom horses have a high oxidative capacity, as indicated by maximal oxygen uptake up to 160 ml/kg body weight per min (Tyler, Golland, Evans, Hodgson & Rose, 1996; Langsetmo, Weigle, Fedde, Erickson, Barstow & Poole, 1997). This is more than twice the value measured in human athletes and about three times that in cattle (Kayar *et al*., 1994) and almost 6 times the value measured in pigs (Perez-de-Sá, Cunha-Goncalves, Schou, Jonmarker & Werner, 2003). Theoretically, if it is assumed that during intense exercise 90% of oxygen is consumed by exercising muscles and that approximately 40% of the body weight is muscle, it can be calculated that with the reported maximal oxygen uptake of horses, aerobic ATP production in the equine muscle may approach 2 µmol/g per s and a similar calculation for pigs gives a value of 0.35 µmol/g per s. Although this calculation underestimates the true production of ATP in working muscles, because all muscles are not equally active as assumed in the calculation above, the values are well below the approximated maximal ATP demand, the calculated value of which for human muscle is about 3 to 5 µmol/g per s (Newsholme & Leech, review 1986). The difference between the demand and aerobic production has to be met by anaerobic glycolysis, the end product of which is lactic acid. This is possible, because the capacity of glycolytic enzymes, at least in equine and porcine muscles, is high enough to support the ATP production that allows maximal rate of ATP consumption (Essén-Gustavsson, Karlström & Lindholm, 1984; Newsholme & Leech, review 1986; Cutmore, Snow & Newsholme, 1993; Karlström, 1995).

The aerobic capacity is determined by the capacity of cardiovascular system and muscle related factors, such as fibre composition and mitochondrial density. On the cardiovascular side, the cardiac output and capillary density in muscles determine the availability of oxygen and inside the muscle the mitochondrial density is a key factor in determining the rate of oxygen utilization. In meat animals the aerobic capacity decreases in the following order cattle > pig > poultry. The size of the heart in beef cattle has been reported to be approximately 0.44% of live weight (Sainz & Bentley, 1997) and in pigs 0.33% (Ruusunen & Puolanne, unpublished), and even greater difference is seen in the capillary density. In the longissimus muscle of cattle the capillary density is approximately 450/mm^2 (Karlström, Essén-Gustavsson & Lindholm, 1994), but in pigs the value is only 150/mm^2 (Ruusunen & Puolanne, 2004). It is generally accepted that the blood flow into skeletal muscle at rest is about 20% of cardiac output, but it may increase to up to 80% of cardiac output

during intense exercise. When this is combined with the increase in cardiac output, the actual increase in blood flow may be 15-fold (or in the case of athletic animals such as horses even more). In such situations the capillary density of the muscles may play an important role. Higher capillary density in the muscles of cattle may result in a better supply of oxygen and efflux of end products of metabolism than is possible in porcine muscles. Thus it can be speculated that during stress both the production of lactic acid as well as accumulation of lactate will be greater in the muscles of pigs than of cattle.

The amount of glycogen in muscles varies from species to species. In the longissimus muscle of cattle the measured concentrations vary between 60-100 mmol/kg (wet) tissue (Immonen, Kauffman, Schaefer & Puolanne, 2000a), in pigs values are around 85 mmol/kg (Rosenvold, Laerke, Jensen, Karlsson, Lundström & Andersen, 2001), but in horses glycogen concentration is usually 1.5 times the concentration measured in cattle (Lindholm, Bjerneld & Saltin, 1974; Hyyppä, Räsänen & Pösö, 1995).

The Glycogen Molecule Complex

The glycogen molecule contains a core protein, glycogenin (MW 37,300 Da), which has enzyme-like properties and supports and catalyses the synthesis of an 8 glucosyl-unit-long primer, necessary for the activity of glycogen synthase (Nelson & Cox, review 2005). As glycogen synthase takes over, the chain grows and forms a branched structure. Each linear glucose chain contains 13 units, bound together with α-1,4-glycosyl bonds. At the fourth and eighth glucosyl units, each branched chain (B-chain) has a 1,6-bond which gives rise to new unbranched chains of 13 units (A-chains) (Figure 1). Consequently, after twelve branchings (13th tier) the number of chains is $1+2^{12}$, or about 4,100. A glycogen molecule with the molecular weight of nine to ten million Da contains about 55,000 glucose residues, the diameter of the molecule is close to 40 nm and the number of available non-reducing ends is approximately 2,100. The full outermost tier contains always roughly 50% of the total carbohydrate of the molecule. Each glycogen particle is covered with up to 40-50 phosphorylase dimers (or 20-25 tetramers). The structure of the glycogen molecule optimizes its usefulness: it packs glucose into the smallest possible volume, maximizes the number of non-reducing ends, and thus maximizes the proportion of glucose units to be removed by phosphorylase before the proximity of a branching point stops its activity (Meléndes-Hevia,Waddel & Shelton, 1993).

Proglycogen and Macroglycogen

The glycogen molecules exist in two forms: proglycogen (PG) and macroglycogen (MG) (Adamo and Graham, 1998). In resting human muscle, in which glycogen stores are full, the acid insoluble proglycogen (protein content about 10 %, MW 400,000 Da) represents approximately 60% of the total glycogen, while in stressed muscle with less glycogen, its proportion is about 90% (Adamo & Graham, 1993). The relative amount of the acid soluble macroglycogen (0.4% protein, MW 10^7 Da) accounts for the rest of the total glucose content, 10-40%. In pigs, similar PG/MG ratios, approximately 68-82% to 18-32%, have been reported, the variation depending on the level of stress and diet (Rosenvold, Essén-Gustafsson & Andersen, 2002). It remains to be seen, how much of glycogen in the form of acid-insoluble PG has not been taken into account in the earlier published studies in which the glycogen has been extracted by acid.

As each chain, also in PG, has 13 glucosyl residues (MW: 13*162 = 2106/chain) it can be calculated that the PG molecules have 6 (MW ca 300,000 including glycogenin) to 7 tiers (MW ca 575,000). In theory, this provides 64 to 128 non-reducing ends and thus sites for phosphorylase action. This also means that the number of phosphorylase units bound to each PG molecule and the number of non-reducing ends are practically the same. In comparison, in a MG molecule, the number of tiers with a molecular weight of 10^7 Da is 13 and the number of non-reducing ends approximately 2,100.

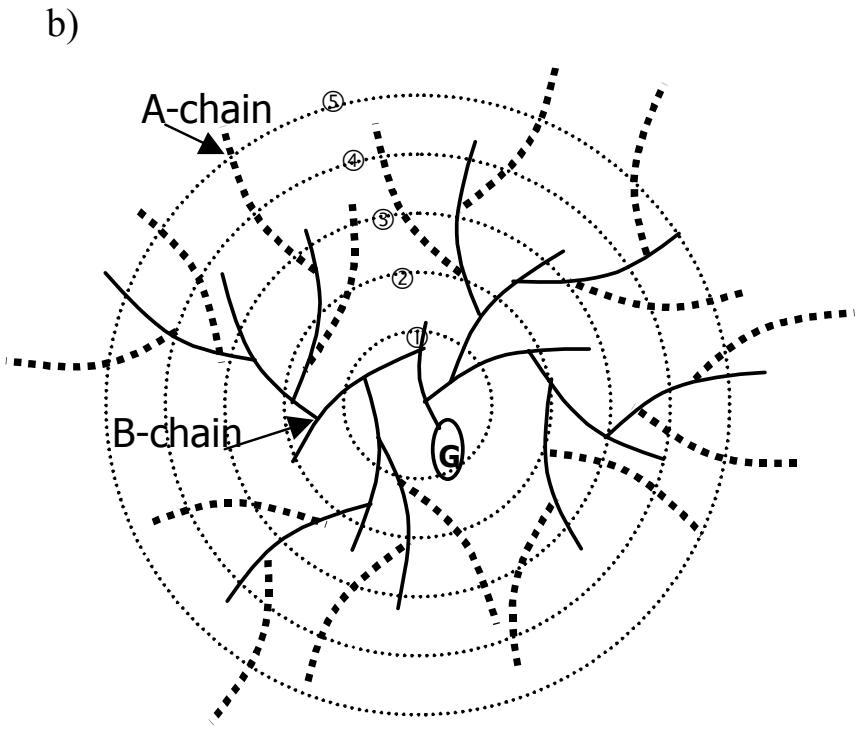

Figure 1. Scheme showing the structure of the glycogen molecule as stated in Whelan's model (Adopted from Immonen, 2000)

Glycogen breakdown: phosphorylase

In muscle, the main sources of glucose are blood glucose (from liver glycogen) and glycogen stored in muscles (Hocquette *et al*., review 1998). During stress, hormonal mechanisms are important for the mobilization and utilization of carbohydrates. In muscle, catecholamines, released from sympathetic neurons and adrenal medulla, induce rapid degradation of glycogen through the activation of glycogen phosphorylase and the inhibition of glycogen synthesis. In addition phosphorylase is under allosteric (AMP and/or Ca^{++} activated) control. Activated phosphorylase cleaves glucosyl units as glucose-1-P from a glycogen molecule at an extremely high speed. The reaction cascade is explicitly described in every textbook of biochemistry and therefore, will not be presented here. The sequence is blocked when the influx of blood glucose meets the demand of energy, and when the enzymes of glycogen synthesis are activated (Nelson & Cox, review 2005).

The catalytic subunit of a glycogen phosphorylase dimer (or tetrame) is bound to glycogen, whereas the other subunit regulates the function of the enzyme (Goldsmith, Sprang & Fletterick, 1982). The phosphorylase content is very high, about 2% of the total protein in muscles (Ryman & Whelan, 1971). Glucose residues from the non-reducing end of the uppermost, unbranched A-chains, are cleaved until the fourth glucosyl unit from the branching point. Phosphorylase cannot cleave glucosyl units from the branched B-chain that is too short. Thus, theoretically 34.6% of the units of the outermost tier are available to phosphorylase, i.e. in the case of 100 mmol/kg glycogen (as glucosyl units) in muscle about 35 mmol/kg glucose-1-P will be produced. This results in the formation of 70 mmol/kg lactate (and 105 mmol/kg ATP), if all energy were produced anaerobically (which is not the case *in vivo*). It has been shown that an increase in the number of non-reducing ends enhances, for spatial reasons, the binding of phosphorylase to the glycogen molecule and therefore, enhances the phosphorylase activity as well. The same spatial factor may limit the release of glucosyl units of the lowermost tiers, when the glycogen content is low (Meléndes-Hevia *et al.*, 1993).

Recently it has been shown in humans and horses that MG is preferentially used in long-lasting aerobic stress (Asp *et al*., 1999; Essén-Gustavsson & Jensen-Waern 2002), but PG is utilized more during anaerobic stress (Graham, Adamo, Shearer, Marchand & Saltin, 2001; Bröjer, Jonasson, Schuback & Essén-Gustavsson 2002) as well as in pigs post mortem (Rosenvold *et al.*, 2002). It can be speculated that the mechanism of phosphorylase activation is different in these cases. Although exact mechanisms are not known, these may involve the allosteric activation of phosphorylase b kinase by calcium ions and/or by AMP (Nelson & Cox, review 2005).

Glycogen breakdown: Debranching Enzyme

When phosporylase has cleaved the glucosyl units to the level of four units from the 1,6-branching point (limit dextrin), the bifunctional glycogen debranching enzyme (GDE) transfers maltotriosyl groups from the 1,6-branching point (A-chain) (transferase function) and then cleaves the remaining 1,6-glucosyl unit as free glucose (1,6-glucosidase function). This enables the continuation of the action of phosphorylase (Nelson & Cox, review 2005). Taking both activities of the debranching enzyme into account the total activity is less than 10% of that of phosphorylase. While phosphorylase is able to cleave 12 glucose residues as glucose-1-P, the debranching enzyme cleaves only one as glucose (Meléndes-Hevia *et al.*, 1993). There is some evidence that the activity of the debranching enzyme limits the rate of glycogen breakdown in situations where more than the uppermost layer is to be used (Nelson, White & Gillard, 1969). It can also be anticipated that because of the activity of phosphorylase on glycogen molecules with low number of non-reducing ends is reduced due to spatial reasons, the glycogen molecule may not be fully utilized. Experimental results show that at least 10 to 20 mmol/kg glycogen is always left in muscles, even post mortem and in well-fed, non-stressed animals the residual glycogen may be much higher, up to 80 mmol/kg, even when the ultimate pH is 5.5 (Immonen & Puolanne, 2000).

Kylä-Puhju, Ruusunen & Puolanne (2004b, c) were able to show that the activity of GDE is not particularly affected by the pH in the pH range 5.5–7. But, on the contrary, temperature fall had a very strong effect on the activity, which was close to zero at temperatures below 15 ºC. This may indicate that the positive effects of fast chilling of porcine PSE carcasses (Honikel, review 1984; Offer & Knight, review 1988; Schäfer, Rosenvold, Purslow, Andersen & Henckel, 2002) may be partly based on the elimination of a source of rapidly fermentable glucose due to inactivation of GDE. In the case of beef, where the rate of glycogenolysis as well as carcass chilling are much slower, the lowering of the temperature may block the GDE activity. However, it is not known, how long the A-chains are at death or how long it takes before 15 ºC is reached. Thus there could be variable amounts of glucose-1-P available. The lactate derived from glucose is effective at lowering the pH. Although the buffering capacity, depending on animal species and type of muscle, is from 40 to 60 mmol/(kg∗pH), already small decreases in pH, e.g. 0.2–0.3 pH units, that can be a result from the accumulation of 10 to 20 mmol/kg of lactic acid derived from 5 to 10 mmol of glucose equivalents, are relevant and have a marked effect on water-holding, colour and tenderness. In addition, small differences in the rate of post mortem pH decline have huge effects on the traits mentioned above.

A limited meta analysis of the data EU Concerted Action CT94-1881 coordinated by Joseph and Troy (1998, see the references in the Proceedings; numbers refer to the papers in the Tomes 1, 2 and 3) revealed that in most cases fast chilling produced beef where the pH_{24} was ca. 0.1–3 units higher than by conventional cooling (e.g. Sheridan, McGeehin & Butler, 1.10; Ronchales & Beltram, 2.23; Beltram & Ronchales, 2.24; Beltran, Jaime & Ronchales, 2.5; Ronchales, Jaime & Beltràn, 2.8; Beltran, Tomas & Ronchales, 3.14; Tomas II176, Steen, Claeys & Demeyer, 3.6, Claeys, Demeyer & Van de Voorde, 3.12; Richardson & Perry, 3.15), although in several studies this was not found, or it was even the opposite (e.g. Klont & Eikelenboom, 1.11; Montanac-Bissay & Lepetit, 2.10; Troy & Vidal, 3.4; Taylor, Richardson & Perry, 3.10; O'Mahony, Joseph, McKenna, 3.17; Trevisani, Loshi & Severini, 3.19; Smulders, van Laack & Hofbauer, 3.20). Sometimes there was only an initial reduction in pH fall suggesting that the remaining activity of phosphorylase and GDE could be enough when the time available is long enough (White, Troy & McKenna, 1.13; Steen, Claeys & Demeyer, 3.6; Trevisani, Loshi & Severini, 3.11). This, however, needs further research, and a similar study on electrically stimulated carcasses should be done. It should also be pointed out that pH and temperature change rates differ much in carcasses, which makes the scrutiny of these aspect difficult for practical considerations (Puolanne & Ruusunen, 1998).

Lactate Dehydrogenases

Pyruvate is the junction point in carbohydrate metabolism. When oxygen is available and the density of mitochondria is not a limiting factor, the citric acid cycle and oxidative phosphorylation are the preferred pathways of oxidation and energy production. When the demand for ATP exceeds the capacity of aerobic metabolism, ATP will be produced anerobically, which, as previously explained, involves the reduction of pyruvate to lactate. The reaction is catalyzed by lactate dehydrogenases in cell cytosol (Nelson & Cox, review 2005). In muscles, as in other tissues, lactate dehydogenases occur as five tetrameric isoenzymes (LDH-1 ... LDH-5). The four units in each LDH molecule are composed of muscle-type (M) or heart-type (H) chains. The extreme combinations are H_4 (LDH-1) and M_4 (LDH-5) (Dawson, Goodfriend & Kaplan, 1964; Fieldhouser & Masters, 1966). LDH-5 has a high K_m for pyruvate, thus favoring the formation of lactic acid when the rate of glycolysis is high. Furthermore it is not inhibited by an excess of pyruvate as is LDH-1. Although the M-type dominates in dark and white muscles, the dark muscles contain more H-type activity when compared to light muscles. For example in infraspinatus muscle about 30% of the chains in LDH isoenzymes are H-type while the percentage in longissimus muscle is only 4 (Ruusunen, Sepponen, Puolanne & Pösö, unpublished). Porcine muscles have an exceptionally high LDH activity (Hamm & El-Badawi, 1991; Suuronen, 1995). Acute stress, coupled with a low capillary and mitochondrial density, will favor the formation of lactic acid, which as it is a utilizable source of energy, is later converted back to pyruvate. This takes place more efficiently in the heart and dark (oxidative) muscles than in light (glycolytic) muscles.

The Formation of Lactic Acid

In the muscle fibres of a living animal, small amounts of lactic acid is produced almost constantly. The activation of glycogen phosphorylase during stress increases the accumulation of lactic acid and consequently that of protons causing fatigue, and ultimately, pain and distress (Gregory, review 1998). The acidification of the muscles leads to attenuation of the rate of glycolysis, because protons inhibit the activities of glycogen phosphorylase and phosphofructokinase and thus energy production from carbohydrates (Fitts, review 1994). Protons may also inhibit the function of myosin ATPase (Fitts, review 1994; Schiaffino & Reggiani, review 1996) and thus impair muscle contractions. Furthermore, both the uptake and release of calcium ions from the sarcoplasmic reticulum are disturbed due to acidification (Westerblad, Lee, Lännergren, & Allen, review 1991; Williams & Klug, review 1995). In fatigued muscle the pH may be as low as 6.5 to 6.3 (Lowell, Reid & Rose, 1987; Juel, review 1996), but this value is significantly higher than the ultimate pH in muscles after slaughter that is usually around 5.4–5.8

When a glucose molecule is broken down into two molecules of pyruvate, two to three molecules of ATP are generated. In addition, two molecules of NAD^+ are reduced to NADH, which must be reoxidized in order to maintain the rate of glycolysis. When oxygen is available, electrons from NADH are transferred to molecular oxygen via the mitochondrial electron transport chain. However, when oxygen is lacking, oxidation of NADH is coupled with the reduction of pyruvate to lactate, i.e. lactate formation is a prerequisite for anaerobic energy production (Nelson & Cox, review 2005). Lactic acid formed is either converted back to pyruvic acid to be used oxidatively via the tricarboxylate acid cycle, or when there is a lack of oxygen and/or mitochondria, transported out of the fibre.

When pH in muscles is 6.2, the concentration of lactic acid in the muscle fibres must be about 50 to 60 mmol/kg. In a 100-kg live weight modern lean pig (47 kg muscle tissue) this would mean 47 kg*55 mmol/kg*90 mg/mmol lactic acid, i.e. ca 230 g. Whether or not this overestimates the amount of lactic acid formed (all the muscles do not produce simultaneously this maximal amount of lactic acid), it means that after a stress situation this amount should be utilised in the adjacent fibres or released to blood. For aerobic tissues lactate is an excellent source of energy, because it contains most of the energy of glucose. In live animals all the lactate formed during stressful situations is either oxidized in heart, liver and aerobic muscles or converted back to glucose in liver (Pösö, 2002). It is also generally accepted that, within the muscle tissue, some lactate may be transported via the interstitial fluid from white, glycolytic, fibres to red fibres (type 1 and IIA) which have higher mitochondrial density. It can be speculated that in domestic pigs this

phenomenon is of minor importance, because the percentage of red fibres is small in muscles such as *M. longissimus, gluteus* and *semimembranosus* (Ruusunen 1994; Karlström, 1995; Ruusunen & Puolanne 2004). Without uptake of lactic acid into tissues for oxidation, only small amounts can be released into blood. Lactic acid concentration in blood may vary between 5–25 mmol/l, which in a 100-kg pig corresponds to about 10 g. The imbalance between formation and transport capacity of blood is non-physiological, and problems caused by the low oxidative capacity of modern pigs and poultry can be expected to rise if the increase in percentage of glycolytic muscle tissue will continue, due to the better feed conversion rate of glycolytic fibres (Hocquette *et al*., review 1998). The problem is not as severe in ruminants, which are lethargic and have higher oxidative capacity than pigs. When they are stressed and catecholamines evoke glycogenolysis, a large part of pyruvic acid will be utilised aerobically, and therefore large variation in pH in living muscle will not be probable.

The Buffering Capacity

Muscles are well adapted to their function. The buffering capacity keeps their pH at a level that allows an effective function of vital enzymes. The buffering capacity is greater in muscles needed for fast, bursts of short duration, and lower in muscles prone to long-lasting activity at relatively low intensity. Therefore, as a general rule, buffering capacity is greater in large glycolytic muscles with large-diameter muscle fibres and sparse capillarization. This suggests primarily anaerobic metabolism. Oxidative muscles with a small fibre diameter and high capillary density have a lower buffering capacity.

At rest the pH of porcine longissimus muscle varies from 7 to 7.2 (Tarrant, McLoughlin & Harrington, 1972; Kivikari, 1996; Kylä-Puhju, Ruusunen, Kivikari & Puolanne, 2004a). Because oxidative pathways produce carbon dioxide, protons are continuously formed in muscle cells according to the following equation:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO^-_3.$$

Large part of the carbon dioxide diffuses from the muscle into red blood cells and protons that are formed there are buffered by hemoglobin. In the muscle cells the formation of protons activates Na^+/H^+ exchange protein that carries one H^+ out from the cell and simultaneously one Na^+ into the cell (Madshus, 1988). This carrier is driven by the Na+ gradient (Madshus, 1988). There are no studies on the activity of Na^+/H^+ exchange in the muscles of meat animals, but in human muscle this carrier plays the key role in the regulation of cell pH at rest (Juel, Lundby, Sander, Calbet & van Hall, 2003).

A major difference in buffers between muscle and meat is the bicarbonate system that is very efficient in the live animals, but does not have any major role post mortem. Low pH acts as a signal to peripheral chemoreceptors and causes an increase in the rate and intensity of respiration. In lungs the reactions that in the tissues lead to formation of protons proceed in the opposite direction and the carbon dioxide is subsequently exhaled:

$$H^+ + HCO^-_3 \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O\ .$$

Together these two reactions show that for each mole of CO_2 exhaled through the lungs one mole of protons is neutralized. Furthermore, the kidneys participate in the compensation by increasing the reabsorption of bicarbonate and also synthesizing it. In live animals lactate is also used in tissues, such as heart and liver, where metabolism is aerobic. Bicarbonate buffering system and the use of lactic acid in oxidative tissues prevent the drop of pH in live animals to such a low values seen post mortem, but after slaughter, the two mechanisms above have no bearing.

Most studies have found the buffering maximum at pH 6.8 and the minimum at pH 5.0. If pH is further lowered to values below 5, there is again a large increase in buffering capacity (Kivikari, review 1996). The latter increase is due to accumulation of lactic acid (Kivikari, review 1996). In addition to pH, the buffering capacity of post mortem muscles also varies according to the method used for its determination. Especially important is the amount of water used in the titration method determination. Kivikari (1996) and Puolanne & Kivikari (2000) found that with high water additions, the buffering capacity $\beta = dA/dpH$ (A= the amount of

added acid or base) has the maximum of ca 70 mmol H^+/(pH*kg) at the pH of ca 7.0, and the minimum of ca 30 mmol H^+/(pH*kg) at the pH of ca 5.5. This is in accordance with many other studies. With lower water additions, the minimum and maximum tend to level off. Kivikari (1996) also suggests that the buffering capacity in an intact muscle is somewhat lower, ca 40 mmol H^+/(pH*kg).

In the physiological pH range myofibrillar proteins have a buffering capacity of about 20 to 25 mmol H^+/(pH*kg). The soluble components influence the buffering capacity by about 10 (pH 5.5) to 30 mmol H^+/(pH*kg) (pH 6.8), carnosine and inorganic phosphate being the most important compounds (Kivikari, review 1996). Because post mortem reactions cause and increase in buffering capacity of about 8 to 10%, the buffering capacity in most post mortem muscles is between 40 to 60 mmol H^+/(pH*kg), but both lower and higher values have been reported. The reported values in beef are slightly lower and less variable than in pork (can be compared only if determined in the same study). In practical terms and within the pH limits from 7 to 5.5, lactic acid is by far the most important free variable in muscle to determine the actual pH value at any given time. The low pKa value of lactic acid (3.86) means that at the physiological pH range it is almost completely dissociated to a lactate anion and a proton. Without buffers, accumulation of lactic acid would mean a very rapid drop of pH. For example, Lindinger, McKelvie and Heigenhauser (review 1995) have estimated that without buffers, human arterial blood lactate concentrations would be 162 mmol/l and that plasma pH would drop almost to 1 after four 30-second bouts of high-intensity exercise. Kivikari (1996) concludes that the buffering capacity value of '50 mmol H^+/(pH*kg)' can be used as a "rule of thumb" in calculations to estimate the relationship of lactic acid content and pH value within the physiological range.

We have done a meta-analysis on literature data on relationships between glycogen contents, lactic acid contents, pH-values and buffering capacities in *M. longissimus dorsi* (Puolanne, Yli-Hemminki & Kylä-Puhju, 2004). The pH value of 7.2 was used as the zero lactate value. Based on the meta-analysis we found that the best fit between lactic acid, pH value and buffering capacity can be found when using buffering capacity value of 62 mmol H^+/(pH*kg). This was markedly higher than the 49 mmol H^+/(pH*kg) found by Kylä-Puhju *et al.* (2004a), who calculated the values on the basis of pH-lactic acid data of muscle analyses. These findings show once again that the buffering capacities depend on the methods by which they are determined, and much still remains to be studied.

Monocarboxylate transporters

When the rate of the formation of protons is high in living animals, buffering capacity alone is not sufficient to maintain pH homeostasis. In addition to Na^+/H^+ exchange, low pH activates also another proton carrier, the monocarboxylate transporter (MCT). MCTs form a transmembrane protein family, which cotransport a proton together with a lactate anion. In addition to lactate, MCTs also facilitate the transport of other monocarboxylate anions, such as short chain fatty acids (SCFA) and ketone bodies, through cell membranes (Halestrap & Meredith, review 2004). MCT-proteins are also involved in the absorption and delivery of monocarboxylic drugs, such as salicylic acid and simvastatin (Enerson & Drewes, review 2003). Recently isoform 8 (MCT8) was shown to transport thyroid hormones into cells (Friesema, Ganguly, Abdalla, Manning Fox, Halestrap & Visser, 2003).

Monocarboxylate transporter family is comprised of at least 14 members, which differ in their tissue and species specificity as well as in substrate affinity (Halestrap & Price, review 1999; Halestrap & Meredith review 2004). Among the best characterized are isoforms 1-4, but the role and characteristics of several isoforms are not known. Very little is also known about the regulation of MCT genes. Leptin has been shown to upregulate MCT1 mediated butyrate uptake in colonocytes (Buyse, Sitaraman, Liu, Bado, & Merlin, 2002) and erythropoietin increases the amount of MCT1 protein in erythrocyte membranes (Connes , Caillaud, Mercier, Bouix & Casties, 2004).

The topology of MCTs shows that they have 12 transmembrane domains with both C- and N-terminae in the cell (Halestrap & Price, review 1999; Halestrap & Meredith, review 2004). At least 3 isoforms, MCT1, MCT2 and MCT4, are expressed in skeletal muscle tissue (Juel & Halestrap, review 1999). MCT1 is a 53 kDa protein which, when expressed in *Xenopus* oocytes, has a K_m for lactate of 3-5 mM. Similarly expressed MCT2 has low K_m for lactate, 0.7 mM, while MCT4 expressed especially in glycolytic tissues has a much

lower affinity for lactate (K_m 28 mM) (Halestrap & Price , review 1999; Halestrap & Meredith, review 2004). The apparent V_{max} values for the influx of lactate into *Xenopus* oocytes are rather similar in MCT1 and MCT4, which is about 17-18 times that of MCT2 (Bröer, Bröer, Schneider, Stegen & Halestrap, 1999; Dimmer, Friedrich, Lang, Deitmer & Bröer, 2000). MCT1 and MCT4, but not MCT2, need a chaperone protein CD147 (basigin, EMMPRIN, neurothelin) to translocate and obtain active conformation in the cell membrane where they form a complex that consists of two MCT molecules and two CD147 molecules (Halestrap & Meredith, review 2004).

In most species including beef cattle (Koho & Pösö, unpublished results), MCT isoforms 1 and 4 are expressed in muscle tissue (Halestrap & Meredith, review 2004). In glycolytic muscle fibres both MCT1 and MCT4 facilitate the efflux of lactate when the rate of its production is high, whereas in oxidative fibres (type I) the dominant isoform is MCT1 which facilitates either influx or efflux of lactate depending on the prevailing electrochemical gradient of lactate (Halestrap & Meredith, review 2004).

In the muscles of domestic pig (Sepponen, Koho, Puolanne, Ruusunen & Pösö, 2003) and also those of wild boar (Sepponen, Ruusunen, Puolanne & Pösö, unpublished) only traces of MCT1 can be found. The low amount of MCT1 is not due to the lack of the MCT1 gene, since in porcine heart and intestines it is expressed (Sepponen, Ruusunen & Pösö, manuscript in preparation). Instead, the pig muscles express MCT2, which has high affinity for lactate (Halestrap & Meredith, review 2004). We have speculated that MCT2 is needed, because of the anaerobic nature of the porcine muscle fibres, which may involve continuous production of small amounts of lactate (Sepponen *et al*., 2003). The role of MCT2 would thus be to facilitate the efflux of lactate from cells where mitochondrial density is low. Although our knowledge on monocarboxylate transporters is increasing, there is no data available on their role post mortem.

The Rate of ATP Consumption and Production

ATP is used for contraction of sarcomeres and other processes in muscle, maximally 3 to 5 μmol/(g*s) (Lister, 1988). In a resting muscle, the consumption is about 1/100 of the maximum (0.03–0.05 μmol/(g*s)) which is needed to maintain the ionic balance and provide the basic heat of the body (69% of the energy produced in the reaction ATP → ADP + P + heat). It can be calculated that during maximal exercise an animal can increase its oxygen muscle consumption by more than 20 to 40 fold from the resting level. The increase is based on increase in cardiac output, increased relative amount of circulation through muscles, and increased release of oxygen from blood to muscles. Because the energy consumption may increase 100 fold, the difference must come from some other source, which is the anaerobic energy production via glycogenolysis. It can be estimated that in an extreme case, the pH value of living muscle may fall to 6.2-6.4 in less than 30 seconds. This is the case only in an anaerobic muscle, because in dark muscles do not easily show such an extensive decrease in pH *in vivo*. This pH change would need about 40–60 mmol H^+/kg.

Post-mortem the rate of pH fall may be in beef and sheep 0.005 and in porcine muscle 0.01 pH units/minute (Pearson & Young, 1989) or in PSE pig 0.02 (extreme PSE pig 0.1), in normal turkey 0.03 and in PSE turkey 0.06 pH units/minute (Sosnicki, Creaser, Piertrzak, Pospiech & Santé, review 1998). From that it can be estimated, using the buffering capacity of 60 mmol H^+/(pH*kg) and ATP/lactic acid molar rate of 1.5/1, that the ATP production varies in post mortem muscles of different species from 0.008 (beef and sheep), 0.015–0.03 (pig – PSE pig) (0.15 extreme PSE pig) to 0.05–0.09 μmol/(g*s) (turkey – PSE turkey) which is well in accordance with the values estimated in living resting muscle. It is not fully known, what are all the relevant reactions where ATP is consumed post mortem and why there are differences like between normal muscle – PSE muscle.

Immediately post mortem ATP is used in muscles for involuntary slow contractions, maintenance of membrane potential and especially to keep the calcium ions within the sarcoplasmic reticulum. Bendall (1979) showed that the ATP content remains at the normal level (8–10 mmol/kg) until half of the ultimate amount of lactic acid has been produced. Then the ATP content starts to decline, and when it reaches about 1 mmol/kg, there will be the onset of rigor mortis (which depend on the temperature of the muscle) (Honikel, Ronchales & Hamm, 1983).

ATP, creatine phospate, and oxygen bound to myoglobin contribute to the ATP level during the immediate post mortem phase. When one molecule of lactic acid is produced, 1 or 1.5 molecules of ATP/lactate are also produced. Therefore, all the metabolic factors discussed here are inter-linked and should be handled simultaneously when discussing the pH of muscle and meat and its effects on meat quality.

Post Mortem Oxygen Utilization

In a living animal, the partial pressure of oxygen in venous blood from resting muscles is about 40 torr, with oxygen saturation of haemoglobin of about 75% and in intensively working muscle the respective values are 20 torr or less and about 38%. If the physical stress further increases, myoglobin which is saturated up to 90%, starts to provide oxygen. When oxygen derived from myoglobin has been utilised, the oxygen pressure is approaching zero, and the fibre will be produce energy anaerobically via glycogen breakdown as described above. Consequently, both routes of ATP production are active simultaneously. The literature provides very variable data on the myoglobin contents of various meats. Generally, the content in light muscles ranges from 0.06 to 0.2 and in dark muscles 0.2 to 0.3 mmol/kg. In beef, the myoglobin content is higher and strongly age-dependent ranging from 0.1 to 1 mmol/kg. The full oxygen saturation of heme would then mean equivalent concentration of molecular oxygen. One 1 mmol oxygen enables an aerobic production of 6 mmol ATP. Consequently, the oxygen stored in myoglobin, allows the production of 0.06*6=0.4 to 1*6=6 mmol ATP, depending on animal species, age and muscle type. In addition, meat contains minute amounts of blood. Depending on the degree of bleeding and the oxygen saturation of blood in various muscles, additional oxygen would be available. No published data on this is available, but based on our preliminary data on hemoglobin hemi (not published) we estimate that the amount of available oxygen is no larger than the myoglobin reservoirs. The amount of oxygen in sarcoplasma is also very small.

The amount of ATP produced by the formation of about 80 mmol/kg lactic acid is 120 mmol/kg (the post mortem formation of lactic acid molecule results in 1.5 molecules ATP). Consequently, we suggest that oxygen in total heme content theoretically equals about 5% of the post mortem production of ATP via glycolysis in beef and less than 1% in pork. This difference might be one of the factors causing the lower initial rate of pH decline in beef than in pork. The variation in the oxidative status of muscles at death and amount of residual blood may also have an influence on the onset and rate of glycolysis, respectively.

Creatine Phosphate

The content of creatine phosphate is *in vivo* 20–25 mmol/kg. The production of ATP through the reaction catalyzed by creatine phosphokinase represents roughly 1/5 of the amount of ATP formed via glycogenolysis post mortem. When CP is broken to C and inorganic P, one proton is bound, which means an increase in pH as follows (Hyyppä & Pösö, review 1998).

$$CP^{2-} + ADP^{3-} + H^{+} \rightarrow ATP^{4-} + H_2O + C$$

This might, explain the initial increase in pH that is sometimes seen to take place during the slaughter process (unpublished observations). Taking the direct formation of ATP and also the elimination of protons into the account it can be calculated that this means a transient initial “buffering of the pH fall of almost one pH unit” compared to the situation when all creatine phosphate resources have been exhausted, and ATP will immediately be formed directly via glycolysis. Later ATP will, however, be formed by glycolysis anyway, and only the effect of the utilisation of protons (see equation above) will remain. Therefore, the content of creatine phosphate at the moment of slaughtering could be of importance. This has been recently thoroughly discussed by the similar way by Henkel, Karlsson, Jensen, Oksbjerg & Pedersen (2002).

Concluding Remarks

In living animals, the accumulation of lactic acid causes pain and distress and can result in a reduction in life quality. Our present knowledge of the cardio-respiratory capacity of meat animals, especially modern pigs and poultry is insufficient. This, together with glycogen and the anaerobic end product of its metabolism, lactate, has a strong influence on animal welfare and meat quality, which underlines the importance of further research on this field.

Background

The quality of pork covers several properties, which have to meet the increasing demands of consumers and processors. The main attributes of interest are color, pH and water-holding capacity, fat content and composition, and also the oxidative stability.
The meat is very sensitive to oxidation leading to quality deterioration and loss of value. The tissues contain antioxidant defence systems. Superoxide dismutase, catalase and glutathione peroxidase are antioxidative enzymes contributing to the oxidative defence, as well as the fat-soluble α-tocopherol and ubiquinone, along with the water-soluble ascorbic acid and glutathione. The adequate activity of these defence systems are essential to develop appropriate meat quality.
The perimortal effects on meat quality and animal welfare are widely investigated. It is generally accepted, that the different environmental factors have a stronger impact than the genetic background. On the other hand the decreasing variance of Hal and RN genes, moreover the elimination of these genes makes it necessary to reevaluate the effect of environmental factors. Many studies showed differences in case of these effects when the experiments were carried out with halothane negative pigs.
The optimum lairage time for pigs is a question of compromise. Very short lairage time does not allow sufficient time for recovery leading to a higher incidence of PSE-meat. No prolonged lairage time is recommended after a long-term transportation, because the animals are already exhausted, so the further lairage may increase the incidence of DFD-meat.

Objectives

- study the effect of transportation as a stress factor,
- the effect of transportation and lairage on the antioxidant defence system,
- effect of lairage time on physiological and meat quality traits.

Materials and methods

The present study was conducted at the Gyula Packing Plant Ltd (Hungary). A total of 40 Dumeco hybrid pigs were transported from one of the largest producer of the meat company were transported to the abattoir. The pigs were assumed to be halothane negative (NN), even though they were not tested, as the gene has been practically eliminated from the breeds used by the pig farm.
Animal were fed 4 hours prior to transportation. They were driven out from the piggery to the waiting pen right before the blood samples were taken. For further identification, the animals were marked individually by ear tag. After sampling the animals were driven up to a three-decker lorry. The experimental animals traveled on the lowest level. The distance between the pig farm and the slaughter-house is 70 km, which lasted 1,5 hr for the lorry. After arrival the animals were weighted, which was followed by the second blood sample taking. Then the pigs were divided into two groups: one hour lairage time (Group A), and 16 hours lairage time (Group B) according to the local practice. Showering was used only in the case of the longer lairage.
After lairage the animals were stunned using electrical stunning method and slaughtered. During exsanguination the third series of blood samples were taken. The further processing method was carried out according to the local practice. After evisceration liver samples were taken from the *lobus caudatus*. The

meat quality traits were measured two times: (1) 45 minutes after slaughtering, right after the slaughter value determination by Fat'o'Meater and (2) after chilling, at the 24th hour.

The blood samples were taken from v. jugularis before and after transportation and during exsanguination. The following indicators of stress were determined from the samples: cortisol, NEFA, lactic acid and glucose. Blood sampling tubes contained sodium-fluoride and potassium-oxalate. After centrifugation (10 min, 2500 rpm) the samples taken were stored at -20 °C until further analysis. For the cortisol assay a direct RIA method, developed in the laboratory of Szent István University, Faculty for Veterinary Sciences (Budapest, Hungary) was applied. For determination in blood plasma 1,2,6,7-3H-cortisol (TRK 407; Radiochemical Centre, Amersham, UK) and a highly specific polyclonal antibody raised against cortisol-21-HS-BSA in rabbit was used. The radiactivity was measured by Beckman Instrument Typ LS 1701 liquid scintillation counter.

NEFA, lactic acid and glucose was analysed with enzyme-colorimetric method using standard kits (*L-Lactate (PAP) kit*, Cat. No. LC 2389, Randox Laboratories Ltd., UK; *NEFA kit*, Cat. No. FA 115, Randox Laboratories Ltd. UK; Glucose kit (Cat. No. 40851, Diagnosticum Ltd.., Hungary).

Indicators of lipid peroxidation processes and antioxidant defence system were measured as follows: MDA (malondialdehyde), GSH (reduced glutathione), GSHPx (glutathione-peroxidase activity) and ascorbic acid. The MDA, GSH and GSHPx values were determined from liver, blood plasma and red blood cells (RBC). The concentration of ascorbic acid was analyzed in liver samples and blood plasma. The blood samples were collected into heparine containing tubes, and centrifugated for 10 minutes (2500 rpm). The RBC hemolisate consisted of 1 vol RBC and 9 vol distilled water. Both hemolisate and blood plasma were stored at -20 °C until analyses.

The liver sample taking was followed by marking, packaging and storing at -20 °C. Immediately before analyses a sample of 0.5 g was homogenized in 9 vol of 4 °C physiological saline using Ultra Turrax (Donau Lab AG, Switzerland) homogenizer. For determination of MDA concentration the original homogenate, for the GSHPx, GSH and protein content the supernatant of the homogenate (centrifugation 10000 g, 20 min, 4 °C) were used.

MDA content describing the level of lipid peroxidation was carried out with 2-thiobarbituric acid determination. In case of blood plasma and RBC hemolizate the method of *Placer et al.* (1966) was followed, while the liver samples were analysed by the method described by *Mihara et al.* (1980).

The examination of antioxidant defence system included the determination of GSH concentration and GSHPx activity. The methods of *Sedlak et al.* (1968) and *Matkovics et al.* (1988) were used, respectively.

The protein content of blood plasma and RBC homogenizate was estimated by a modified biuret method (*Weichselbaum, 1948*), using egg protein (Randox Laboratories, UK) as standard. The protein content of liver homogenates was analyzed using Folin-Ciocalteau phenol reagent (*Lowry et al.,* 1951), and bovine serum albumin (Reanal, Hungary) as standard.

For the ascorbic acid determination 1 ml blood plasma was added to 1 ml 10 % TCA (trichloric-acid) and followed by centrifugation (20 min, 3500 rpm). 0,5 ml of the supernatant was stored at -20 °C until the further analyses. A liver sample of 0,5 g was homogenized in 9 vol 5% TCA, which was followed by centrifugation (20 min, 3500 rpm). The analyses were carried out using the method described by *Omaye et al.* (1979).

Meat quality parameters were measured two times: 45 minutes after slaughtering and after chilling at the 24th hour. The first measurement included pH and core temperature determination in the most valuable muscles: *m. longissimus dorsi* and *m. semimembranosus*. We registered the chilling loss, which was computed from the difference of carcass weight before (approx. 50 min after slaughtering) and after chilling. 24 hour after slaughtering we measured the pH and the color properties (L^*, a^*, b^*, Japanese color scale) of the loin. Temperature was measured with common meat industrial core thermometer, the pH measurement with a WTW 330 portable pH meter (WTW Gmbh., Germany) attached with WTW SenTix sp electrode and the color determination with a Minolta Chromameter CR-300 (Minolta Co., Japan) were carried out.

The data were analyzed with SPSS for Windows 10.0 Program Package, using t-test with independent samples and paired samples.

Results and discussion

Transportation as a stress factor is considerable in case of properties measured. The significance values are summarized in *Table 1*.

The activation of hypothalamus-pitiutary-adrenal cortex (HPA) axis results in a higher cortisol level, which is followed by the increase of NEFA, glucose and lactic acid values. The state of antioxidant defence system is affected by transportation, which is demonstrated by reduced GSH level. However, the oxidative load is not so significant to enhance the activity of GSHPx, moreover both in blood plasma and RBC hemolizate decreasing has obsessed. The MDA concentration differs significantly only in case of RBC hemolizate. The transportation affects also the ascorbic acid concentration, although the level of significance is low ($P<0,05$).
The effects of lairage on biochemical parameters measured are summarized in *Table 2*. The data measured at arrival and during exsanguinations and the data of the two different lairage time were compared.
Both 1 hour and 16 hour lairage increases the level of lactic acid, glucose and ascorbic acid. No significant difference is revealed in case of cortisol and NEFA or in the most of the parameters characterizing the antioxidant defence system.
Statistical analysis did not reveal any difference between the two groups. Only the GSHPx activity measured in RBC hemolizate increases at a low significance level ($P<0,05$).
The results of the liver samples analysis are shown in *Table 2*. Significant differences were found in case of GSH and ascorbic acid. The level of lipid peroxidation increases, which is illustrated with the reducing MDA values, although it is not significant in consequence of high individual variance. No difference is experienced in case of GSHPx.
The results of meat quality measurements are summarized in *Table 3*. Significant differences were found in case of pH_{45} and core temperature, along with the chilling loss. No difference was revealed in any of the meat quality traits measured after chilling, at the 24th hour.

Considering the biochemical parameters measured, we can state that the transportation causes high stress for the animals. The activation of HPA-axis results in an increased cortisol level. This hormone has a key-role in the gluconeogenesis. It is conducive to transform some amino acids and other gluconeogenetic substances (lactic acid, proprionic acid, glycerin) to glucose and glycogen. Addition to the stimulation of gluconeogenesis, the cortisol inhibits glycolisis. The enhanced production and decreased metabolism of glucose resulted in approx. 25 % higher blood glucose level, in spite of the short transportation time. The catabolic effect of cortisol on lipid metabolism is also manifested. This physiological process is important to ensure the energy requirement of animals during stress. The effect of lipid mobilization is revealed in level of NEFA, which increased approx. 100 %.
The increase of lactic acid is a bit surprising. As it was mentioned above, one effect of cortisol is to enhance gluconeogenesis, which changes the lactic acid level negatively. This phenomenon can be explained by the high physical exertion caused by transportation and the surrounding animal handling. These physical loads can enhance the depletion of lactic acid from muscles to blood.
The effect of transportation on the antioxidant defence system is revealed. The considerable oxidative load results in lower level of GSH both in blood plasma and RBC hemolizate. These changes are not so significant to enhance the activity of GSHPx, moreover a slight decrease can be seen. The reduced level of ascorbic acid was induced by stress. The change can be explained by its role in antioxidant defence system, and in the synthesis of cortisol in adrenal cortex.
During 1 hour lairage the stress was further enhanced. It is shown by increasing cortisol level, although it was not significant. The lactic acid enhanced three-times higher during lairage, which means that driving to stunning creates a very stressfull situation. The 16 hour lairage has quite similar results. No significant change in cortisol comparing the arrival state with the exsanguinations state is revealed. The level of lactic acid and glucose enhances with a high degree, along with the other group. The NEFA level do not changes either of the two groups, remains at the level measured at time of arrival. Changes of antioxidant defence system are obsessed only in case of blood plasma, the GSH reduces during lairage.
No significant differences were revealed between the two different groups. Two conclusions might be drawn from the results. (1) It is possible, that the lairage conditions are not adequate, and it not ensures enough rest for the animals. (2) It is also possible, that driving to stunning, and the stunning itself causes such a high stress for the animals, which is enough to eliminate the positive effect of lairage. This is suggested by the biochemical parameters.
The results of the meat quality measurements are in agreement with the biochemical measurements. Even though the pH_{45} and temperature values were lower in case of Group B (the lactic acid values were also higher at the time of stunning), these differences were equalized up to the second measurements. Thus, no significant differences are revealed in case of pH_{24} and meat color.
The analyses carried out on liver samples resulted in differences for two parameters. Ascorbic acid reduces drastically, which is caused by the enhanced metabolism, and depletion to blood. The GSH also decreases

significantly. It is presumable that the large-scale changes in both parameters are caused by fasting. At the case of longer lairage the fasting time exceeded 20 hours, so the reduced GSH level is explainable with the lack of supply of amino acids required for GSH synthesis.
Summing up the results, we can conclude that transportation, lairage and driving to stunning cause a heavy distress effect for the animals. On the other hand, these factors do not cause such a high oxidative damage, which appears in the meat quality. Negative changes in the antioxidant defence system are shown, which is traceable in the level of glutathione and ascorbic acid. The lipid peroxidation processes are not influenced significantly by short-term transportation or lairage. The oxidative stability of liver after long lairage was highly reduced, thus, if it is planned to have further processing from the liver, long lairage and fasting is not recommended.

Conclusions

It can be concluded that when using halothane free animals, meat quality is largely independent of lairage time. It is important to underline, that the decision of lairage time is a question of compromise. In addition to meat quality it is influenced by hygiene and the question of work organization. It can be required to have the animal transportation on the day before slaughtering to have a safely continuous working of the abattoir.

Background

There is an increasing concern in developed countries about the consumption of dietary fat due to its association with cardiovascular and other lifestyle diseases, and for many years there has been emphasis on reducing the fat content from our diets. Meat producers have responded by reducing the fat content of beef by selective breeding, feeding practices and also by new butchery techniques (Hornick *et al*., 1998).
Both the amount and the composition of fat depots in beef may be influenced by factors such as breed or genotype, age or live weight, castration and gender, and feeding regime (Rule *et al*., 1995). In this sense, some breed effects on meat quality have been described out of two local breeds from Asturias in Northern Spain: "Asturiana de los Valles" and "Asturiana de la Montaña" (Oliván *et al*., 1999; Gil *et al*., 2001). On the other hand, steer production is gaining renewed interest because its effect on physico-chemical and sensory traits of meat (Steen, 1995; Osoro *et al*., 2001).

Objectives

The purpose of the present study was to examine the differences in fatty acid composition of muscle fat between bulls and steers in two different Spanish beef breeds ("Asturiana de los Valles" & "Asturiana de la Montaña") managed under grazing conditions.

Materials and methods

Animal management

Eight yearling bulls from "Asturiana de los Valles" (AV) (beef breed adapted to extensive production systems) and eight yearling bulls from "Asturiana de la Montaña" (AM) (small to medium-sized hardy animals, adapted to mountain systems) were reared under extensive conditions on ryegrass and clover pastures. Four animals from each breed were castrated between 10-12 months of age. All animals received a finishing concentrate diet during 60 days (84% barley meal, 10% soya meal, 3% fat, 3% minerals, vitamins and oligoelements) and barley straw *ad libitum* at the housing facilities of the Institute (S.E.R.I.D.A.). Animals were slaughtered with an average weight of 504 kg for AV bulls and 534 kg for AV steers, and 461 kg for AM bulls and 481 kg for AV steers. Slaughtering was performed in a commercial abattoir according to a routine procedure, and after dressing the carcasses were chilled at 3ºC for 24h.

Measurements

Twenty four hours *post-slaughter* the left half carcass was quartered and the part of the rib joint comprised between the 6th and 9th ribs extracted and transported to the laboratory. The 6th rib was excised and *Longissimus thoracis* (LT) muscle was separated, aged at 4ºC for 7 days and then minced with an electrical chopper, vacuum packed and kept at –20ºC until determination of intramuscular fat content by near infrared spectroscopy (Oliván *et al*., 2002). The LT of the 8th rib was extracted, vacuum packed and frozen at –80ºC for subsequent fatty acid composition analysis by gas chromatography (GC).

Total fatty acid analysis

The fatty acids were extracted in 5M KOH in methanol/water (50:50) at 60ºC for 1 hour and esterified at 40ºC during 10 min with 2M trimethylsilyl-diazomethane in *n*-hexane according to Elmore *et al*. (1999) with some modifications. Separation of fatty acid methyl esters was performed on a Varian CX3400 GC with a flame ionisation detector (FID) and a split/splitless injection port (50:1). GC analysis was performed using a B-PX 70 for FAME column (120m x 0.25mm i.d., 0.2µm film thickness) with programmed oven temperature. Injector and detector ports were set at 270°C and 300°C respectively. The carrier gas was hydrogen and the flow rate 1.6ml/min. measured at the initial temperature. Esterified fatty acids were

identified according to similar peak retention times using standards and quantified according to internal standard method ($C_{23:0}$ methyl ester) with its addition prior to saponification.

Statistical analysis
The statistical analysis was conducted using the SPSS11.5 program (2002). The effect of breed, castration and their interaction were studied by ANOVA analysis. Significance level of $p \leq 0.1$ was also considered.

Results and discussion
Table 1 shows the effect of breed, separately in bull and steers, and the effect of castration within both breeds on intramuscular fat and total fatty acid contents of *Longissumus thoracis*.

Breed effect on intramuscular fat percentage was seen in steers, but not in bulls, where AM steers showed more (4.74%) IM fat than AV steers (2.59%). Castration effect was significant only for AM breed where steers had (4.74%) a higher IM fat level than bulls (2.80%).

Breed effect on total FA composition was more pronounced in steers where significant ($p \leq 0.1$) differences were observed in 37% of the individual FAs, while in bulls only 18% of the individual FAs where significantly affected. In castrated animals, AV showed significantly higher quantities of *n-3* FAs than AM animals, and $C_{22:1}c13$ and $C_{18:2}$ *n-6* were also significantly higher in AV castrated animals. However, these differences were not observed in entire animals.
Studying FA groups, in general, breed effect was not significant, except for PUFA group because AV steers showed more PUFAs than AM steers. It should also be emphasised the significant difference in *n-6/n-3* and P/S ratio between steers of both breeds; AV steers showed lower *n-6/n-3* ratio (4.07) than AM steers (5.50). Higher P/S ratio was found in AV (0.49) than in AM (0.22) steers. Therefore, AV castrated animals meat would be the best adapted to the nutritional guidelines recommendations (P/S ratio between 0.45 and 0.70 and *n-6/n-3* ratio about 4.0) (Williams, 2000), and could happened due to a lower IM fat level of AV steers in comparison to AM steers (related also with the overall fatness; Osoro *et al*. 2001) probably reflecting the greater contribution of polar lipids located in membranes (phospholipids) and characterised with a high PUFA content in comparison to neutral lipids, storage lipid fraction (triacylglycerides) that are mainly composed of SFAs and MUFAs (Eichhorn *et al*., 1985; Choi *et al*., 2000; Lorenz *et al*., 2003).

Castration effect on total FA composition was low in AV breed, it significantly affected only to 22% of individual FAs where all of them were unsaturated FAs and appeared in higher quantities in steers than in bulls. This could be because of hormonal differences on enzyme activities (elongation & desaturation) (Malau-Aduli *et al*., 1998). However, castration effect was more remarkably for AM breed where significant differences were given for 70% of the individual FAs studied. AM steers showed in general higher quantities in comparison to AM bulls, particularly for saturated, branched and monounsaturated FAs, resulting significantly different also SFA and MUFA groups. But, it has to be pointed out that some FAs ($C_{18:2}$ *n-6*, $C_{20:2}$ *n-6* and $C_{18:3}$ *n-3*) appeared in higher quantities in bulls than in steers. These differences could be explained also with the lower fat quantity of bulls in comparison to steers and the greater contribution of phospholipids (PUFA) in comparison to triacylglycerides (MUFA & SFA) in this animals. In AM steers, they have higher IM fat proportions, individual FA variations may be more related to this fat content instead of to hormonal differences and enzyme activities caused by castration as might have happened in AV steers.
Studying FA ratios, there was not castration effect in *n-6/n-3* ratio for any breed. However, castration effect was observed in P/S ratio for AM breed, where bulls showed (0.48) a higher P/S ratio than steers (0.22).

Conclusions
Data from this preliminary study indicated that breed effect on intramuscular fat quality was more pronounced in steers than in bulls, what meant that breed effect was significant only when comparing animals with high IM fat level. Castration effect was more remarkable in AM breed than in AV breed. In general, AV steers produced the most nutritionally recommendable meat because of the good *n-6/n-3* and P/S ratios presented, and AM bulls produced a healthy meat from the P/S point of view.

LARGE WHITE AND DUROC HEAVYWEIGHT CROSSBRED PIGS: INTERACTIVE EFFECTS OF GENETIC TYPE, REARING AND SLAUGHTER CONDITIONS ON STRESS REACTIVITY AND TECHNOLOGICAL AND SENSORY MEAT QUALITY ASPECTS

Thierry Astruc, Alban Berne, Gabriel Monin, Martine Morzel, Véronique Santé-Lhoutellier, Pierre Vernin and Claudia Terlouw

Meat Research Unit, INRA de Theix, 63122 St-Genès-Champanelle, France

Background

There is an increasing demand for alternatively produced pork. Outdoors produced pork has a good image. However, the effect of rearing environment on technological meat quality varies across studies. To our knowledge, no study reports an improvement in meat quality from outdoor pigs. Use of other genetic types of pigs might improve gustatory acceptability of outdoor produced pork. Increased slaughter weight may increase the effects of rearing environment. As stress at slaughter may reduce or cancel potentially improved pork quality, it is necessary to determine effects of genetic background and rearing environment on reactivity to potentially stressful situations, including slaughter.

Objectives

To study 1) interactive effects of genetic background and rearing environment on stress reactivity and 2) interactive effects of genetic background, rearing environment and slaughter conditions on technological and sensory quality of pork slaughtered at 150 kg live weight.

Materials and methods

Twenty-five Large White (LW) and 52 Duroc (D) crossbreds (barrows and females) were reared indoors (slatted floor, 6.3 m^2) or outdoors (850 m^2 fields with huts) over two consecutive years (April-October), in an unequally balanced design. To study cardiac reactivity, each individual has been subjected to a 5 h isolation test at about 70 kg. In order to obtain similar pre-slaughter and carcass weights, in contrast to outdoor pigs, indoor pigs have been slightly food restricted. At 150 kg, half of the pigs were mixed for 1.5 h and transported for 30 min to the abattoir on the day before slaughter. The other half was unmixed, and slaughtered immediately upon arrival. All pigs had been food deprived for 22 h before slaughter. After bleeding, temperature (15 and 45 min and 24 h), glycogen and lactate content and pH (45 min, 24 h), colour (days 1, 4, 8) and drip (days 3 and 5) were measured on the Longissimus lumborum (LL), the Semispinalis capitis (SC) and the Semimembranosus (SM). Glycolytic potential ([lactate]+2x[glycogen]; GP) was calculated for samples obtained 45 minutes post-bleeding as it reflects muscle glycogen content at the moment of slaughter (Monin and Sellier, 1985). Sensory analysis was performed on half of the loins and on a quarter of the hams, after dry curing, by 12 and 8 trained pannellists, respectively. Data were analysed with analysis of (co-)variance and with pooled Pearson correlations which take into account the means of each treatment group, rather than the overall means. Only main significant effects are reported.

Results and discussion

All pigs showed a similar initial heart rate acceleration following start of isolation, but outdoor pigs showed subsequently a faster decrease ($p<0.01$). Thus, rearing environment influenced cardiac reactivity.

Compared to the no mixing/no lairage group, pigs of the mixing/lairage group had generally lower glycogen levels for the three muscles (Table 1). Compared to indoor pigs, outdoor pigs had generally higher glycogen content for the three muscles. GP of the SM and SC of outdoors pigs was also higher. Effects on glycogen content were partly due to a rearing and slaughter conditions interaction as indoor reared pigs of the mixing/lairage group had lower glycogen content (LL: 24 h, Table 3; SC: 45 min, $p<0.05$ and SM: 45 min, $p=0.06$) than the other three groups. Ultimate pH of the LL and SC reflected main differences in glycogen (Table 2). Lactate content at 24 h was negatively correlated with ultimate pH for the SM ($r=-0.30$; $p<0.01$) and LL ($r=-0.45$; $p<0.0001$) muscles. A slaughter treatment effect was found for lactate content (24

h) of the LL (Table 1). Absence of differences in lactate content (24 h) in the SC despite variations in ultimate pH may be explained by the overall lower lactate production in this muscle, due to its lower glycogen content (Bendall, 1973). Despite their effects on pre-slaughter glycogen content, genetic and rearing background did not influence pH values of the SM. Correlations between pre-slaughter glycogen (glycolytic potential, 45 min) and ultimate pH were stronger for the LL (Pearson, pooled over two years and over LW and D: ($r=-0.42$; $p=0.0001$) and SC ($r=-0.53$; $p<0.00001$) than for the SM ($r=-0.30$; $p<0.01$) suggesting that compared to the SC and LL, ultimate pH of the SM was more strongly influenced by other factors.

The effect of gender depended on genetic type and rearing conditions: female LW had a higher LL glycogen content (Table 3) while outdoor reared barrows had a higher SM glycogen content (24 h; 16.3 ± 1.6 µmol/g) than indoor reared barrows (7.9 ± 1.3 µmol/g; $p<0.01$).

The effect of year depended on the parameter and muscle: for example, the first year, higher levels were obtained for GP of the LL ($p<0.001$), while the SC had lower glycogen content (45 min, 24 h; $p<0.0001$) and GP ($p<0.05$). Ultimate pH did not vary between years, but the first year, at 45 min pH of the LL was higher ($p<0.01$) and of the SM was lower ($p<0.05$). Colour was strongly influenced by slaughter, and to a lesser extent by rearing conditions. LL and SM meat produced by the mixing/lairage group showed overall lower b* and L* values (p varying between 0.06 and 0.0001). Lower a* and b* values ($p<0.05$) of this group of the SC muscle were partly due to the LW of the lairage/mixing group that had significantly lower a* (day 4; $p<0.02$) and b* values (days 4 and 8; $p<0.01$) than the other three groups. Outdoor reared pigs produced meat with higher a* (SM, LL; $p<0.01$) and b* values (LL; $p<0.01$).

In contrast to objective colour data, dry-cured hams of the mixing/lairage group were perceived as redder and in addition, with a higher overall intensity of taste (Table 4). Their loins were also perceived as pinker ($p<0.08$), with a higher colour intensity ($p<0.07$). Dry-cured hams from outdoor produced and D pigs had higher marbling scores and were perceived as fattier. Their hams were overall better appreciated: easier to chew, more tender, less dry although pastier. D hams were found less smoky, while outdoor reared pigs gave softer meat, with more piquant and a longer persistence of taste. Loins from D were also more marbled ($p<0.001$) and had less intense colour ($p<0.05$), pig odour ($p<0.05$) and abnormal taste ($p<0.05$). Outdoor produced pigs gave loins with a stronger grilled aspect ($p<0.03$) which was probably due to an increased Maillard reaction due to their lower humid aspect ($p<0.06$; Bejerholm and Aaslyng, 2003) as these two aspects were negatively correlated ($p<0.02$). Loins from barrows were described as more marbled ($p<0.01$) and with more intramuscular fat ($p<0.001$). Their hams were more also marbled ($p<0.05$) and had a thicker fat layer than females ($p<0.01$), were drier ($p<0.05$) and had a saltier taste ($p<0.05$). Interactions between gender and crossbreed showed that hams from female D had less rancid and spicy odour, and less acid, piquant and spicy taste than the other three groups ($p<0.05$). D barrows produced hams with a peppery taste ($p<0.05$).

Technological and sensory meat quality aspects were not correlated with cardiac stress reactivity measured during rearing, suggesting that rearing or genetic effects are not explained by differences in cardiac reactivity to the slaughter procedure.

Conclusions

Overall, data show that in heavy pigs, meat from an outdoor production or a Duroc genetic background is better appreciated, especially dry-cured ham. Present data show no synergism between outdoor production and Duroc genetic background. The increased appreciation may be related to increased fat content of outdoor or Duroc types of pigs which would also support the advantage of using heavier pigs for high quality dry-cured ham production. However, although fatter than females, castrated males of the Duroc cross were slightly less appreciated, probably due to hormonal differences. Despite large effects of year of experimentation, reported effects of outdoor rearing, genetic type and slaughter conditions were consistent.

MORPHOMETRIC CHARACTERISTICS OF PIG CARCASSES: EFFECTS OF GENETIC AND REARING BACKGROUND AND CONSEQUENCES FOR POST-MORTEM METABOLISM

Thierry Astruc, Elisabeth Laville, Thierry Sayd and Claudia Terlouw
Meat Research Unit, INRA de Theix, 63122 St-Genès-Champanelle, France

Background

Pig selection companies aim to improve simultaneously carcass morphology, especially muscularity, defined as muscle thickness relative to skeleton dimensions (Purchas, 1991), and meat leanness. It is likely that post-mortem metabolism and muscle morphology are related. Post-mortem metabolism is strongly influenced by metabolism during the pre-slaughter period (Lawrie, 1966). During this period, muscle morphology, which influences the way muscles are used, probably affects post-mortem metabolism and consequently technological meat qualities. Improvement of muscularity may influence post-mortem metabolism in relation to changes in contractile and metabolic fibre type (Klont et al. 1998, Laville et al., 2002). As alternative pork production (outdoor production, different genetic types) gains an increasingly important place on the market, it is further relevant to evaluate effects of rearing environment and genetic background on carcass composition and meat quality. This study is part of a larger study (see Astruc et al, 2004, for more details).

Objectives

To study 1) effects of rearing environment and genetic background on carcass morphology and on technological meat quality and 2) possible relationships between shape and size of body parts and post-mortem metabolism.

Materials and methods

Twenty-five Large White (LW) and 52 Duroc (D) crosses (pure bred LW and D sires, LW x French Landrace dams) were reared indoors (slatted floor, 6.3 m^2) or in fields (850 m^2) with huts over two consecutive years (April-October), in an unequally balanced design. Pigs were slaughtered at 150 kg body weight; half of each treatment group after mixing and overnight lairage, the other half immediately upon arrival at the abattoir. Various morphometric measurements were taken on carcass images (Fig. 1). Glycogen and lactate content, temperature and pH, at 45 min and 24 h after bleeding, were evaluated in the *Longissimus lumborum* (LL) and the *Semimembranosis* (SM). Treatment effects have been assessed with analyses of variance. For the study of correlations, simple and multiple regression analyses have been associated analyses of covariance to correct for treatment effects and with pooled Pearson correlations, which take into account the means of each treatment group, rather than the overall means.

Results and discussion

The second year, summer temperatures were exceptionally high, repeatedly reaching 35 to 40 °C. Carcass weight was not influenced by genetic background or type of housing, but tended to be lower the second year (128.8 ± 2.5 *vs* 123.1 ± 1.5; p=0.08). Carcass weight was positively correlated with leg and body lengths for the both crosses (Table 1). Due to these combined effect, leg and body lengths were lower the second year. LW crosses or indoor reared pigs had longer legs ($p<0.05$) and this was not caused by differences in carcass weight. The D cross had a larger external angle of the ham ($p<0.05$) while outdoor bred pigs had greater thoracic depth ($p<0.00001$). Compared to the first year, the second year, length of the iliac bone and thoracic depth were reduced and pelvis width, and posterior and internal angles of the ham were increased (p between 0.03 and 0.00001), but these variables were unrelated to carcass weight. For the LW cross, body length was negatively and for the D cross, positively correlated with posterior angle of the ham (Table 2). Internal angle of the ham was correlated with iliac bone length, pelvis width and posterior angle of the ham for the D cross (Table 2). Similar tendencies existed for the LW cross, but Pearson correlations, pooled over the two years did not reach significance, possibly to insufficient animal numbers. For example, unpooled Pearson

correlations found a positive correlation between internal and posterior angle of the ham ($r=0.43$; $p<0.05$) for the LW cross.

Thus, data show only a few direct effects of genetic and rearing background on morphometric characteristics. Year of rearing had more pronounced effects on all parameters. Data on the D cross show that shapes and sizes of different body parts are related to each other: pigs with a rounder interior angle of the ham have a rounder posterior angle of the ham and a larger pelvis with a shorter iliac bone. The different fused bones of the pelvis receive attachments from various muscles of the thigh and from the *Psoas major*, allowing posture maintenance and flexing of the thigh upon the pelvis (Barone, 1980). Muscles and bones act together in growth and movement (Barone, 1980) and the observed relationships show that size and length of the pelvis and shape of the ham are connected. More data are needed to determine exact relationships between shape of the pelvis and of ham muscles in the LW cross. The two genetic types showed opposite correlations between body length and posterior angle of the ham indicating that differences between breeds exist also.

Glycogen content was higher in LW than D crosses at both times in both muscles (p between 0.08 and 0.001) and higher in outdoors than indoors reared pigs ($p<0.001$). Lactate content was higher the first year for both sampling times in both muscles ($p<0.01$). For the LL, lactate content (24 h) was lower and ultimate pH was higher in pigs slaughtered after mixing and lairage ($p<0.01$).

For the D cross, SM glycogen content (both times), and lactate content (24 h), were negatively correlated with external angle of the ham (Table 3; Fig. 2). These correlations were probably due to negative correlations between this angle of the ham and pre-slaughter glycogen of the SM muscle: glycolytic potential (GP; [lactate]+2x[glycogen]) at 45 minutes, reflecting muscle glycogen content at the moment of slaughter (Monin and Sellier, 1985), was also negatively correlated with external angle of the ham. GP was further positively correlated with glycogen content of the SM at both times ($p<0.0001$) and lactate content at 24 h ($p<0.0001$). SM lactate content (24 h) was simultaneously, negatively correlated with iliac bone length (Table 3). For the LW cross, the external angle of the ham was negatively correlated with SM lactate content (24 h) and positively with SM and LL temperature (45 min; Table 3). Lactate content of the LL (24 h) was negatively correlated with the iliac bone length and positively with pelvis width for D and LW crosses, respectively (Table 3). Temperature (both times) of the LL was positively correlated with iliac bone length for the D cross (Table 3).

For both genetic types and for both muscles, at 45 min, pH was positively correlated with glycogen content (e.g. D, SM: $r=0.45$; $p<0.01$) and negatively with lactate content (e.g. D, SM: $r=-0.73$; $p<0.001$). Ultimate pH was negatively correlated with GP (e.g. D, SM: $r=-0.31$; $p<0.05$) and with lactate content at 24 h (e.g. D, SM: $r=-0.28$; $p<0.05$). Despite these correlations, initial and ultimate pH's of the 2 muscles were not correlated with morphometric measurements.

Thus, morphometric characteristics are related to post-mortem metabolism, with similarities and differences between the two genetic types. LL post-mortem metabolism was related to pelvis shape and size, differently according to genetic cross. Pigs of both genetic types with rounder posterior angles of the ham had lower SM lactate content. Data on the D cross suggest that lower pre-mortem glycogen levels explain at least part of this effect. Data show further that D crossbreds with a longer iliac bone produce less post-mortem lactate. Lower pre-mortem glycogen content may be simultaneously related to lower resting glycogen levels (i.e. before mixing/transport) and higher energy expenditure of the muscle during the pre-slaughter period. However, generally, the larger a given muscle is, the more glycolytic fibres it contains (Laville et al., 2002), it is therefore expected that pigs with rounder external angles of the ham had higher muscle glycogen content. Shape of the external angle measures predominantly the thickness of the *Biceps femoris* and may be a poor estimate of SM size, more closely related to the posterior angle of the ham. Possibly, pigs with a rounder external angle or longer iliac bone had higher energy expenditure during the pre-slaughter period, indicating that efficiency of certain muscles in terms of energy use depends on shape or other characteristics of surrounding muscle and bone structures.

Conclusions

Shape and size of bones and muscles influence post-mortem metabolism. While data on the D cross show clearly relationships between the shape of pelvis and ham and post-mortem glycogen metabolism, more data on LW crosses are needed to confirm that at least part of these relationships exists in this breed. The observed variations between genetic types and years suggest that other factors (possibly related to pre-slaughter stress reactions) may intervene and modify or cancel some of the relationships between conformation and post-mortem metabolism.

Ackowledgements

The study is part of the EU-project "Sustainability in the production of pork with improved nutritional and eating quality using strategic feeding in out-door production". QLK5-2000-00162. Semen has been supplied by Pig Improvement Company. The authors thank J.F. Chazeix and E. Haye (INRA, Theix), B. Aubard, F. Cinquin et C. Pontet (LEGTA, Roanne), JY. Tixier and J. Thevenet (abattoir Charlieu) for their valuable contributions.

THE EFFECT OF INTRAMUSCULAR WATER FLUID TRANSPORT ON *RIGOR MORTIS*

Balevik, S.B.[1], Botha, S.St.C.[2], Hoffman, L.C.[2] Slinde, E.[1]

[1]Institute of Marine Research, P.O.Box 1870, Nordnes, N-5817 Bergen, Norway, and [2]Department of Animal Sciences, Private Bag X1, Matieland 7602, South Africa.

Background

Rigor mortis is one of the main macroscopic events after death in all animals, and it is of importance to understand how this event affects the quality and quantity of meat. For the meat producer it is important to understand *rigor mortis* in order to optimise slaughter and processing procedures for different meats. Our understanding of the biochemical reactions *post mortem* and how these affect the meat quantity and quality from different animals is limited (Devine *et al.*, 1999, Erikson, 2001).

Development of *rigor mortis* has been studied by several methods such as loss of extensibility (Bendall, 1973, Briskey *et al.*, 1962, Honikel *et al.*, 1983, Schmidt *et al.*, 1968) muscle shortening (Currie and Wolfe, 1979), tension development (Nuss and Wolfe, 1980-81), resistance to strain (Lepetit *et al.*, 1998) and by combination of muscle tension and shortening (Hertzman *et al.*, 1993, Olsson *et al.*, 1994, Rosenvold *et al.*, 2003).

After death, catabolic reactions predominate. ATP concentrations decline, and pH in mammalian meat are lowered to around 5.6 as a result of the formation of lactic acid. ATP is continuously used for muscle relaxation and transport of Ca^{2+} across the sarcoplasmatic membrane. Partially due to the interactions between actin and myosin after death, ATP is lowered to around zero and the actomyosin bridges formed are used to explain *rigor mortis*. These bridges are also used to explain the stiffness that characterizes *rigor mortis*. The actomyosin bridges are judged as irreversible. However, it is also agreed that the stiffness is resolved without any changes in the binding between actin and myosin. Thus, another factor has to be introduced to explain the resolution of *rigor mortis*.

All the catabolic reactions after death increase the number of molecules within the muscle. Glycogen is converted to glucose that is further metabolised to lactate. Proteolysis and lipolysis give amino- and fatty acids and ions are released. Together with other enzymatic reactions the increased number of molecules changes the osmotic pressure ($\pi = cRT$) to a higher value. It has been found that the osmotic pressure increased from an at-death level of 379 to 528 mOsmole in lamb *M. longissimus dorsi,* and one-third of the increase occurred after 24 hours (Veiseth *et al.,* 2003). It was also found that the conductivity changed from 11.3 to 5.7 mS/cm during the 12 first hours.

The volume of muscle cells, however, does not change during *rigor mortis* (Kobayashi *et al.*, 2001). In addition, our morphological study of muscle cells, immediately after death and in the *rigor* state, indicates that the shape of cells changes from a circular to a more squared form, and this is calculated to be statistically significant (Slinde *et al.*, 2003). Since the volume of the whole muscle is the same at slaughter and in *rigor* this means that the intracellular volume has increased, and this space filling create stiffness.

Tenderness of meat is a very important quality parameter, but the tenderisation process is very variable in meat. Different apparatus determines the toughness of meat that characterizes the tenderness mechanically, and the Warner-Bratzler (WB) shear force is often used. Unfortunately, most experimental measurements are generally done after the animal has passed through *rigor mortis*. These texture analyses have in general a rather high standard deviation since it is measured in many individuals, but also due to the difference in muscle fibre types and variation in the amount of connective tissue. We have found that when WB shear forces are measured from slaughter and onwards in Atlantic salmon, the WB shear force decline from the first measurement onwards (Roth *et al.*, 2002, Slinde *et al.*, 2003). Partman (1963) showed that texture analysis of fish and other animals showed such high standard deviations after slaughter that the effect of *rigor mortis* was not detected.

Objectives

It is generally agreed that after death, the main catabolic biochemical reactions and formation of the actomyosin bridges leading to *rigor mortis* are the same in muscle of animals, birds, reptiles and fish (Partman, 1963). The purpose of the present study was to strengthen the evidence that changes in osmolarity and the flow of water into the cells are the main cause of the macroscopic felt stiffness of *rigor mortis* (Roth *et al.*, 2002, Slinde *et al.*, 2003),

Materials and methods

Atlantic salmons (*Salmo salar*) were stunned by a blow to the head, and gill arches were cut. Muscle samples were taken from the region behind the dorsal fin. A blow by a nail through the crocodile's (*Crocodylus niloticus*) head followed by decapitation killed the animal. Crocodiles, approximately 150 cm long, were reared at ambient temperature 18 – 20°C. Right and left tail muscles *M. caudal femoral, M. longissimuis caudalis* and *M. ilioishiocaudalis* were used for measurements.

Shear forces were measured on individual fishes and crocodiles using a Warner-Bratzler blade connected to a texture analyser. *Rigor* index was measured as "tail bending" and calculated as $IR=(L_0-L_t)/L_0 \times 100$ where L represents the vertical drop of the tail when half of the length was outside the table. L_0 represents the vertical drop at start and L_t represents measurement during the experiment (Bito *et al.*, 1983).

Results and discussion

We have selected fish muscle as a model to study development of *rigor mortis,* since the large swimming muscle is very homogenous with regard to fibre- and connective tissue composition. Partman (1963) states that penetration measurements show high average deviations in different fish species and an increase in rigidity in each fish during *rigor* is therefore not seen. There are also great deviations in *rigor* development within a single species. When following *rigor* development in each salmon separately as shown in Figure 1, the variation in both *rigor* index and shear force is clearly different. This is due to the biochemical status of each individual animal at slaughter. But it is very clear that the animal's shear force decreases from slaughter through *rigor mortis* while the measured *rigor* index goes through a maximum. Crocodiles are regarded as more developed than fish and have a fibre- and connective tissue structure that is more complex. Figure 2 shows that the shear force spans a much wider range in individual crocodiles reared at similar conditions when chilled at 20 and 30°C when compared to fish. The changes in shear force from slaughter and onwards decrease slightly but the standard deviations are high. We have therefore concluded that another factor besides the actomyosin binding has to contribute to the stiffness observed in *rigor mortis,* and this has to be a property that is of general nature, and must be found in all animals.

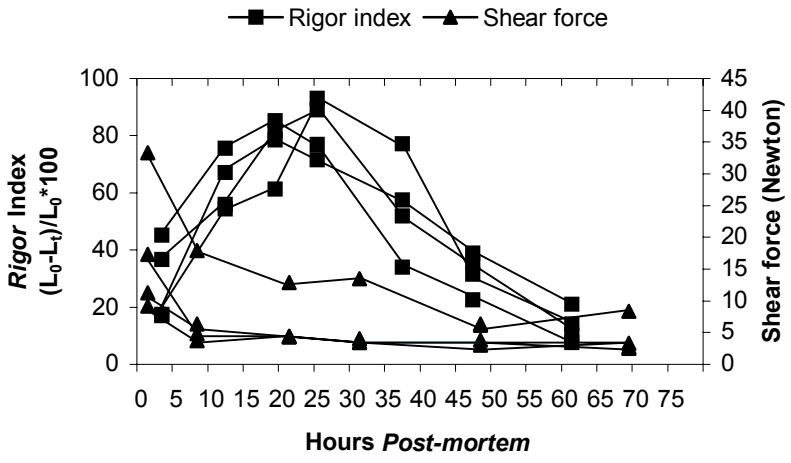

Figure 1. Measurements of Warner-Bratzler (WB) shear force and *rigor* index in four Atlantic salmon (*Salmo salar*).

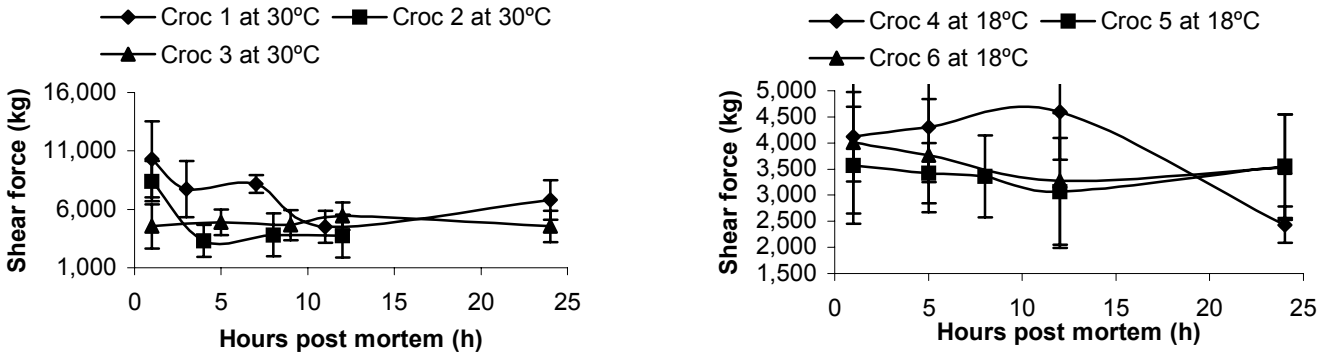

Figure 2. Change in Warner-Bratzler (WB) shear force (kg) in individual crocodile tail muscles during *rigor mortis*.

Catabolic reactions are a general property in all animals after death. Veiseth *et al*. (2004) have performed measurements of osmolar changes. Figure 3 shows the osmolarity within lamb muscle together with the change in pH. We can see that these two properties are mirror images of each other. The rather large change in osmolarity causes water to flow from the extracellular space into the cell. The volume of the cells expands and the cell walls follow the surrounding connective tissue more closely (Slinde *et al*., 2002). In Figure 4, a model of this water transport between intra- and extracellular space within a muscle has been drawn. The increase in cell volume strengthens the structure of the connective tissue and give rise to stiffness. A better understanding of the osmotic behaviour in the muscle after slaughter might increase our understanding of meat texture, as well as its water binding properties. Preliminary studies indicate that the conductivity in cells are low after slaughter, but a sudden raise is observed after some time indicating cellular membrane rupture. The osmotic changes found (Veiseth *et al*., 2004) and shown in Figure 3 may also be studied using NIR (Near Infrared Reflectance), since this method has the property of measuring water in different environments *i.e*. the intra- and extra cellular compartments.

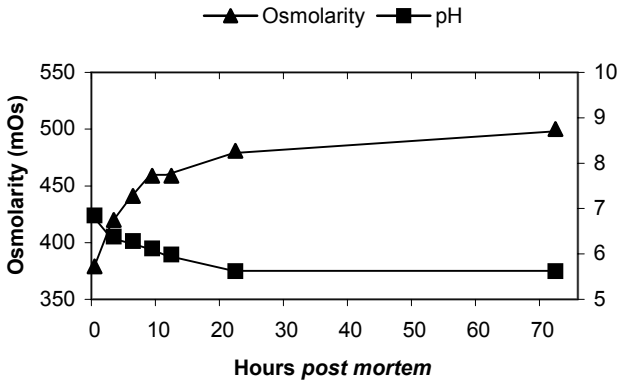

Figure 3. Data from lamb *M. longissimus dorsi* (Veiseth *et al.*, 2004) shows how the osmotic pressure increases after death, Note that the pH is almost a mirror image of the change in osmolarity.

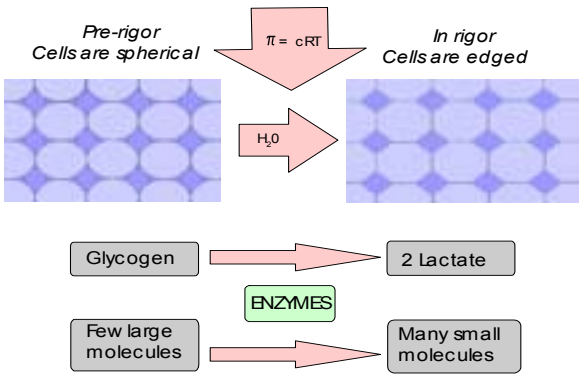

Figure 4. The osmotic change in muscle cells during *rigor mortis*. The enzymatic breakdown increases the number of molecules within the muscle cells. The contour of the cells changes from a spherical to a more edged form due to osmotic influx of water ($\pi = cRT$).

Conclusions

Figure 1 and 2 shows the same tendency, that in individual animals, the water being intra- or extracellular does not affect the WB shear force. The WB shear force is not affected by *rigor mortis* as opposed to the *rigor* index (Figure 1 and 2). The *post mortem* reactions increase the number of molecules within the muscle cells and causes an alternation in the osmotic potential (Veiseth *et al.*, 2004). Since the volume of the muscle is constant (Kobayashi *et al.*, 2001) the increased cell volume makes the muscle stiff. Further investigation of the transport of muscle juice will increase our understanding of *rigor mortis*, the DFD and PSE syndrome as well as the water holding capacity of meat. It will also increase our understanding of tenderisation.

METMYOGLOBIN REDUCING ACTIVITY IN VEAL AND VENISON MEATS

Bekhit, A. E. D ., Cassidy, L., Dobbie, P., Simmons, N. and Daly, C.
Food systems and Technology, MIRINZ Centre, Agresearch Limited, Hamilton, New Zealand

Background

The colour of fresh meat is an important quality attribute which influence the consumers purchase decision. The failure to have an attractive colour will affect the dynamics of meat sales and have financial consequences[1,2]. Meat discolouration is caused by the accumulation of metmyoglobin (MetMb) during aerobic retail display[3]. The existence of enzymatic system/s capable of reducing MetMb has been reported[4]. Such system/s can reduce MetMb to myoglobin (Mb), hence potentially decrease the degree of discolouration and increase shelf life. While there is agreement on the presence of MetMb reducing systems in meat, their role in maintaining fresh meat colour is more controversial. Metmyoglobin reducing activities were measured and characterized in beef[5], pork[6] and lamb[7]. To our knowledge such information is not available for other economically important meats, depending on availability and cultural preference, such as veal and venison. In normal fresh meat when colour stability is not altered through special dietary or processing regimes, different species exhibits different colour stabilities and consequently different shelf lives. Information on MetMb reducing activities in meat from these species could advance our knowledge on the relationship between MetMb reducing activity and fresh meat colour stability.

Objectives

The current study was undertaken to characterize and measure MetMb reducing activity in veal and venison and to compare the activity in these meats with the reported MetMb reducing activities in beef, pork and lamb meats with the aim of investigating whether a meaningful relationship could be found between MetMb reducing activity and the known shelf life of these meats.

Materials and methods

Venison: samples from longissimus dorsi (LD) muscles of two years old stags (n=8) were obtained from carcasses (average weight 55.3 ± 4.1 kg) and vacuum packed for 3 weeks (standard aging time according to the New Zealand game industry board specifications).
Veal: samples were obtained at 48 h post mortem from LD muscles of 75 (± 2) days old male calves (n=6, average live wt 88 ± 5 kg).
Metmyoglobin reducing activity. A sarcoplasmic and particulate metmyoglobin reducing activity (SMRA and PMRA, respectively) were obtained from the samples as described ealier[8]. The supernatant and the particulate extracts were oxidised with a slight excess of $K_3Fe(CN)_6$, dialysed (10000 MW cut-off membrane) against 2.0 mM phosphate buffer (pH 7.0) at 4 ^{0}C several times. Metmyoglobin reductase activity was determined as described[6,7] using $VERSA_{max}$ microplate reader (Molecular Devices, Sunnyvale, CA, USA) after scaling down the assay final volume to 200µl. The standard assay mixture contained 15 µl 5 mM EDTA; 15 µl 50 mM phosphate buffer (pH 7.0); 15 µL 3.0 mM K_4 Fe $(CN)_6$; 50 µl 0.75 mM Mb Fe(III) in 2.0 mM phosphate buffer (pH7.0); 10 µl 2.0 mM NADH; muscle extract (50 µl for SMRA and 10 µL, of 5x dilution of dialysed samples, for MMRA) and water to a final volume of 20 µl assay mixture. The standard assay mixture pH was 6.8 and the assay was carried out at 25 °C. The reaction was initiated by adding NADH and followed by the change in absorbance at 580 nm. Blanks contained all the additions except NADH, which was replaced by water. The activity was calculated as the mean of three replicates and expressed as nanomoles of MetMb reduced per min per gram of meat.

Results and discussion

High propotions (82- 88 %) of the total MetMb reducing activity, were present in the pellet fraction of LD muscles in veal and venison meat (Table 1). SMRA in veal LD muscle was higher than those reported for pork[6,9] and less than that in beef or lamb meats[7,10]. PMRA in veal LD was less than that in beef, but higher than that in lamb LD muscle. Venison on the other hand, had comparable SMRA and PMRA to those reported in beef [10].
The effects of different assay pH and NADH concentrations on MetMb reducing activities in the different fractions of the muscle is presented in Figure 1. The pellet fractions from veal and venison seems to be more

sensitive to changes in pH and NADH which indicate the possibility of different MetMb reducing system/s from that present in the supernatant. Earlier[10], it was suggested that this activity could be activity remained in the pellet fraction due to the hydrophobic segment that binds NADH cytochrome b_5 metmyoglobin reductase to membranes[11], because the current methodology do not employ a detergent to solubilize the enzyme or unsufficient mechanical release of microsomes and mitochondria by homogennization. However, the behaviour of sarcoplasmic and pellet MetMb reducing activities in regard to the effects of assay pH and NADH concentration indicate to a possible different MetMb reducing systems in these two fractions. The capacity of SMRA, beef= venison > lamb > veal > pork, do not correspond with the expected display shelf-life of these meats, beef > veal > lamb > pork > venison. Moreover, given that beef and venison exhibit similar SMRA and PMRA and the shelf-life of beef >> venison, it is unlikely that MetMb reducing activity is contributing to the colour stability of fresh meat during display storage.

Conclusions

MetMb reducing activity is higher in venison than in veal LD muscles. Since the order of the MetMb reducing activity in beef, lamb, veal , pork and venison do not generate a meaninful relationship with their expected shelf-life display, MetMb reducing activity is unlikely to contribute to fresh meat colour stability. However, from a physiological point of view, differences in SMRA and PMRA presented in this study could be of interest.

	-	+	+	+	+	802 ± 43	-	+	+	+	+	1817 ± 81

(+) = presence (-) = absence

-No MetMb reducing activities were found when NADH, muscle extract or equine MetMb was omitted from the assay mixture. The absence of EDTA from the assay mixture decreased MetMb reducing activities in venison extracts but not veal. The absence of $K_4Fe(CN)_6$ from the assay mixture resulted in decreased MetMb reducing activities and the extend of the effect varied between venison and veal. The present results and earlier reports[5-7,10] indicates that MetMb reduction by various species extracts is influenced by the assay components.

PROXIMATE COMPOSITION AND COLLAGEN CONTENT OF BEEF AND PORK MEAT CUTS

DELLA TORRE, Jussara C. M.[1]; BERAQUET, Nelson J.[2]

[1]Adolfo Lutz Institute / São Paulo / Brazil [2]Meat Technology Centre of Institute of Food Technology / Campinas

Background

Both physical and chemical composition parameters and pH of beef- and pork-cuts are highly important for the meat processor, since such parameters are closely connected with the ability of the meats to retain water and fat.

One concern in finely comminuted emulsion-like products such as frankfurter and mortadellas is with levels of collagen free proteins (CFP) and fat. These compounds affect directly emulsion stability and fat and water retention during processing. Meat connective tissue is constituted mainly of collagen that is part of muscle and adipose tissue. Collagen is characterized by a high content of glycine, proline and hydroxyproline and total lack of sulfur containing aminoacids and tryptophane.

Meats with high collagen content or containing tough collagen are used in sausage processing, where collagen is comminuted by the action of grinders, cutters or mills (Bailey and Ligth, 1980; Olivo and Shimokomaki, 2002). The addition of cooked pigskin to sausages also increases its collagen content. Sausage manufacturers use meat with high collagen content although they are aware that its amount in the sausages should be limited to prevent defects like gelatin release, difficulty in peeling, shrinkage, and poor texture (Rao and Henrickson, 1983; Kenney et al., 1992; Olivo and Shimokomaki, 2002). It is clear that the determination of collagen content and proximate composition in meats is essential to predict sausage and other meat processed products quality and for the use of least cost formulation formulae. In Brazil there is a lack of available information on the proximate composition of the main beef and pork cuts used to produce sausages. This knowledge would help industry to better formulate meat products and help inspection services to enforce legislation concerning meat products composition.

Objectives

The purpose of this work was to determine moisture, fat, total protein, collagen content, and pH of meat cuts of hybrid pork and bovine (Nelore) used in the processing of sausage and other meat products.

Materials and methods

Three castrated Nelore (Bos indicus) 30 to 36 months of age, pasture fed, with an average weight of 437,5 kg (±16,2) were slaughtered in intervals of 15 days. The half-carcasses were chilled at 0 ± 4°C for 24 hours. The half carcasses were split into forequarters and hindquarters between the 5th and the 6th ribs. The forequarter beef meat cuts chuck, shoulder, brisket, neck, inside skirt (diaphragm), thick skirt, neck trimmings, foreshank, and plate were analyzed.

Three hybrid male pigs cross from Large White x Pietrain males with Large White x Landrace females and with a live weight of approximately 125-130Kg were slaughtered on the same day. After chilling in storage room kept at 0 ± 4°C for 24 hours, the half carcasses were cut into picnic shoulder, fresh ham, loin, tender loin, shoulder butt, belly, spareribs, neck trimmings and skin. The whole cuts of beef were ground three times in a Hermann grinder with 5mm holes plates. The pork cuts were ground two times in the same grinder with holes plates of 3mm. The cuts were not dressed, to simulate industry procedures. Physico-chemical analysis: moisture (oven at 102-105°C), total protein (Kjeldahl, Nx6,25), fat (diethyl ether extractable) and ash contents were determined following Instituto Adolfo Lutz procedures (São Paulo, 1985). pH values were measured with a spear-tip electrode attached to a digital pH-meter (HANNA Instruments – HI9321 microprocessor). The hydroxyproline assay was carried out according to the method described by AOAC (1996). Hydroxyproline was quantitatively determined, in order to measure the collagen content. Samples were hydrolyzed with 6N HCl for 8h at 110°C. After hydrolysis, 4-hydroxyproline was converted to pyrrole with chloramine T in acetate-citrate buffer pH 6.0, and pyrrole was converted to a red-coloured complex (absorption at 558nm) by reaction with Ehrlich reagent [p-(dimethylamino) benzaldehyde in perchloric

acid/2-propanol]. Total collagen protein was determined by multiplying hydroxyproline contents by 8. The physico-chemical analyses were carried out in duplicate for each pork and beef cut, the average being calculated from the three animals. Statistical analysis: all data underwent analysis of variance and Tukey's Test to determine differences ($p<0.05$) between pairs of means, using GraphPad InStat tm, Copyright 1990-1993, V2.01.

Results and discussion

The weights of the hot half carcasses of the three bovines were 124.6, 130.6, and 135.4 Kg. The weights of the chilled forequarters were respectively 41.1, 46.5, and 51.6 Kg. On Table 1 are shown the means for the proximate composition parameters, hydroxyproline, collagen and relative collagen and pH. Significant differences ($p<0,05$) were observed for all parameters among the different meat cuts except for ash content, which was not significantly different between the different meat cuts. For the three forequarter beef meat cuts of the categories chuck, shoulder, brisket, neck, inside skirt (diaphragm), thick skirt, neck trimmings, foreshank and plate, ranges of percent moisture were 66.5 (plate) to 75.4% (neck); fat, 4.0 (neck) to 15.9% (plate); total protein, 16.4 (plate) to 19.9% (foreshank); ash, 0.8 (plate) to 1.0% (diaphragm); hydroxyproline, 0.19 (diaphragm) to 0.61% (foreshank); collagen (COL) from 1.5 to 4.9%; relative collagen from 8.4 (diaphragm) to 24.77% (foreshank); pH varied from 5.73 (brisket) to 6.00 (plate). Largest variation in composition was found for the brisket, which presented the largest coefficient of variation for most of parameters evaluated. The diaphragm meat was the one with the smallest coefficient of variation for most of the products evaluated.

The swines' hot half carcasses weighted 43.4, 46.2, and 49.0 Kg. The proximate composition, hydroxyproline content, collagen content, relative collagen content, and pH are presented on Table 2. There were significant differences among different cuts for all parameters studied. In the evaluations of pork cuts from picnic shoulder, fresh ham, loin, tender loin, shoulder butt, belly, spareribs, neck trimmings and skin, large variation was found for moisture 20.6 (neck trimmings) to 73.2% (tender loin), fat 5.2 (tender loin) to 75.6% (neck trimmings), total protein 5,4 (neck trimmings) to 20,8% (tender loin), ash 0.3 (neck trimmings) to 1.2%(tenderloin), hydroxyproline 0.08 (tenderloin) to 1.28% (skin), collagen (COL) from 0.6 to 10,2%, relative COL 3.0 (tender loin) to 66.1%(skin), and pH 5.79 (belly) to 6.24 (shoulder butt). The largest variances between the animals in the determinations were those for neck trimmings, while the smallest were those for picnic shoulder and loin. It is important to underline that the variations observed reflect variations between samples from the animals and not analytical. The pork-cuts (except the skin) presented the greatest content of fat and the lowest of water, hydroxyproline and COL, if compared with those of beef-cuts meat.

Conclusions

As expected, the moisture, fat, protein, and collagen content and pH of the different meat cuts from pigs and bovines forequarters showed a large variability. The pig cuts comparable to those of beef had lower moisture and hydroxyproline (collagen) content and higher fat content. It is believed that the meats composition mean values determined in this study can be used in formulating meat products to comply with pertinent Brazilian legislation.

TECHNOLOGICAL QUALITY OF BROILER BREAST MEAT IN RELATION TO MUSCLE HYPERTROPHY

[1]Berri, C., [1]Debut, M., [1]Le Bihan-Duval, E., [2]Santé-Lhoutellier, V., [1]Haj Hattab, N., [3]Jehl, N. and [1]Duclos, M.J.

Background

In broiler, recent studies reported a great variability of the muscle *post mortem* metabolism with both the animal genetic background and the pre-slaughter stresses. Indeed, selection for rapid growth and/or muscle development can produce breast meat with slower pH decline, higher ultimate pH and consequently lower drip loss (Le Bihan-Duval et al., 1999; Berri et al., 2001) and therefore affect processing quality of meat. While some of pre-slaughter conditions which affect *post mortem* pH fall are well identified (Debut et al., 2003), the muscle characteristics responsible of the pH fall variations remains uncertain. In broiler, there is no evidence of changes in breast fibre typing with selection for growth (Rémignon et al., 1995). By contrast, fibre radial and longitudinal growth significantly increased with selection for breast yield (Guernec et al., 2003) but, as far as we know, the impact of such structural changes on further broiler breast meat quality has never been evaluated.

Objectives

The purpose of this study was to relate breast muscle development, including muscle fibre size, to *post mortem* metabolism and further breast meat quality. Phenotypic and genetic relationships between fibre and meat traits were estimated for a total of 600 commercial broilers. For all birds, we measured muscle fibre cross-sectional area, glycolytic potential, lactate content, *post mortem* pH fall and classical meat traits (colour, drip and thawing-cooking loss, Warner-Bratzler shear force). We also determined the proportion of connective tissue and the occurrence of giant fibres in relation to muscle fibre size or *post mortem* metabolism.

Materials and methods

Animals and muscle sampling

A total of 600 broilers (males and females), originating from a commercial grand-parental male line (Hubbard Europe, Chateaubourg, France), were reared under similar conditions in a conventional poultry house at the INRA Avian Research Centre (Nouzilly, France). Birds were reared in 2 successive batches of 300 birds. Feed and water were provided *ad libitum* throughout the growth period. After a 8-h feed withdrawal, six week-old broilers were weighed then slaughtered in the experimental processing plant of the Avian Research Centre. Broilers were electrically stunned in a water bath (60 mA; 125 Hz; 5 s) before bleeding by ventral neck cutting. After scalding (51°C; 3 min), plucking and manual gut removal, whole carcasses were air chilled in a cold room at 2°C for 24 h.

Fifteen minutes after slaughter, two samples of the right *Pectoralis major* (PM) were collected. One sample was rapidly frozen in isopentane cooled with liquid nitrogen and stored at -80°C until histology assays. The other was mixed in 0.55M perchloric acid (1 g / 10 mL) then stored at -20°C until metabolite measurements.

Pectoralis major muscle trait analyses

Lactate, free glucose, glucose from glycogen and glucose-6-phosphate were measured according to Dalrymphe and Hamm (1973). The glycolytic potential was calculated using the equation of Monin and Sellier (1985): glycolytic potential = 2 x [glycogen + glucose-6-phosphate + free glucose] + lactate. The mean cross

sectional area (CSA) of muscle fibres was determined as described by Rémignon et al. (1995) on 12 µm thick-cross sections stained with red azorubin. For 40 birds diverging for fibre CSA, the proportion of connective tissue was quantified by image analysis using the Visilog software (Noesis, France). For 54 animals diverging for fibre CSA and/or pH at 15 min *post mortem*, the occurrence of giant fibres was determined by using a micrometric ocular that comprises 25 intersection points. For each sample, we classified a total of 1000 intersection points in either 'normal fibre', 'giant fibre' or 'connective tissue' to assess the ratio giant fibres/normal fibres.

Meat trait measurements

Fifteen minutes after slaughter, pH of the right PM muscle (pH15) was recorded according to the 'iodoacetate reference method' described by Santé and Fernandez (2000). At this time, the muscle temperature was also checked. Twenty four hours *post mortem*, carcasses were dissected and measured for breast (*pectoralis major and minor*) weight and yield (calculated in relation to body weight). At this time, the PM muscle ultimate pH (pHu) and colour parameters (L*, a*, b*) were measured according to Berri et al. (2001). The upper half part of the PM muscle was hanged in plastic bag to determine drip loss during a 2 day-storage at 2°C (Debut et al., 2003). At 3 day post-mortem, the PM muscle was vacuum packaged, rapidly frozen in ethanol then stored at -20°C until thawing and cooking treatments. Thawing-cooking loss (One night at 4°C and 15 min at 85°C) was determined as: (muscle weight after cooking/muscle weight before freezing) x 100. The Warner-Bratzler maximal shear force (N/cm^2) was measured on cooked muscle samples (1 x 1 x 3 cm). Samples were sheared perpendicular to the longitudinal orientation of fibres using an Instron Universal Testing Machine with a triangular blade (height = 5.2 cm, width = 6.1 cm, thickness = 0.11 cm; speed = 80 mm/min).

Statistics

To assess the relationship between muscle fibre CSA and the other traits, phenotypic correlations were analysed with the CORR procedure of SAS (SAS Institute, 1989). Muscles were also classified in 5 classes of equal numbers according to their mean fibre CSA (RANK procedure of SAS) and a one-way analysis of variance was performed to test the effect of fibre CSA classes on other muscle traits (GLM procedure of SAS). Then, means were compared using a Newman-Keuls test for multiple mean comparisons. A multiple regression test was performed to assess the relative involvement of fibre CSA or muscle pH on the water retention and textural properties of breast meat. Finally, the genetic correlations between fibre CSA and other muscle traits were estimated by the REML (Restricted Maximum Likehood) methodology using the VCE software (Neumaier and Groeneveld, 1998) on a total of 600 birds born of 15 males and 64 females.

Results and discussion

Relationship between the fibre CSA and other muscle traits

The fibre cross sectional area (CSA) was highly phenotypically related to body weight (+0.51) and breast muscle weight (+0.65) and yield (+0.51). The increase in fibre CSA did not affect the proportion of connective tissue (about 21% of the muscle cross section surface) and did not induce fibre necrosis as it has been previously reported in turkey (Sosnicki et al., 1998). According to both the phenotypic and genetic correlations (table 1), as the fibre CSA increased the glycogen reserve of muscle before death (glycolytic potential) decreased. As a consequence, PM muscles with the largest fibres exhibited the highest ultimate pH. Besides, they contained the lowest lactate at 15 minutes *post mortem* and thus exhibited the highest pH15. As a consequence of their *post mortem* metabolism, PM muscles with the largest fibres exhibited the lowest L*, drip and thawing-cooking losses and were more tender after cooking. According to the multiple regression test (table 2), the drip loss and L* of meat appeared chiefly determined by the pHu and at a lower extent by the pH15 of muscle. By contrast, the properties of cooked meat (thawing-cooking loss and shear force) were also partly determined by the fibre CSA and therefore the muscle weight. The analysis of variance by class of fibre CSA confirmed that breast meat traits were greatly affected by muscle hypertrophy (table 3). Indeed, the drip and thawing-cooking losses as well as the maximal shear force of cooked meat were respectively 30% and 16% lower for breast from the highest fibre CSA class (average fibre CSA of 2447 μm^2) than for breast from the lowest fibre CSA class (average fibre CSA of 1257 μm^2).

Occurrence of giant fibres in relation to muscle fibre CSA and rate of pH fall

According to our observations, the occurrence of giant fibres in breast muscle was chiefly determined by the rate of pH fall (Table 4). Whatever the muscle weight and fibre diameter, the occurrence of giant fibres greatly increased when muscle pH15 was below 6.30. However, in muscles with pH15 above 6.30, the proportion of muscles in which giant fibre occurred was dependant of the fibre size. It was greater in muscles exhibiting large fibre CSA than in muscles exhibiting small fibre CSA. Therefore, the occurrence of giant fibres would be more sensitive to pH fall rate in muscles with large fibres than in muscle with small fibres.

Conclusions

According to the present study, the fibre diameter is closely phenotypically and genetically related to the overall and muscle growth of broilers, the increase in breast muscle weight resulting essentially from fibre hypertrophy. We reported that muscle hypertrophy did not alter overall breast muscle structure but induced a significant decrease in muscle glycogen reserve before death and lowered the rate of muscle pH fall *post mortem*. These changes resulted in breast meat with higher pH15 and pHu, and consequently a better water holding ability and a greater tenderness after cooking. In conclusion, this study did not evidence any genetic antagonism between growth rate or muscle development and breast meat quality and suggested that meat of current broiler genotypes selected for growth and breast yield are well adapted to further processing.

SEMIQUANTITATIVE DETERMINATION OF GOAT TISSUE IN MEAT PRODUCTS BY MEANS OF PCR

Binke, R., Altmann, K., Honikel, K.O., Schwägele, F.
Federal Research Centre for Nutrition and Food (Kulmbach),
E.-C.-Baumann-Straße 20, 95326 Kulmbach, Germany

Background

The "Quantitative Ingredient Declaration" (QUID) for important components in food products was put into force as EU-regulation. Therefore for meat products reliable methods for species identification and quantification gained importance. In a previous paper a species-specific primer system BC290501 for the identification of goat in meat products was presented (Altmann et al., 2004). Both primers bind in the 5´-flanking promotor region of the nuclear single-copy gene *beta-casein.* Twelve different species were tested, but only goat-DNA leads to amplification of a specific product by means of PCR.

At the moment PCR systems for quantification of animal tissue in food or feed are only available for the commercially most important species cattle and pig (Wolf and Lüthy 2001; Calvo et al., 2002; Palisch et al., 2003; Frezza et al., 2003) but not for minor relevant species like goat and sheep.

Objectives

In this paper we report about a PCR assay using two different detection systems based on the primer system BC29051 for semiquantitative determination of goat meat in meat products.

Methods

DNA-extraction was carried out applying the CTAB method optimised for meat and meat products (Binke et al., 2003). Emulsified type sausages with varying goat meat content (Tab. 1) filled into cans with a volume of 50 ml were heated under different temperature regimes: home made cans "KK" (20 min/82 °C; $F_C < 0.9$), "normal" cans "VK" (33 min/116 °C; $F_C = 3.4$), up to cans for use under extreme conditions "TK" (60 min/116 °C; $F_C = 12.3$).

Tab. 1: Composition of emulsified type sausages

Reference product	Ingredients	Goatmeat / muscle meat [%]
Sausage 1	50 % goat meat; 25 % oil; 23 % ice; 1.5 % salt; 0.25 % spices; 0.25 % additives (phosphate; ascorbate)	100
Sausage 2	50 % goat meat; 25 % fat (pork); 23 % ice; 1.5 % salt; 0.25% spices; 0.25% additives (phosphate; ascorbate)	100
Sausage 3	25 % goat meat; 25 % pork meat; 25 % fat (pork); 23 % ice; 1.5 % salt; 0.25 % spices; 0.25 % additives (phosphate; ascorbate)	50
Sausage 4	10 % goat meat; 40 % pork meat; 25 % fat (pork); 23 % ice; 1.5 % salt; 0.25 % spices; 0.25 % additives (phosphate; ascorbate)	20
Sausage 5	1 % goat meat; 49 % pork; 25 % fat (pork); 23 % ice; 1.5 % salt; 0.25 % spices; 0.2 5% additives (phosphate; ascorbate)	2.0

The goat specific primers BC290501 F (5´ TCTGGTCCAATTGGTGAGAG 3´) and BC290501 R (5´ AGGCCACAGGTGAAAAAGTC 3´) were commercially synthesized by Qiagen (Hilden, Germany). The amplification products were detected by means of a dual labeled probe BC290501 P (FAM-5´AGGGAAATGTTGAATGGGAAGGATATGC 3´-Tamra) as well as by the intercalating dye SYBR-

Green 1. A 97 bp animal specific DNA fragment based on the myostatin gene, designed by Laube et al., (2002) and a dual labeled probe were used as a reference system for relative quantification.
The amplification of the DNA fragments was performed by Real-Time PCR in a Rotor Gene 2000 with vials containing a final volume of 20 µl: 1x reaction-buffer (Qiagen), 4.5 mM magnesium chloride, 0.05 mM of each dNTP, 0.8 µM of each primer, 0.4 µM dual labeled probe (Qiagen) or 1 µL SYBR-Green 1 diluted 3000 fold, 1.25 unit of HotStarTaq™ DNA-polymerase (Qiagen) and 5 µl DNA solution diluted 40 fold.
The applied PCR-program was the following (40-45 cycles): Initial DNA-denaturation at 95 °C for 15 min; 95 °C for 30 s, 58 °C for 30 s, 65 °C for 30 s for the probe detection system and 72°C for 30 s for SYBR-Green 1 system.
The determination of relative amounts of goat meat per total meat in meat products was calculated according to the equation based on the delta-delta C_T method modified by Pfaffl (2001). Sausage 4 containing 20 % goat meat with a F_C- value at < 0.9 was used as calibrator (tab. 1).

Results and Discussion

For relative quantification it is necessary to have a reference gene which has a constant efficiency for each commercially relevant animal species. DNA from muscle tissue of 12 animal species (Fig. 1) was extracted and diluted under the same conditions.
Figure 1 shows that the most aminal species like goat, pig, cattle have a comparable course of amplification using the myostatin gene. For these animal species the 97 bp fragment of the myostatin gene is suitable as reference gene. In contrast to this the course of amplification in the case of duck, ostrich and kangaroo is different.

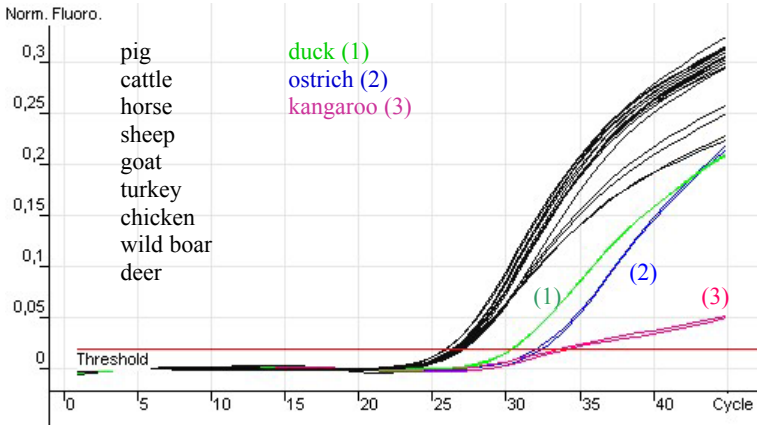

Fig. 1: Course of amplification of the 97 bp myostatin gene fragment of 12 commercially relevant animal muscle tissues

The reaction efficiency is the second critical point for quantification. The efficiency of amplification was calculated for the myostatin and beta-casein systems by means of standard curves (Fig. 2 and 3). A standardized DNA solution (10 µg/ml) obtained from goat meat was 4-fold diluted (2.50, 0.63, 0.16, 0.04 and 0.01 µg/ml). Amplification with a reaction efficiency of 2 means a doubling of amplification product for each cycle resulting in a standard curve graph slope of -3.322. Figure 2 and 3 show a comparable optimum reaction efficiency over 3 magnitudes for the 97 bp myostatin reference gene fragment and the 161 bp goat specific beta-casein gene fragment. A significant difference of efficiency in comparison of the probe and SYBR-Green 1 - systems was not detectable.

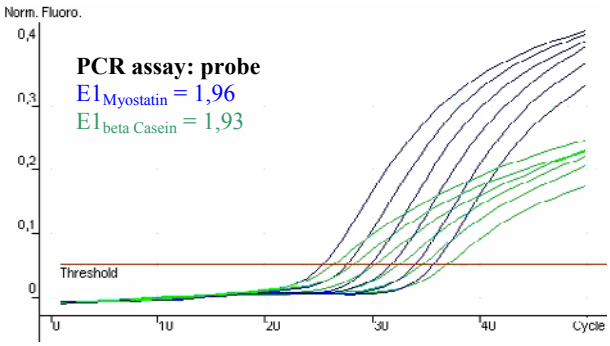

Fig. 2: Determination of reaction efficiencies for the probe assay

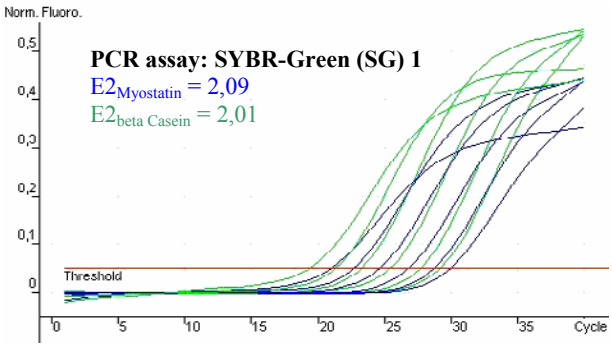

Fig. 3: Determination of reaction efficiencies for SYBR-Green 1 assay

The obtained reaction efficiencies for both assays were applied to determine the content of goat meat in reference products (Tab. 2 and 3). The data show that the probe assay represents a better comparability of the real and calculated content of goat meat than the SYBR-Green 1 assay with a mean coefficient of variation (CV) of 20 %.

Furthermore sausage 2 containing 25 % pork fat shows a lower goat meat content than sausage 1 prepared without pork fat (tab. 1 and 2). Fat tissue contains also DNA like other animal tissues and leads to an increase of total DNA copy number. For this reason the relative content of goat meat is decreasing in comparison to the total meat content. This effect is especially important for the quantification of animal species in liver sausages as liver shows an extremely high DNA content, which is at least tenfold higher than in muscle tissue. In contrast to this the DNA content of fatty tissue is approximately only a quarter in comparison to muscle meat.

With respect to this fact applying this assay a semiquantitative determination of goat meat in meat products is possible for sausages treated at low or medium heating conditions (Tab. 2 and 3).

Tab. 2: Contents of goat meat in reference sausages with standard deviations calculated according to the equation of Pfaffl (2001) in the case of the probe assay (N = 4)

Assay probe	theoretical [% goat]	calculated [%] unheated	calculated [%] KK[1]	calculated [%] VK[2]	calculated [%] TK[3]
Sausage 1	100	103 ± 25	95 ± 25	57 ± 12	29 ± 3
Sausage 2	100	85 ± 7	83 ± 10	60 ± 14	27 ± 7
Sausage 3	50	37 ± 10	43 ± 9	28 ± 6	15 ± 2
Sausage 4	20	20 ± 4	24 ± 2	10 ± 1	8 ± 1
Sausage 5	2	2.3 ± 0.2	2.1 ± 0.1	1.1 ± 0.3	0.3 ± 0.2

Tab. 3: Contents of goat meat in reference sausages with standard deviations calculated according to the equation of Pfaffl (2003) in the case of the SYBR-Green (SG) 1 assay (N = 4)

Assay SG 1	theoretical [% goat]	calculated [%] unheated	calculated [%] KK[1]	calculated [%] VK[2]	calculated [%] TK[3]
Sausage 1	100	129 ± 25	161 ± 22	97 ± 23	63 ± 12
Sausage 2	100	112 ± 27	124 ± 21	98 ± 8	48 ± 4
Sausage 3	50	66 ± 7	73 ± 23	50 ± 12	31± 13
Sausage 4	20	19 ± 2	29 ± 4	14 ± 3	10 ± 2
Sausage 5	2	3.5 ± 1.8	2.6 ± 0.2	1.3 ± 0.2	1.5 ± 1.1

[1]KK = home made cans (F_C-value < 0.9 means 20 min at 82 °C), [2]VK = "normal" cans (F_C-value = 3.4 means 33 min at 116 °C), [3]TK = cans treated for use under extreme conditions (F_C-value = 12.3 means 60 min at 116 °C)

Reference samples heated under extreme conditions are resulting in a significantly reduced content for each sausage. Using the probe assay for samples heated at F_C = 3.4 (VK) a content of about 50 % of the added amounts was determined, whereas samples heated at F_C = 12.3 (TK) showed only about 30 % mean goat meat content (tab. 2). The decreasing content of goat meat is caused by an increase of DNA fragmentation (Binke et al., 2003). Applying a modified myostatin gene fragment with a length of 154 bp (Laube et al., 2002) instead of 97 bp a semiquantitative determination of goat meat in meat products heat treated up to a F_C-value of 3.4 (VK) is also possible. However, the latter system is also not able to quantify the animal species turkey and chicken.

Conclusion

The presented PCR assays are suitable for a semiquantitative determination of goat meat in meat products. A quantitative determination with a small error of determination is only possible if there is sufficient knowledge about the quality and purity of the DNA extracted from processed products. Therefore quantification procedures demand suitable reference standards with a comparable composition and procedure. Further critical points are the specific variations caused by the thermocycler and the DNA extraction as well as the DNA polymerase and the applied dye.
In summary: A quantitative analytical determination of meat (here goat) content in processed food for control of the QUID regulation is not yet possible and needs further studies.

PARAMETERS MEAT QUALITY OF BROILERS FROM DIFFERENT REARING SYSTEMS[1]

Snezana Bogosavljevic-Boskovic, Zivorad Gajic, Sreten Mitrovic[2]
Addresses

Background

The share of certain tissues in major basic carcass parts is no doubt an important element determining broiler meat quality *(Karan-Djuric et al., 1977).*
The quality trait mentioned and also carcass quality are affected by a number of factors. Of the biological ones, the greatest effect was exerted by genotype, sex and age *(Preston et al., 1973, Antonijevic et al., 1982, Orr and Hund 1984 etc.).* Among numerous non-genetic factors that may considerably influence meat quality, the rearing systems, or broiler keeping systems have been particularly stressed by some authors over the past years *(Bogosavljevic-Boskovic et al., 1999, Pavlovski et al., 2001, Milosevic et al., 2003)*. The authors also maintained that intensive industrial production in poultry farming results, among other things, in lower product quality, due to which there is an increasing number of advocates of non-industrial broiler rearing system among not only researchers and consumers but also among producers, particularly with the aim of producing better quality meat.

Objectives

The aim of this paper was to analyze the meat quality of the broilers reared in two different non-industrial ways of rearing (extensive rearing in a chicken pen and free-range rearing). The basic tissues shares in major broiler carcass parts serving as quality parameters were examined. The aim of the paper was a comparative analysis of the broiler meat quality trait mentioned in terms of the effect of the non-industrial rearing systems used.

Materials and methods

The initial experimental material consisted of 200 one-day-old chicks of the line hybrid Hybro G. The fattening of the broilers lasted 56 days. In the first four weeks the rearing was conducted within the same construction with the deep floor covering. Then, at 28 days, the experimental chicks were divided into two groups. One group was reared within a closed object, in a chicken pen, at population density of 12 broilers per square metre (under the extensive production conditions in the chicken pen) - according to the European Union regulations on non-industrial poultry meat production, mentioned by *Tolimir and Masic 2000, as well as by Ristic 2003*. The second group was provided with the same useful area within the closed construction, but there were outlets overgrown with grass for these chickens, too. The free-range area size was such to provide each chicken with 1 square metre of the area. The trial chickens were fed two appropriate complete feed mixtures: the initial one (up to 28th day) and the final one (from the 28th to the 49th day of fattening). In the last week of the fattening period, the chicks diet consisted of 70 % ground corn mixture and about 30 % of concentrate mixture.
Following the fattening period, with the aim of examining major meat quality characteristics, 12 broilers were chosen at random from each experimental group. The dressed and cooled carcasses were then dissected into basic parts (breasts, thighs, drumsticks, wings, pelvis and back). After the dissection, for the purpose of determining the yield and share of basic tissues (muscles, bones and skin) in major carcass parts, the breast and right thigh dissections were made.
The research data analysis was made by using the usual variation statistics methods. The testing of the significance of differences was conducted through the following mathematical variation analysis model:

$$Y_{ijk} = \mu + S_i + (SR)_{ij} + e_{ijk}$$

[1] Original scientific paper
[2] dr Snezana Bogosavljevic-Boskovic, assoc.prof., Faculty of Agronomy, Cacak, dr Zivorad Gajic, ful prof., dr Sreten Mitrovic, ful prof., Agricultural Faculty, Belgrade

that is, the model corresponding to the two-factor experimental plan 2x2 (2 sexes -S and 2 systems of rearing -SR).

Results and discussion

Table 1 shows values of slaughter yields and shares of basic tissues in both hens and cocks reared in two different non-industrial rearing systems (I group – in the free-range rearing and the II one – in the extensive chicken-pen rearing system).

T1

From table 1 one can see a somewhat higher muscular tissue share in breast mass in both hens and cocks of the first experimental group (free-range rearing) compared to the broilers reared extensively, in the chicken-pen (II experimental group). A somewhat higher bone share was registered with the chick of the other trial group. Skin share in the breast mass ranged from 10.96 (males of the II trial group) to 13. 53 % (females of the same group). However, from the point of view of both meat share and bone and skin share in breast mass, the emerged differences between both sexes and the rearing systems investigated were not significant.
The mentioned study results on the participation of basic tissues in broiler breasts are in between the results for free-range-reared chicks by *Bogosavljevic-Boskovic et al. (1999) and Milosevic et al. (2003).*
Table 2 presents the yields and shares of basic tissues in drumstick mass of the males and females investigated.

T2

Based upon the table 2 data it could be concluded that a somewhat higher muscular tissue share in the drumstick mass was recorded in the I experimental group chicks. Furthermore, a somewhat higher participation of the muscular tissue in the basic carcass part mentioned was registered with the females in both rearing systems. However, the emerged differences were not statistically significant neither from the point of view of the sex influence, nor from the viewpoint of the effect of the rearing systems investigated. Further data in table 2 show that the bone share in the experimental broiler drumsticks ranged from 23.52 (females of the I experimental group) to 28.21 % (males of the I investigated group). The data also indicate that the lowest and highest skin shares in drumstick mass were registered with the males fattened extensively in the chicken-pen (9.30%) and with the free-range-reared males (10. 89 %), respectively. However, the differences in terms of both the bone share and the skin share in the drumstick mass between the trial broilers were also not significant.
The established relative values of the occurrence of muscular tissue in drumstick mass were somewhat higher than the results of *Bogosavljevic-Boskovic et al. (1999)* and were in accordance with the results of *Milosevic et al. (2003).*

Conclusions

Based upon the study results on the basic tissue shares in major carcass parts of broilers reared in two different non-industrial rearing systems (I group – rearing using free-range and II – extensive rearing in the chicken-pen), the following may be inferred:

- The free-range-reared broilers had a somewhat higher meat share in breast mass and drumstick mass compared to the ones reared extensively in the chicken-pen.
- A somewhat higher meat share in drumstick mass was recorded with the females than with the males, whereas the other differences in terms of the sex effect were also slight.
- The analysis of the significance of the emerged differences in terms of the effect of the rearing systems investigated and the sex of broilers on the share of certain tissues in major carcass parts has shown that the differences were not statistically significant.

STUDIES ON CHANGES OF SOME SELECTED PORK MEAT QUALITY TRAITS IN RELATION TO THE TIME AFTER SLAUGHTER

Borzuta K., Borys A., Grześkowiak E., Strzelecki J., Lisiak D., Rogalski J.
Meat and Fat Research Institute, ul. Głogowska 239, 60-111 Poznań, Poland

Background

One trait, which can be used to characterise meat technological quality, is meat pH measured 45 minutes after slaughter. This measurement is employed to reveal meat quality defects and is highly correlated with meat colour (Briskey 1964).
For many years two main pork meat quality defects have been discussed in literature, namely watery meat and acid meat. Their occurrence is associated with genetic factors and is attributed to the presence of RYR1 and RN^- genes (Fujii et al. 1991, Monin and Sellier 1985).
Meat colour is an important trait to be taken into account when assessing the commercial meat quality. With regard to the subjective meat colour assessment, the greatest attention is paid to its lightness, which is affected by the optical properties of the surface meat layer.

Objectives

The objective of the performed investigations was to determine changes in colour lightness, pH and electrical conductivity ascertained at different times after slaughter in the *longissimus lumborum* muscle *(m. LL)* in swine carcasses with normal and watery meat.

Materials and methods

The experimental material consisted of 1050 pork carcasses derived from different swine genotypes.
Within 45 minutes after stunning, pH was determined in the LL muscle at the level of the 1^{st} – 2^{nd} lumbar vertebra with the aim to select experimental carcasses. From the population, 25 carcasses with PSE meat (pH_{45} < 6.0) and 25 carcasses with normal meat (pH_{45} 6.50 – 7.00) were selected randomly for further investigations (Kortz 2001, Borzuta et al 1975).
In the LL muscles of both groups of carcasses pH values, electrical conductivity (LF) and colour lightness (L) measurements were performed at the following times after pig stunning: about 45 minutes and 2, 3 and 24 hours.
The values of pH were determined using the Radiometer PHM 80 Portable pH-meter equipped in a complex electrode, whereas electrical conductivity was measured using a pork meat quality tester of MT-03 type manufactured in Poland.
Meat colour lightness was determined in the *LL muscle* after cutting out a slice at the following times *post mortem*: 45 minutes and 2, 3 and 24 hours. The above-mentioned measurements were performed using the Minolta Chroma Metter CR 300 apparatus (Oziembłowski and Grashorn 1997).

Results and discussion

The pH values determined in the group of pigs with normal meat at the examined times after slaughter indicate proper acidification of the muscle tissue (Tab.1). Two and three hours after stunning pH values dropped, on average, by 0.37 unit (pH=6.36), while 24 hours after slaughter – by 0.91 unit. The obtained final pH_{24} – 5.82 value of these muscles indicates the proper process of glycolysis as confirmed by numerous publications (Lambooij et al. 2004, Bertram et al 2003, Kortz 2001).
The examined muscles were characterised by low electrical conductivity ranging from 2.93 to 3.45 mS, which was found not to be dependent on the measurement time after slaughter. The electrical conductivity obtained for this group of carcasses was typical for normal meat (Koćwin-Podsiadła et al 1998).
Furthermore, in this group of carcasses no significant differences were found between the meat colour lightness measured 45 minutes as well as 2 and 3 hours after slaughter. However, a significant brightening of the colour was observed 24 hours after slaughter.
In the group of carcasses with watery meat, the pH value remained on a similar level 2, 3 and 24 hours after slaughter (pH 5.64 to 5.83). The pH value determined 45 minutes after stunning was only slightly higher (by

0.19 unit). These observations are corroborated by data reported by Simek et al. (2004), who also did not record significant differences between the pH_{45} and pH_{24}. On the other hand, significant differences were found between the degree of tissue acidification of normal and PSE meat 45 minutes and 2 and 3 hours after slaughter. However, 24 hours after slaughter pH values of both groups of muscles were quite similar.
The analysis of values of electrical conductivities of the PSE meat revealed its significant increase during the initial hours after slaughter changes. An increase in the electrical conductivity of 3.10 mS was recorded in the period from 45 minutes to 2 hours after slaughter. On the other hand, between the second and third hour after slaughter only a slight, but statistically significant, increase in electrical conductivity (by 0.95 mS) was observed. In the period from 3 hours to 24 hours after slaughter, a significant drop in the LF of 2.61 mS was observed. Nevertheless, the difference in the electrical conductivity between normal and PSE meat became quite conspicuous already 45 minutes after slaughter (3.45 and 7.41 mS, respectively), which indicates that this measurement can be very useful for the identification of PSE meat already 45 minutes after slaughter. Also LF measurements 2, 3 and 24 hours after slaughter were significantly different between the two groups of carcasses.

45 minutes after slaughter the colour of PSE meat was uneven and pale with the colour brightness reaching 43.2%. The colour became much lighter in the following hours. In the period from 45 minutes to two and three hours after slaughter, a significant increase of the light reflection, on average by 8.6%, was recorded and 24 hours after slaughter this value increased by 11.5%, in relation to the colour lightness measured 45 minutes after slaughter. The PSE meat 24 hours after slaughter was usually pale and exudative on the entire slice surface.
During the analysed periods of time the percent of light reflected from the watery meat tissue was higher and differed significantly when compared with normal meat (<0.01). The recorded differences were as follows: after 45 min. – 4.08%, after 2 and 3 hours – 13.35%, after 24 hours – 8.26%. It is evident from the above-presented data that the measurement of colour 45 minutes after slaughter was not a good indicator for the identification of PSE meat as differences in the colour brightness were the smallest at this point in time. However, this indicator can certainly be used effectively already 2 hours post mortem.

Conclusions

- The pH of PSE meat after 45 minutes as well as 2, 3 and 24 hours after slaughter exhibited almost similar values, whereas in the case of normal meat, a gradual acidification of tissue occurred.
- The electrical conductivity of PSE meat increased the 3rd hour after slaughter, while that of normal meat remained at similar level during the entire 24-hour period. It was stated that the measurement of electrical conductivity 45 minute after slaughter could serve as a good parameter identifying PSE meat.
- The colour lightness of PSE meat, from the 2nd hour post mortem, increased progressively, but measured after 45 minutes was not a good indicator of PSE meat. In normal meat, colour lightness remained on a similar level during the period from 45 minutes to 24 hours after slaughter.

THE EFFECT OF STORAGE ON THE OXYGEN CONSUMPTION RATE OF BOVINE M. *LONGISSIMUS DORSI* AND M. *PSOAS MAJOR*

K. Brandon[1], F. Butler[1] and P. Allen[2]

[1]Department of Biosystems Engineering, National University of Ireland, University College Dublin, Earlsfort Terrace, Dublin 2, Ireland.
[2]The National Food Centre, Teagasc, Ashtown, Dublin 15, Ireland.

Background

Colour is the most important factor determining acceptability of beef steaks. Consumers associate a bright cherry red colour with quality. The *longissimus dorsi* (LD) and *psoas major* (PM) muscles exhibit very different colour stabilities. The LD is considered to be a colour stable muscle with a colour shelf life of 4 - 5 days, while the PM has a colour shelf life of 1 - 1.5 days and is thus regarded as being very colour unstable (O'Keeffe and Hood, 1982; Isdell *et al.,* 1999). The oxygen consumption rate (OCR) influences colour stability by altering the depth at which the metmyoglobin (brown) layer forms. When the OCR is high, oxygen does not penetrate far into the meat, the metmyoglobin layer that forms at the limit of penetration will be near the surface, and colour deteriorates rapidly as this thickens and reaches the surface (Madhavi and Carpenter, 1993).

Objectives

The objective was to determine if time post mortem has an affect on the OCR of bovine LD and PM muscles. A secondary objective was to determine whether the OCR is affected by anatomical location within the muscle and whether there is variability within individual steaks.

Materials and methods

M. *longissimus dorsi* and M. *psoas major* (n=6) (pH 5.4 - 5.8) were excised from steers (≤ 36 months) at 48h post mortem at a commercial meat plant (Kepak Group, Clonee, Ireland). A steak (20 - 25mm thick) was cut from three areas of each muscle – posterior, centre and anterior to account for variability within muscle. The steaks were then placed in laminated retail polystyrene trays (Linpac 2-37 EPS) and overwrapped with a high oxygen permeable film (OTR: 20,000cm^3 m^{-2} $24hr^{-1}$ atm^{-1}). All steaks were stored in a cooled incubator (LMS, Davidson & Hardy Ltd, Ireland) at 4 ± 0.5ºC for 2 hours in the dark to allow them to bloom. The remaining portion of each muscle was vacuum packed (20/70 PA/PE; OTR: 40-50cm^3 m^{-2} $24hr^{-1}$ atm^{-1} at 23ºC, 75% RH) and stored at 0 ± 0.5ºC in a coldroom until 4, 7, 14 and 21 days post mortem. The temperature in the coldroom and incubator was recorded every 5 minutes using a Tinyview temperature logger (Gemini Data Loggers (UK) Ltd, Chichester, UK).

Bloomed steaks were vacuum packed (20/70 PA/PE; OTR: 40-50cm^3 m^{-2} $24hr^{-1}$ atm^{-1} at 23ºC, 75% RH). To account for any variability within the steaks, circles (3 for the LD and 2 for the PM) were marked on each pack and labelled 'a', 'b' and 'c' so that colour readings during storage could be taken at the same places. Reflectance spectra (360-750nm at 10nm intervals) were taken after 0, 10, 20, 30, 40, 50, 60 minutes in a vacuum pack using a HunterLab UltraScan™ XE spectrophotometer (Hunter Associates Laboratory, Inc. Reston, USA). During this time the samples were held in the incubator at 4 ± 1ºC in the dark, except while reflectance measurements were being taken. Reflectance values were used to determine the proportions of the three colour pigments (oxymyoglobin, myoglobin and metmyoglobin) present, using the method described by Kryzwicki (1979). Reflectance values at wavelengths not given by the instrument (473, 525 and 572nm) were calculated using linear interpolation. The OCR was determined by following the pigment changes that occur since oxygen, present as oxymyoglobin would be converted to myoglobin or metmyoglobin after vacuum packaging (Madhavi and Carpenter, 1993). The OCR was expressed as 'oxymyoglobin converted to myoglobin after 10 minutes in vacuum'.

Statistical analysis

At each storage time the effects of anatomical location and within steak location on the percentage of each form of myoglobin and on the OCR were tested using a tow-way ANOVA using SYSTAT (Systat Inc. Illinois, USA). For OCR, the difference between the two muscles was tested in a one-way ANOVA.

Results and discussion

There was no significant difference in oxygen consumption rate as a result of positional effects within the muscle or within the steak for the LD at each time post mortem. This is in agreement with Young, Priolo, Simmons and West (1999) who found no significant positional effects for bovine LD pieces. There was no significant difference within the PM steak ('a' and 'b'). However on days 7, 14 and 21 the posterior section was more susceptible to metmyoglobin formation than the centre and anterior sections ($P<0.01$).

The initial oxymyoglobin concentration increased with time post mortem from 58% to 66% on days 2 and 21 respectively. This trend was reflected in a decrease in the % myoglobin from 20% on day 2 to 14 % on day 21. The initial percentage metmyoglobin was consistent with respect to storage time at 20-22%. This increase in the % oxymyoglobin and decrease in the % myoglobin during storage would be expected to reflect a decline in the OCR of the LD with time post mortem.

The rate of conversion of oxymyoglobin to myoglobin for the LD was highest on day 2 post mortem, intermediate on days 4 and 7 and almost non-existant on days 14 and 21 post mortem (Figure 1). Oxymyoglobin was converted mainly to myoglobin and to a lesser extent to metmyoglobin on days 2, 4 and 7 post mortem. The metmyoglobin concentration remained constant on days 14 and 21, with a slight decline in oxymyoglobin and increase in myoglobin. This suggests that LD steaks are more susceptible to metmyoglobin formation in the first days post mortem.

PM oxymyoglobin concentration varied between 55% (day 2) and 66% (day 21) and decreased rapidly with time in vacuum at all days post mortem, the rate of decline being highest at day 2. As in the LD, storage time had no effect on the initial % metmyoglobin, but the % myoglobin ranged from 12% at days 7, 14 and 21 to 23% at day 2 post mortem. A concurrent increase in the myoglobin concentration occurred at each storage interval. Unlike the LD, the metmyoglobin concentration increased with time in vacuum for all storage times, indicating that the PM is susceptible to metmyoglobin formation up to 21 days post mortem.

The OCR of both muscles decreased with time post mortem (Figure 2), however there were differences between the muscles at each storage time. PM had a higher OCR than the LD at all times post mortem ($P<0.01$). The OCR of the LD was almost completely exhausted by day 7. The OCR has a direct influence on the colour stability of a muscle through its effect on the penetration depth of the oxygen; therefore the findings here are in agreement with O'Keeffe and Hood (1982) who found that the PM is the most colour unstable, has a high OCR and a colour shelf-life significantly shorter than that of any other muscle. On the other hand they found that the LD was the most colour stable. Madhavi and Carpenter (1993), when comparing the biochemical characteristics of LD and PM discovered that PM had a significantly higher OCR and lower NAD ($P<0.05$) than LD steaks up to day 7 post mortem. However, on days 14 and 21 they did not detect a significant difference between the LD and PM, which is not in agreement with the present work.

Conclusions

The OCR of the PM is higher than that of the LD, with the PM continuing to have an active OCR up to 21 days post mortem. The OCR of both the LD and PM stabilised from 7 days post mortem onwards. From this it can be concluded that the optimum storage time prior to anoxic packaging of beef steaks is on or after 7 days post mortem.

THE CORRELATION OF SLIGHT, MEDIUM AND EXTREME RIGOR MORTIS CARCASS TO HALOTHANE GENOTYPE, SARCOPLASMIC CALCIUM AND PROTEIN FUNCTIONAL CHARACTERISTICS IN ABATTOIR SLAUGHTERED PIGS

[1]Chang K. C. , [1]Wang S. C. , [1]Lin K. J.

[1]Department of Animal Science, National Chia-Yi University, Chia-Yi, 600 Taiwan, R.O. C.

Background

Halothane gene (HAL gene) is a genetic defect that can be triggered by stress during hog's handling treatments . The clinical symptoms of Halothane gene are gross muscular rigidity, high temperature, and arrhythmia. After the exsanguination of the animals, the blood circulation stops, and consequently, the hogs muscle couldn't obtain energy by respiration. Then, the energy is depleted which results in the development of carcass's rigor mortis. Glycogen transfers to ATP as an energy resource during rigor mortis and consequently affects the rigor development, because of the accelerated rigor mortis caused by the lack of calcium ion recovery activity during rigor mortis. After the hogs have been hanged and have been dressed, shaking hand method (Swatland, 1995) might give information about softening and tendering of the meat in which softening and tendering are in relation to muscle protein functional characteristics.
There have been shown three kinds of rigor mortis degrees (extreme, medium and slight) in abattoir slaughtered pigs in Taiwan. The different kinds of developed rigor mortis carcasses are measured by shaking hand method in early abattoir slaughtered pigs. The sarcoplasmic calcium concentration and glycolysis may be involved in extreme, medium and slight rigor mortis carcasses. The sarcoplasmic calcium concentration and glycolysis at postmortem carcasses play important roles in the formation of normal or pale, soft and exudative meat. The rate of glycolysis is controlled by sarcoplasmic calcuim levels; the carcass's rigor mortis might be affected by sarcoplasmic calcium concentration and rate of glycolysis. Rapid glycolysis within the first hour post mortem results in a low muscle pH value and high body temperature, leading to denaturation of muscle protein and development of inferior meat quality.

Objectives

The objective of this study was to determine the correlation of slight, medium and extreme rigor mortis carcass to halothane genotype, sarcoplasmic calcium and protein functional characteristics in abattoir slaughtered pigs.

Materials and methods

Materials

The live weight of the hogs were approximately 100-110 kg. They were slaughtered at local abattoir and stunned electrically. Within 45 min after exsanguination, the three groups of rigor mortis degree carcasses (slight, medium and extreme) were determined by tension load tester (Fig. 1). Longissimus dorsi (LD, from 4th to 5th rib) samples were subsequently excised within 45 min and 24 h after post mortem from 10 carcasses of three groups of rigor mortis degree, respectively, and immediately stored at -70℃ until analysis.

Methods

Halothane genotype identified

Halothane genotype of three kinds of rigor mortis degree carcasses were identified by mutagenically separated polymerase chain reaction (MS-PCR) (Liaw *et al.*, 2000).

Measurements of sarcoplasmic calcium concentration and the products of glycolytic metabolic response

Sarcoplasmic Ca^{2+} concentration in LD muscle was determined by using 10 g sample in 10ml of 150mM KCl (Cheach *et al.*, 1984). The Ca^{2+} was analyzed by an atomic absorption spectrophotometer at 422.7 nm. The concentration of glycogen was analyzed by a method of Hartschun *et al.* (2002), and glucose, glucose-6-phosphate, adenosine triphosphate（ATP), and creatine phosphate（CP）concentration were analyzed by a enzyme analyze method (Yang，1993). The R value was analyzed by a method of Thompson *et al.* (1987).

Measurements of protein functional characteristics

The pH, lightness value, protein solubility, myofibrillar ATPase activity, water-holding capacity(WHC), and myofibril fragmentation index (MFI) were determined at 45 min and 24 h post mortem, respectively. The protein solubility and WHC were measured by Joo *et al.* (1999). The assayed method of myofibrillar ATPase activity was modified from Lin *et al*. (1999). MFI was determined by Hopkins and Thompson (2002).

Statistical analysis

The data from the three kinds of rigor mortis degree carcasses were compared by analysis of variance (ANOVA) using the General Linear Model (GLM) of SAS（1988).

Results and discussion

The results showed that there was one heterozygote in the samples of extreme rigor and medium rigor mortis carcasses; however, the Halothane gene did not exist in the samples of the slight rigor mortis carcasses. Within 45 min of post mortem, both sarcoplasmic Ca^{2+} and R value in the extreme rigor mortis carcasses were significantly higher than those in the others ($p<0.05$); on the other hand, the adenosine triphosphate (ATP) and the creatine phosphate (CP) content in the extreme rigor mortis carcasses were lower than those in the slight rigor mortis carcasses ($p<0.05$), and the sarcoplasmic Ca^{2+} concentration did not have difference among the three groups at 24 h of post mortem. The results were similar to Cheah *et al.*(1984).

The increased level of sarcoplasmic Ca^{2+} in extreme rigor mortis carcasses was due to a disturbed regulation of calcium release channel in sarcoplasmic reticulum, and Ca^{2+} was fast releasing in sarcoplasmic reticulum. Cheah *et al*.(1986) indicated that Ca^{2+} release of sarcoplasmic reticulum might be caused by the mechamism of Ca^{2+}-induced Ca^{2+} released. Monin *et al*.(1980) indicated that the rigor mortis score was higher in Halothane positive pigs at 1 hour post mortem, for explaining that the extreme rigor mortis might to have a mutational Halothane gene. The faster rate of glycolysis in extreme rigor mortis carcasses is caused by the higher sarcoplasmic Ca^{2+} concentration they have. The rate of glycolysis was controlled by Ca^{2+} concentration which stimulated the degradation of glycogen. This study showed that the extreme rigor mortis carcasses were higher in free sarcoplasmic Ca^{2+} concentration and the ATP as well as the CP content to be lower. The results also indicated that the rate of glycolysis was faster within 45 min post mortem due to the extreme rigor mortis carcasses which had a higher Ca^{2+} concentration in sarcoplasmic.

Additionally, the solubility of sarcoplasmic protein, total protein, myofibrillar ATPase activity and WHC in the extreme rigor mortis carcasses were lower than those in the slight rigor mortis carcasses ($p<0.05$), but the extreme rigor mortis carcasses had significantly higher lightness value, drip loss and MFI than the other rigor mortis carcasses ($p<0.05$). Protein denaturation was quantified by myofibrillar ATPase activity and protein solubility. Within 45 min post mortem the extreme rigor mortis carcasses had a faster rate of glycolysis and it would result in lactate accumulation, pH value decrease and protein denaturation in muscle. Our study showed that extreme rigor carcasses had lower protein solubility and ATPase activity, in which it supported that extreme rigor carcasses had lower protein function characteristics than the others.

Conclusions

The results showed that although the relationship between hog carcasses and halothane genotypes did not reach to a significant level, extreme rigor mortis carcass had significantly higher sarcoplasmic Ca^{2+} level and caused rapid glycolysis and decreased pH value in pork muscle. Thus, the meat qualities were seriously affected.

EFFECT OF HCG STIMULATION ON ANDROSTENONE, SKATOLE AND INDOLE LEVELS IN ENTIRE MALE PIGS

Chen, G., Zamaratskaia, G. and Lundström, K.
Department of Food Science, PO Box 7051, 750 07 Uppsala, Sweden

Background

Skatole, indole and androstenone are the compounds responsible for boar taint, an offensive odour detectable when cooking pork. Due to their lipophilic properties, they accumulate in adipose tissue of some entire male pigs. Skatole and indole are formed from tryptophan in the colon of pigs (Claus et al., 1994). Skatole passes through the liver where most of it is metabolised by cytochrome P450. The activity of this enzyme system, therefore, affects skatole levels (Babol et al., 1998). Environmental factors and nutrition are also important in the regulation of skatole levels (Walstra et al., 1999).

Androstenone is a testicular steroid and its production is linked to the synthesis of anabolic testicular hormones. Puberty development results in increased androstenone levels (Claus et al., 1994). Environmental factors such as season, photoperiod (Andersson et al., 1998) and nutrition levels can influence the time of puberty and thus androstenone levels in adipose tissue at slaughter.

HCG injection causes an abrupt increase in androstenone both in plasma and fat (Carlström et al., 1975; Andresen, 1975; Bonneau et al., 1982), but to our knowledge an eventual effect on skatole has not been studied. High level of androstenone may inhibit the expression of CYP 2E1 in liver (Doran et al., 2002), one of the enzymes involved in skatole metabolism. Subsequently, much skatole remains unmetabolised and can then accumulate into fat. Some researchers showed that androstenone levels correlated positively with skatole levels in adipose tissue at slaughter age as reviewed by Walstra et al. (1999). A positive correlation between androstenone and skatole levels in plasma at 20 weeks of age was also found (Zamaratskaia et al., 2004a). Generally, however, results vary on the relationship between androstenone and skatole levels.

Objectives

The aim of the present study was to investigate the effect of hCG stimulation and the relationships of androstenone, skatole and indole levels in plasma and fat after hCG stimulation in entire male pigs.

Materials and methods

Animals

A total of 34 entire male pigs of a crossbred (Swedish Yorkshire dams x Landrace sires) were used in this study. Animals were raised in single-sex pens with 7 pigs in each. All pigs were fed the same commercial diet according to the standard feeding regimen for finishing pigs in Sweden (restricted, 12 MJ ME per kg, digestible CP 13%).

HCG injection was performed (Pregnyl, 30 IU/kg body weight) 4 days prior to slaughter. Control pigs were injected with sterile saline the same day. Blood samples were taken from all pigs twice: before injection and the day before slaughter. Plasma samples were kept in -80°C until analysis. Back fat was taken at slaughter and kept in -20°C until analysis.

Analysis of skatole, indole and androstenone

Skatole and indole levels in plasma were measured with HPLC as described by Zamaratskaia et al. (2004a). Skatole levels in fat were measured with a colorimetric procedure (Mortensen and Sørensen, 1984). Androstenone levels in plasma and fat were measured with an ELISA method described by Squires and Lundström (1997). Androstenone was extracted from plasma with ethyl acetate and from fat with methanol.

Statistical analysis

All data were analysed with the Statistical Analysis System, version 8.2 (SAS Institute, Cary, NC, USA). Procedure Mixed was used for evaluating the results. The model included treatment and time of sampling as fixed factors, and individual pig within sire, dam and treatment as random factors. A logarithmic transformation was applied to the levels of skatole, indole and androstenone to normalise the distributions of observed values. Results are presented after back transformation.

Results and discussion

Androstenone analysis in plasma with ELISA method has been used by many researchers. The direct plasma analysis (without extraction), however, led to overestimation and extreme values could be observed (above 200 ng/ml). To avoid this overestimating effect, extraction procedure was used prior to analysis in this study.

Three pigs were used in a pilot study to evaluate the experimental design. The blood samples were taken at five occasions: before hCG injection, each day during three days after injection and the day prior to slaughter. The results showed a rapid increase in androstenone level, a plateau on the second day and a subsequent decline. This is in line with the former Swedish results (Carlström et al., 1975), where maximum levels of androstenone in plasma were found the second day after hCG-injection. Overall, no effect on skatole or indole levels was observed; however, a pronounced increase in both compounds was observed within some individuals causing a high variation (Figure 1).

HCG stimulation significantly increased androstenone levels in plasma ($P < 0.001$; Table 1), whereas skatole levels in plasma did not differ between treatments. Surprisingly, plasma indole levels increased significantly ($P = 0.03$; Table 1). This increase is difficult to explain. Probably, high androstenone levels inhibit the enzymes involved in indole metabolism more efficiently than skatole levels. Both skatole and indole are metabolised in the liver with the same enzymatic system (Gillam et al., 2000). However, the precise metabolism of indole has not been the subject of intensive research, and factors affecting indole metabolism are not yet known. The effect of hCG administration on both skatole and indole levels needs to be further studied.

HCG injection also caused a significant increase in androstenone levels in fat ($P < 0.001$; Table 1). The mean androstenone level for the control group was 1.03 µg/g and for hCG treatment group 4.22 µg/g, approximately four fold higher than the control. Skatole levels in fat were significantly higher in the hCG-treated group compared to the control. It should be noted that skatole levels in fat in this study were measured by the colorimetric method. This method is not specific for skatole, but measures the total amount of indolic compounds. Therefore, the observed differences between treatments in fat might rather be due to indole than skatole concentrations. Indole may also partially contribute to boar taint (Garca-Regueiro and Diaz, 1989). However, the level above which consumers can perceive indole odour is not specified. It is assumed that indole is not of the same importance for boar taint as skatole and androstenone because of weaker odour.

The mean skatole levels in fat in control and hCG injection groups were 0.09 µg/g and 0.13 µg/g, with 1 and 4 pigs exceeding the rejection level of 0.20 µg/g respectively. The androstenone levels were relatively high even in pigs without hCG-stimulation. The mean value for androstenone in the control group was 1.03 µg/g. In this group, 13 and 8 out of 17 pigs exceeded the threshold levels for androstenone in fat of 0.5 and 1.0 µg/g respectively.

The correlation coefficients between skatole and androstenone levels in plasma at the two sampling occasions were 0.22 ($P = 0.44$) before hCG stimulation, and 0.03 ($P = 0.88$) after hCG stimulation. The relationship between skatole and androstenone levels in plasma after hCG stimulation has not been studied previously. Androstenone might be involved in skatole metabolism by the inhibition of CYP2E1 in vitro (Doran et al., 2002). High androstenone levels would then lead to high skatole levels. However, in an in vivo study, high androstenone levels did not result in immediately increased skatole levels (Zamaratskaia et al., 2004a, b). In these studies, the pubertal increases in testicular steroids preceded the rise in skatole levels. In the present study, skatole and androstenone in plasma were measured three days after hCG stimulation.

Probably, this time was not enough for androstenone to perform its action on liver enzymes. In this case, the increase in skatole levels can be delayed. The other explanation could be that androstenone levels after hCG stimulation still did not reach a sufficient level to inhibit CYP2E1 in vivo. The androstenone levels used in the in vitro study by Doran et al. (2002) were probably much higher than can be achieved in the liver in vivo. If so, no increase in skatole as a result of inhibiting action of testicular steroids could be anticipated.

The positive correlation between skatole and indole levels in plasma (r = 0.49) is probably due to the same intestinal origin and the linked metabolic pathway. Skatole levels in plasma and fat strongly correlated (r = 0.83). This is in agreement with previous studies (Zamaratskaia et al., 2004a). The correlation between androstenone and skatole levels in fat at slaughter was 0.47 in control animals and 0.39 after hCG stimulation. The lower correlation coefficient in the hCG-treated group may be related to the fact that androstenone levels in this group increased rapidly, whereas no such high increase in skatole levels was observed.

Conclusions

HCG stimulation significantly increased androstenone levels in both plasma and fat. Skatole levels in fat were also higher in hCG-treated pigs. This increase might be related to the variations in indole levels, since indole but not skatole levels in plasma were higher after hCG stimulation. High androstenone levels did not cause increased skatole levels in plasma with the sampling pattern used in this study. This would have been expected if androstenone inhibited the expression of the main enzymes of skatole metabolism.

EFFECT OF LACTOFERRIN LEVELS ON TBARS AND NONHEME IRON OF GROUND PORK

Chiu, C. H. and Kuo, C. C.
Department of Food Science, Tunghai University, Taichung, Taiwan

Background

Lactoferrin is an iron-binding glycoprotein that belongs to the transferring family, and mainly exists in mammalian milk. Iron ions are an important catalyst of lipid oxidation which could be bound by lactoferrin (Naidu, 2002). Probably due to this reason, the natural bovine lactoferrin could inhibit lipid oxidation in corn oil emulsions and lecithin liposome systems (Huang *et al*., 1999). Lactoferrin could be used as a dual-purpose additive in infant formulas and similar food products for its antioxidant and antimicrobial properties (Satué-Gracia *et al*., 2000). In the USA, lactoferrin is permitted at levels of 65.2 mg/kg of beef. In Taiwan, lactoferrin may be used in special nutritional foods under the condition "only for supplementing foods with an insufficient nutritional content and may be used in appropriate amounts according to actual requirements". Currently, the European Union does not have a specific regulation for lactoferrin. Higher levels of bovine lactoferrin had been administered orally to mice and rats, as high as 20 g/L of milk for fourteen days and 20 g/kg for thirty weeks, respectively, with no known side effects (Naidu, 2002).

Objectives

Lactoferrin was reported to inhibit various microorganisms, but only limited information has been reported on the effect of lactoferrin on lipid oxidation in food systems and to what extent the antioxidative effect of this additive exerts when used in ground pork and what influence it could have. The purpose of this study was to investigate the effect of lactoferrin levels on TBARS values, total and nonheme iron and pH of ground pork during storage at 4 ℃ for 9 days.

Materials and methods

Bovine lactoferrin was obtained from DMV International (Veghel, the Netherlands).
Ground meat samples were divided into three batches (1 kg/batch). To each batch was added 0, 40 or 80 mg lactoferrin/kg meat, respectively. Samples were stored at 4 ℃ for 0, 3, 6 and 9 days. TBARS (2-thiobarbituric acid reactive substances) values of meat samples were determined by using the distillation method (Ockerman, 1985). TBARS values were expressed as mg malonaldehyde/kg meat. Total iron concentration of the samples was determined on dry ashed samples by an atomic absorption spectrophotometry (Hitachi Z-8000, Tokyo, Japan) according to the AOAC method (1995). A modification of the method of Rhee and Ziprin (1987) as described by Schricker *et al*. (1982) was used to determine nonheme iron. The pH values of ground pork were determined according to Ockerman (1985).

Results and discussion

Mean total and nonheme iron concentration of samples is shown in Fig. 1. Due to that lactoferrin is an iron-containing protein; therefore, the treatments with the addition of lactoferrin (40 and 80 mg/kg) had higher (P<0.05) total iron concentration than the controls. The higher the levels of lactoferrin added, the higher the total iron. However, the differences in total iron concentration between the treatments with the addition of 40 and 80 mg/kg lactoferrin were not significant (P>0.05). On the contrary, nonheme (free) iron concentration was higher for the controls (14.2 μg/g), compared to the treatments with the addition of 40 mg/kg (12.0 μg/g) or 80 mg/kg lactoferrin (10.5 μg/g). The higher the levels of lactoferrin added, the lower were the nonheme iron. The differences in nonheme iron between the controls and the treatment with the addition of 80 mg/kg lactoferrin were significant (P<0.05). Lactoferrin used in this study is partially saturated with iron, which has the ability to bind free iron; therefore, nonheme iron concentration was lower, but total iron concentration was higher, in the treatments with the addition of lactoferrin when compared to the controls. In general, nonheme iron in all treatments increased slightly during storage at 4 ℃ for 9 days; however, the results were not consistent (data not shown). Kanner *et al*. (1988) reported that free iron in raw turkey and chicken muscles increased during storage at 4 ℃, and suggested that this free iron increase was important in lipid oxidation in stored meat.

TBARS values were lower (P<0.05) in lactoferrin-treated samples (40 and 80 mg/kg) than in controls at 3, 6 and 9 days of storage, except at day 0 (Fig. 2). This suggested that lactoferrin addition could inhibit lipid oxidation and decrease TBARS values in ground pork. This was due to the iron-binding properties of lactoferrin (Naidu, 2002). From our results, it seemed that nonheme (free) iron was probably more important than total iron in lipid oxidation in ground pork. Satué-Gracia *et al*. (2000) reported that lactoferrin could be used as an additive in infant formulas and similar food products for its antioxidant properties. The differences in TBARS values between the treatments with the addition of 40 and 80 mg/kg lactoferrin were not significant at each interval of storage time. Increasing the concentration of lactoferrin at 80 mg/kg could only slightly enhance its antioxidant activity in ground pork. This suggested that the addition of 40 mg/kg lactoferrin in ground pork (20% fat) was probably sufficient to retard the lipid oxidative rancidity. TBARS values in controls increased as the storage time increased up to 9 days. TBARS values in the treatments with the addition of 40 and 80 mg/kg lactoferrin were not significantly changed at 3 days of storage; however, the TBARS values significantly increased at 6 and 9 days of storage. It seemed that lactoferrin could be more effective in inhibiting lipid oxidation in ground pork at the early storage time. All samples with or without the addition of lactoferrin had TBARS values below 0.5 during 9 days of storage, which were relatively low and well below the threshold value (1.0 mg malonaldehyde/kg meat) for detection of warm-over flavor (Boles and Parrish, 1990).

The differences in pH values among the treatments were not significant (P>0.05) at each storage interval (Table 1). The results indicated that lactoferrin addition has little effect on pH values of ground pork. The pH values of all meat samples slightly increased (from 6.19 to 6.31) during 9 days of storage; however, the differences were very small.

Conclusions

Ground pork containing 20% fat was treated with 0, 40 and 80 mg/kg bovine lactoferrin and stored at 4 ℃ for 0, 3, 6 and 9 days. Total iron concentration was lower, but nonheme iron was higher in controls than in lactoferrin-treated samples. The higher the levels of lactoferrin added, the higher were the total iron, and the lower were the nonheme iron. The addition of lactoferrin decreases TBARS (thiobarbituric acid reactive substances) in ground pork. The antioxidant activity increased with lactoferrin concentration.

ASSOCIATION BETWEEN DNA MARKERS OF CANDIDATE GENES AND CARCASS COMPOSITION AND MEAT QUALITY IN KOREAN CATTLE

Chung, K.Y.[1], Kim, W.T.[2], Shin, S.C.[2], and Chung, E.R.[2]

Department of Animal Science, University of Missouri, Columbia 65201
Nutreco Swine Research Centre, P.O Box 220, 5830 AE Boxmeer, The Netherlands

Background

The challenge to the beef industry is the production of cattle that exhibit favorable or superior carcass composition and meat quality due to the increasing demand of the consumer for high quality meat. Advances in molecular techniques have made it possible to select animals based upon desirable genotypes to meat production, regardless of age or sex of individual. It has been proposed that candidate gene analysis can be used to identify individual genes affecting the carcass traits and meat quality in beef cattle (Beever et al., 1990; Sellier, 1994; Haegeman et al., 2003). Candidate genes are selected on the basis of known relationship between physiological or biochemical processes and quantitative traits of interest. Leptin is a hormone in the fat metabolism pathway that has been shown to affect the amount of marbling in beef (Willis et al., 1998). The myogenic factor 5 (MYF5) gene plays a role in myogenic lineage determination and/or myocyte differentiation (Li et al., 2004). Heart fatty acid-binding proteins (H-FABP) are involved in fatty acid transport from the cell membrane to the intracellular sites of fatty acid utilization (Gerbens et al., 1999). Therefore, the leptin, MYF5 and H-FABP genes are important candidate genes for the identification of genetic markers for carcass composition and meat quality in Korean cattle.

Objectives

The objectives of this study were to analyze DNA markers of three candidate genes and to investigate their possible association with carcass composition and meat quality in Korean cattle.

Materials and methods

A total of 215 Korean cattle registered in the official performance-testing program from the National Livestock Research Institute, R.D.A. were used in this study. Carcass traits studied were carcass weight (CW), dressing percentage (DP), eye muscle area(EMA), backfat thickness(BMT) and marbling score(MS). The meat quality was classified according to Korean beef carcass grading from 1(high quality grade) to 3(low quality grade). Genomic DNA was extracted from blood samples and dissolved in TE buffer and kept at -20℃. Genotyping of the leptin, MYF5, and H-FABP genes were carried out using the PCR-RFLP technique. Primer sequences and restriction enzymes used in PCR-RFLP analysis are presented in Table 1.
Allele frequencies in the two groups selected for high and low quality grades were tested using chi-square test. The GLM procedure of SAS was used to test the association between the genotypes of the candidate genes and the carcass traits.

Table 1. Primer sequences and restriction enzymes of candidate genes used in PCR-RFLP analysis

Candidate gene	Primer sequence (5′ to 3′)	Enzyme	Fragment size (bp)
Leptin	GTCACCAGGATCAATGACAT AGCCCAGAATGAAGTCCAA	BgI Ⅱ	1,820
MYF5	ACAGCGTCTACTGTCCTGATG CGTGGCATATACTAAGGACAC	Taq Ⅰ	890
H-FABP	TACCTGGAAGTTAGTGGACAGC CTTGGCTCTGCTTTATTGACCT	Msp Ⅰ	612

Results and discussion

The three candidate genes of leptin, MYF5 and H-FABP were genotyped using PCR-RFLP method to determine their association with carcass composition and meat quality in Korean cattle. Representative results of PCR-RFLP analysis detected on polyacrylamide gel electrophoresis are shown in Figure 1, 2 and 3.

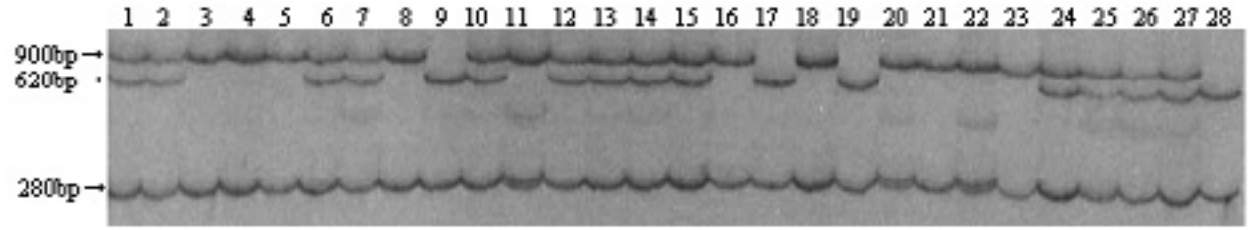

Fig. 1. RFLP genotype markers of leptin gene in 12% polyacrylamide gel following digestion with *BgI II* restriction enzyme of PCR products. In the gel, lanes 3~5, 8, 11, 16, 18, 20~22 and 23 represent AA genotype, lanes 1, 2, 6, 7, 10, 12~15, 24~26 and 27 represent AB genotype and lanes 9, 17, 19 and 28 represent BB genotype.

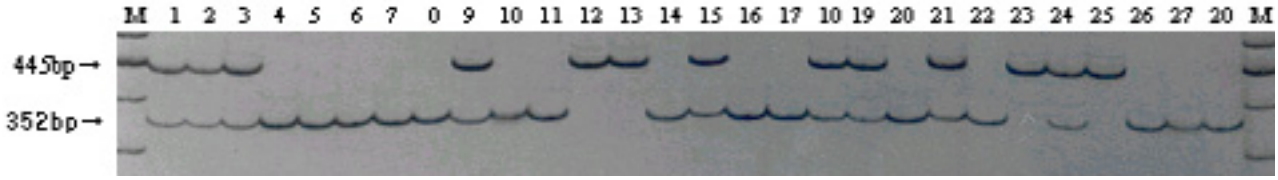

Fig. 2. RFLP genotype markers of MYF5 in 13% polyacrylamide gel following digestion with *Taq I* restriction enzyme of PCR products. In the gel, lanes 12, 13, 23 and 25 represent AA genotype, lanes 1~3, 9, 15, 18, 19, 21 and 24 represent AB genotype and lanes 4~8, 10, 11, 14, 16, 17, 20, 22, 26, 27 and 28 represent BB genotype. M : molecular size marker(100bp DNA ladder)

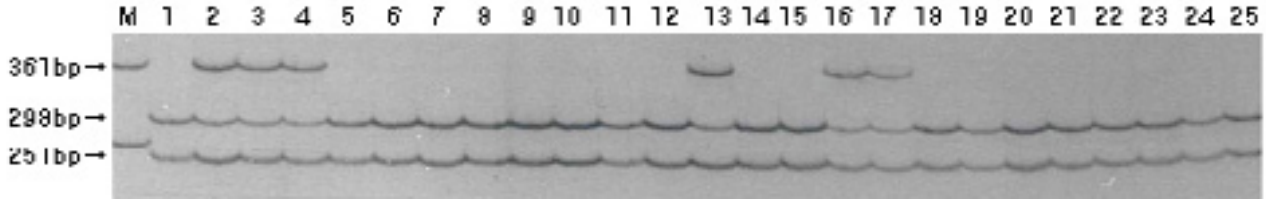

Fig. 3. RFLP genotype markers of H-FABP in 12% polyacrylamide gel following digestion with *Rsa I* restriction enzyme of PCR products. In the gel, lanes 1, 5~12, 14, 15, 18~24 and 25 represent AA genotype, lanes 2, 3, 4, 13, 16 and 17 represent AB genotype. M : molecular size marker(100bp DNA ladder)

The gene frequencies for A and B alleles in all animals were 0.57 and 0.43 for leptin, 0.61 and 0.39 for MYF5 and 0.90 and 0.10 for H-FABP, respectively. The difference in allele frequencies between the two groups selected for high and low quality grades was significant (P<.05) at leptin and MYF5 genes (Table 2).
Least squares means and standard errors of carcass traits for different genotypes of three candidate genes are given in Table 3. The gene frequencies for A and B alleles in all animals were 0.57 and 0.43 for leptin, 0.61 and 0.39 for MYF5, and 0.90 and 0.10 for H-FABP, respectively. The difference in allele frequencies between the two groups selected for high and low quality grades was significant (P<.05) at leptin and MYF5 genes(Table 2).
The effect of leptin gene was significant for backfat thickness (P<.01). The backfat thickness of animals with the BB genotype (1.43±0.64cm) was significantly higher than that of animals with the AA genotype (0.66±0.52cm). The MYF5 gene was found to be significantly associated with eye muscle area (P<.05). Animals with the AA genotype (98.82±7.92cm^2) produced a higher eye muscle area than animals with the BB genotype (81.94±8.37cm^2).

Table 2. Comparisons of allele frequency between the two groups selected for high (n=52) and low(n=43) quality grades using chi-square test

Candidate gene	χ^2	df	P
Leptin	5.6461	1	P<.010
MYF5	4.4731	1	P<.025
H-FABP	1.7412	1	P<.100

Table 3. Least square means and standard errors of carcass composition for leptin, MYF5 and H-FABP genotypes in Korean cattle

Candidate gene	Genotype	Carcass traits				
		CW(kg)	DP(%)	BFT(cm)	EMA(cm^2)	MS
		LSM±SE	LSM±SE	LSM±SE	LSM±SE	LSM±SE
Leptin	AA	481.43±78.47	60.80±2.35	0.66±0.52^{b}	91.63±7.92	3.92±1.01
	AB	479.43±78.02	60.54±1.56	0.94±0.38^{ab}	89.23±8.53	3.83±0.94
	BB	486.82±77.25	60.51±2.84	1.43±0.64^{a}	88.26±8.23	3.82±0.48
MYF5	AA	482.35±81.71	61.29±2.13	0.94±0.38	98.82±7.92^{a}	3.94±0.98
	AB	487.58±94.47	60.27±2.22	1.04±0.45	86.52±8.22^{ab}	3.77±0.96
	BB	479.75±90.46	61.26±2.52	1.03±0.54	81.94±8.37^{b}	3.59±0.72
H-FABP	AA	485.39±94.25	59.27±2.46	0.98±0.42	93.00±7.60	3.71±0.83
	AB	488.76±98.94	61.66±2.04	1.09±0.53	96.13±7.60	3.64±0.88

Superscripts with different letters in the same column significantly differ (P<.05).
CW=Carcass weight; DP=Dressing percentage; BFT=Backfat thickness; EMA=Eye muscle area; MS=Marbling score (ranges 1-5)

However, there were no significant effects of H-FABP gene on carcass traits. The significant association between the specific gene and quantitative traits suggests that the gene may be one of the causative genes or that the gene is very close to the causative gene(s)(Li et al., 2004). These results suggest that the leptin and MYF5 may be candidate genes that influences some carcass traits and meat quality in Korean cattle. The gene-specific RFLP markers of leptin and MYF5 genes could be used as genetic markers to select for increased backfat thickness and eye muscle area in breeding programs. Further investigations are needed in other populations of Korean cattle to verify the associated effects of the candidate gene-specific DNA marker.

Conclusions

In other to find DNA markers to improve the carcass and meat quality of Korean cattle we studied the association between genotypes in the three candidate genes (leptin, MYF5 and H-FABP) and carcass composition and meat quality. Genotypes of three candidate genes were determined for 215 animals using PCR-RFLP method. Allele and genotype frequencies were calculated for each genes. The allele frequencies were different between the two groups selected for high and low quality grades at leptin and MYF5 genes (P<.05). The leptin genotype was found to have significant association (P<.05) with backfat thickness. A significant association (P<.05) was also found between the MYF5 genotype and eye muscle area. No significant association, however, was defected for the H-FABP genotype. The results indicate that the leptin and MYF5 gene-specific RFLP markers could be used as DNA markers to select animals with desirable meat quality.

Background

The calpain system, a Ca^{2+}-activated protease family, and indirectly calpastatin (*CAST*), a calpain inhibitor, plays an important role in postmortem tenderization of skeletal muscle due to its involvement in the degradation of important myofibrillar and structural proteins (Koohmaraie, 1992; Sensky et al., 2001; Ciobanu et al., 2002). Two new *CAST* polymorphisms, *CAST Arg249Lys* and *Ser638Arg*, are located in or close to subdomain C of their respective domains. This subdomain potentiates the inhibitory activity of CAST. In order to investigate whether the alleles/haplotypes of the *CAST* gene are associated with meat quality traits such as ultimate pH, Minolta L*, cooking loss, tenderness and juiciness, a large number of pigs was harvested at commercial processing plants and screened for these two markers.

Objectives

Estimate the association of the *CAST* alleles with meat quality traits using a large number of commercial pigs harvested at commercial processing plants.

Materials and methods

Tissue Sampling and DNA Isolation. Tail and muscle samples and phenotypic data were collected from four different groups of commercial pigs. Genomic DNA was isolated using the DNeasy tissue kit (Qiagen, Valencia, CA).

Phenotypic measurements. Four separate experiments were conducted on four different commercial pig crosses: Group A: N=205; Group B: N=161; Group C: N=691; Group D: N=1829. All test pigs were harvested at two different commercial processing plants. *Longissimus dorsi* and *Gluteus medius* (ham) muscle pH was measured 24 hours post-mortem directly on the carcass using a Start Probe pH meter. Additional meat quality measurements such as Minolta L*, a*, a, b* (both muscles), instrumental tenderness (shear force, star-probe), cooking loss, sensory measurements (juiciness and tenderness), and pH (Longissimus muscle) were evaluated after 14 days of ageing. In experiment A, shear force was measured with an Instron 1222 Universal Testing Machine (Instron, Canton, MS) fitted with a Warner-Bratzler shear attachment. In experiment B, two chops were evaluated for instrumental texture using a circular, five-pointed star-probe attached to a texture analyzer (Texture Technologies, Scarsdale, NY). The star probe attachment was used to determine the amount of force needed to puncture and compress the chop 80% of the sample height. Subjective juiciness and tenderness were scored from 1 to 10 with higher values indicating more tender/juicier meat. For cooking loss measurements, a chop was cut from the muscle after ageing, weighed, cooked to 70C^{o} in a Faberware open hearth electric grill, refrigerated until cool, and re-weighed. During the time of cooking, temperature in each chop was monitored in its center with thermocouples. Cooking loss was calculated from weights taken before and after cooking and was expressed as a percentage.

Genotyping and PCR-RFLP Analysis. The region flanking each missense polymoprhism (*Arg249Lys* and *Ser638Arg*) was amplified by PCR and then digested with *Hpy*188I (*Arg249Lys*) and *Pvu*II (*Ser638Arg*).

Statistical Analysis. Haplotypes defined by the *CAST Arg249Lys* and *CAST Ser638Arg* polymorphisms were assigned based on inferences derived from the genotypes of homozygous individuals: haplotype 1, *249Lys – 638Arg*; haplotype 2, *249Arg – 638Arg* and haplotype 3, *249Arg – 638Ser.* All the predicted haplotypes were

present in all four groups of commercial pigs analyzed. The substitution effects of the haplotypes were estimated using a mixed model (SAS procedure MIXED, SAS Institute Inc., Cary, NC) and were considered as deviations from the effect of haplotype 3, which was arbitrarily set to zero. Analysis of haplotype associations was based on a model with genetic background of the four commercial pig groups included as a fixed effect.

Results and discussion

CAST Arg249Lys and *Ser638Arg*, are located in or close to subdomain C of their respective domains. This subdomain potentiates the inhibitory activity of CAST (Takano and Maki, 1999). Both substitutions (*Arg249Lys* and *Ser638Arg*) are outside the most conserved area of subdomain C: KPxxEDDxIDALSxDF (reviewed by Takano and Maki, 1999), but *Ser638Arg* is separated by just one amino acid from this sequence. An additional substitution, the *Ser66Asn,* is situated in Domain L. The function of this domain is not clear even though its sequence is well conserved among mammalian species. Recently, a role of the L domain was identified in regulation of L-type Ca^{2+} channels in guinea pig cardiac myocytes, suggesting the involvement of CAST in restoring Ca^{2+} channel activity, which facilitates Ca^{2+} influx and subsequently activation of calpain (Hao et al., 2000).

Detailed results representing Group A test pigs (N=205) are provided in Table 1. For all traits measured in this group of pigs, haplotype 1 was the favorable one and it was associated with higher pH, better tenderness and juiciness, lower shear force and cooking loss (Table 1). For instance, the effect of haplotype 1 was significantly different from the effect of haplotype 2 for shear force ($P < 0.04$), and for percentage of cooking loss ($P < 0.001$). The effect of haplotype 1 was also significantly different from that of haplotype 3 for muscle pH ($P < 0.03$), cooking loss ($P < 0.002$), juiciness ($P < 0.008$), and tenderness ($P < 0.09$) in this test group.

The results were not so clear for Group B test pigs (N=161), although some associations were detected. For example, for meat firmness, haplotype 2 had a higher substitution effect than that of haplotype 1 ($P<0.05$), and haplotype 3 ($P<0.01$). A suggestive association was also discovered for star probe with haplotype 1 being associated with a better meat quality than haplotype 2 (as for Group A). No significant differences were found for meat pH at 24hr and cooking loss.

Data from Group C pigs (N=691) revealed that haplotype 1 and haplotype 3 were again associated with higher quality pork. These haplotypes were significantly different from haplotype 2 for loin pH at 24 hr ($P<0.01$), and ham Minolta L* ($P<0.05$).

Commercial pigs from Group D (N=1829) were characterized by a significant association of Loin Minolta a* with haplotype 1 ($P < 0.0001$) and haplotype 3 ($P < 0.05$). Haplotype 1 and 3 were associated with lower value for this component of color and were significantly different from haplotype 2.

Conclusions

The results indicate that the porcine calpastatin variants have significant effects on meat ultimate pH, tenderness, cooking loss, and other economically important pork quality traits. It remains to be further demonstrated if the observed effects were caused by these polymorphisms alone or by their linkage disequilibrium with the causative mutations. Genetic background may be responsible for the differences in effects observed in the different commercial populations analyzed. The polymorphisms, or DNA markers, can potentially be incorporated into breeding programs to improve overall meat quality and hence the economic value for the pork supply chain and quality products for consumers.

STUDY OF THE EFFECT OF THE SEXUAL CONDITION ON THE pH AND TEMPERATURE OF MEAT FROM CROSSBRED BRAHMAN TO THE 0 AND 24 HOURS POSTSLAUGHTER

Colmenarez, D[1].; Pargas, H[1].; Meléndez, S[1].; Ciria, J[2].

Background

The carcass and meat quality of ruminants is influenced by various factors such as transport (vehicle type, animals/m^2, and journey times), loading and unloading, stay of the animals in the slaughterhouses, type of stockyard, climate, and breed, among others. In a wide review, Ciria and Asenjo (2000) indicates that the genetic type, feeding, sex, age, season, handling during breeding or prior to slaughter can affect that quality. The low checking of these factors is a constant threat to the organoleptic, technological and sanitary quality of meat in Venezuela, and particularly in Lara state, opposed to the European Union and USA where some minimum conditions prior to the sacrifice are imposed by means of the "Animal Well-being" and the "Law of Humanitarian slaughter (Humane Slaughter act)", respectively. On the other hand, transport is an event highly stressor for the bovine (Van de Water et al., 2003), and might have a tremendous significance in Venezuela because of the existence of lines of high crossbred Brahman that they are easily excitable and susceptible to suffer of stress. Preslaughter conditions, therefore, can affect muscle pH, color, texture and water-holding capacity of meat.

Objectives

With the purpose of evaluating in the Venezuelan tropic the influence of the preslaughter parameters on the carcass and meat quality of crossbred Brahman, a series of experiments are carrying out. The pH and temperature at 0 and 24 hours postslaughter of young bulls, cows, heifers, and steers that arrive to the slaughterhouse were observed in this particular study.

Materials and methods

This study was developed at the Western Center Slaughterhouse localized in the semi-arid climate of Lara state, Venezuela with an annual half temperature between 22º and 28º Celsius, annual precipitations greater than 1000 mm and a relative humidity between 77 and 85%. A total of 78 crossbred Brahman animals were slaughtered as discriminated as followed. Thirty-eight young bulls (whole males) of 2.5 to 3.5 years old and average half carcass weight of 135.6 Kg and 15 steers (castrated males) of 2.5 to 3.5 years and average half carcass weight of 134.4 Kg. Twelve 2.5 year-old heifers with average half carcass weight of 83.4 Kg, and thirteen 3 to 6 years old cows with average half carcass weight of 95.8 Kg. The animals were loaded among 14:30 to 17:00, and traveled for 4 to 6 hours. Arrival in slaughterhouse occurred between at 20:00 and 20:30. The animals were placed by discharge lots in stockyard separated by metallic rails with free readiness of water. Stay time in slaughterhouse went from 11 to 12 hours. After giving a shower with cold water, the animals were stunned with gun of captive bullet in the cranial region. Chronological age was estimated through the dental characteristics, and approximately 25 minutes after the stunned state of the animal, both initial pH and temperature (pH O and Temp O) were measured in the Gracilis muscle of the half left carcass by using a pHmeter (3030N Neukum) with penetration electrode and sensor of temperature. A final pH and temperature (pH 24 and Temp 24) were also measured after 24 hours refrigerated. Values obtained were analyzed by the general lineal model of variant analysis of computer software SPSS, version 10.0 for Windows.

Results and discussion

Temp 0 of carcass were lower ($p < 0.01$) for young bulls than for cows, heifers and steers probably due to differences in the way genders handle the preslaughter stress. Sañudo (1992) explains that the females of calmer character increases the corporal temperature when suffering stress in the moment prior to the

sacrifice, accelerating glycogen degradation and glycolisis. The fat cover of the carcass might also affect the initial and final temperature by avoiding heat dispertion, since according to Aalhus et al. (2001), thicker back fat corresponded with slower temperature decline. Young bulls may deposit less fat cover because of their hormonal condition. On the other hand, Temp 24 was higher ($p < 0.01$) in steers and cows as compared to heifers and young bulls.

Table 1.Values of pH 0, pH 24, Temp 0, and Temp 24 in crossbred Brahman of different gender

	Young bulls	Cows	Heifers	Steers	Signification
pH 0	6,66a	6,52a,b	6,48b	6,51b	**
	±0,21	±0,26	±0,15	±0,21	
pH 24	5,90a	5,85a	5,64b	5,63b	**
	±0,20	±0,14	±0,08	±0,19	
Temp 0	35,01a	38,38 b,c	37,59b	39,50c	**
	±2,22	±1,91	±0,60	±0,99	
Temp 24	3,86a	6,58b	3,09a	9,58c	**
	±2,36	±1,79	±0,58	±1,93	

* * Significative difference (p = 0.01)
Differents letters in the same row means significant differences between young bulls, cows, young bulls and heifers. (p = 0.01).

The pH 0 and pH 24 were higher ($p < 0,01$) for the young bulls than all the other groups evaluated. These results suggest a greater glycogen consumption preslaughter (Mojto et al, 1998), because of greater physical activity, biggest excitability, maintained muscular contraction and catecolamines hipersecretion before the sacrifice (Tarrant, 1981). In fatigued animals prior to sacrifice, the pH descends little and very slowly, because glycogen depletion which causes elevated values of final pH (Sañudo 1992).

The steers and heifers had lower values of pH 24 ($p < 0,01$) as compared to the cows and young bulls, however, the total average of pH 24 (5,79) is higher than the observed in other studies (Page et to the, 2001), which could indicate that the preslaughter conditions are significantly affecting muscle glucogen in this group of animals.

Conclusions

With the material and used methods, and starting from the results obtained in this study and lower these experimental conditions, we can conclude that the sexual condition has influence in the initial and ultimate pH and temperature of the meat of crossbred Brahman.

Background

Little is known about the combined or interactive effect of growth rate and final weight of pigs on pork carcass and meat quality characteristics. Increasing slaughter weight has the advantage of reducing overhead costs per unit weight of output for producer, slaughterer and processor, increasing carcass yields, improving meat to bone ratio and reducing chilling and processing losses (Ellis and Bertol, 2001). However, research showed that starting from 100 kg live weight each increment of 10 kg in body weight leads to a slightly lower average daily gain, a significant deterioration in feed efficiency, reduced lean deposition and poorer meat quality (Albar et al., 1990; Cisneros et al., 1996; Latorre et al., 2004). To get to heavier weights without affecting carcass leanness, the simplest approach is to restrict the amount of feed supplied to the animal, especially in the later stage of the finishing period when fat deposition rates increase dramatically (Ellis et al., 1996; Candek-Potokar et al., 1998). However, this practice may eventually lead to negative age-related effects, such as slower growth rate and reduced intramuscular fat content and, consequently, poorer quality of pork meat (Candek-Potokar et al., 1998). The use of modern, high-lean growth potential genotypes may represent a valid solution as in theory they can be taken to heavier weights without compromising growth performances and carcass traits.

Objectives

The aim of this project was to evaluate the effects of growth rate, sex and slaughter weight on carcass and meat quality traits in commercial pigs.

Materials and methods

A total of three hundred and forty (340) Duroc x (Landrace x Yorkshire) crossbred piglets were allotted into 28 pens and raised until slaughter at the experimental farm of the Centre de développement du porc du Québec (CDPQ) in Deschambault (QC, Canada). The animals were equally distributed according to an experimental design including the following independent variables: 1) growth rate, which was set according to two different EBVs (estimated breeding values) for age at 100 kg (fast growth: around -10 days and slow growth: around + 2 days) of the sire-line, 2) the sex (barrows and gilts) and 3) the liveweight at slaughter (107, 115 and 125 kg). The selected sire-lines had similar EBVs for backfat thickness at 100 kg slaughter weight. At the end of the finishing period, a sub-population of 119 pigs (10 carcasses per treatment) was selected for the carcass and meat quality evaluation trials.
After slaughter, warm carcass weight (kg) and loin eye area (cm^2) between the 3rd and 4th last ribs level were recorded. After conventional overnight chilling, one side of each carcass was dissected in order to estimate the effects of the treatments on the proportions of the lean, fat and bone tissue in the carcass. Full dissection did not include the front shank and the belly. Meat quality was assessed on the *longissimus* (L) muscle by measuring pH1 on the day of slaughter (45 min. post mortem) and ultimate pH (pHu), drip loss (%) and light reflectance (Minolta Chromameter CR 300) at 24 h post mortem. Furthermore, L muscle chops were ground and frozen pending the analysis of dry matter,

collagen and collagen heat-solubility, protein and intramuscular fat (IMF) content (Soxtec extraction with ethanol and dichloromethane). All analyses were conducted as described by AOAC (1990). Data were analysed according to a 2 x 2 x 3 factorial design by using the GLM Procedure of the SAS System (SAS, 1999).

Results and discussion

The selection by the EBV for growth rate of the sire-line successfully led to a difference in the age at slaughter, with pigs from the high growth rate line being a week younger than the slower growth rate ones. As liveweight at slaughter increased there were significant increases in hot carcass weight ($p<0.001$) and dressing percentage ($p<0.05$) (Table 1). These results are in agreement with those reported by Garcia-Macias et al. (1996) and Candek-Potokar et al. (1998). However, contrary to Garcia-Macias et al. (1996) and Beattie et al. (1999), in our study the increase of carcass weight did not result in a variation of lean and fat proportions (%). Globally, loin eye area (LEA) increased ($p<0.001$) with weight and gilts showed greater loin eye area than barrows. Loin eye area was dependant on a significant triple interaction of treatments. LEA increased with weight and this effect was more pronounced and larger in gilts. Main variation, however, arose from fast growing barrows which have readily completed their cross sectional muscle growth as they reached 115 kg, while, in opposite, a late but rapid development occurred from 115 to 125 in the slow growing ones which attained a LEA comparable to that of gilts of the same group. Final LEA of fast growing barrows was much smaller at 125 kg than that of the three other sex and growth rate combination of treatments at the same weight. Bone proportion was globally affected ($p<0.05$) by sex and growth rate, with gilts and slower growing pigs having higher proportions than barrows and fast growing pigs, respectively. However, a significant triple interaction also characterizes bone content (%). Percentage in gilts increased with weight, but the slope was more pronounced in the fast growing group, although slower gilts displayed a larger overall content. Slower growing barrows had lower bone content than their female counterpart and the changes from 107 to 125 kg followed a "V" shape pattern, while the opposite characterized faster growing barrows. These results are in contrast with Beattie et al. (1999) who reported a clear effect of weight increase on bone proportion in the carcass.

As already observed by Cisneros et al. (1996) and Eggert et al. (1996), gilt carcasses had higher ($p>0.001$) lean proportion and, thus, lower ($p>0.001$) fat proportion than barrow. Furthermore, slower growing pigs had a higher lean and lower fat proportion compared to high growth rate pigs, similar to McGloughlin et al. (1988) who have reported a negative relationship between high growth rate and carcass quality in Duroc parental line of pigs.

Muscle pH, drip loss and reflectance values were not affected by growth rate, sex and slaughter weight (Table 2). Except for Latorre et al. (2004), who reported a higher initial pH in the semimembranosus muscle and a lower L* value in the longissimus muscle with a weight increase from 116 to 133 kg, no consistent pattern of changes in these pork quality traits with weight have been reported in the literature (Eggert et al., 1996; Ellis and Bertol, 2001).

Only protein, IMF and collagen contents were affected by the factors under study. Protein was affected by slaughter weight and sex. Indeed, a lower ($p<0.05$) muscle protein content was found at 107 kg compared to 115 and 125 kg in the L muscle of both growth rate pigs. The effect of weight on protein content is in disagreement with a number of studies which showed inconsistent changes in protein content with slaughter weight (Ellis and Bertol, 2001; Latorre et al., 2004). In accordance with Latorre et al. (2004), muscle protein content was higher ($p<0.05$) in gilts than in barrows. As reported by several authors (Beattie et al., 1999; Ellis and Bertol, 2001; Latorre et al., 2004), no change in IMF was observed with increasing slaughter weight. On the other hand, IMF content was higher in barrows ($p<0.01$) than in gilts, as found by Barton-Gade (1987) and Van Oeckel and Warnants (2003). Contrary to Candek-Potokar et al. (1998) and Beattie et al. (1999), slaughter weight did not influence dry matter and total collagen content. However, the content of heat-soluble collagen content decreased ($p<0.001$) with weight. This may mean that tenderness of cooked pork

could be somewhat reduced in heavier animals, as already reported by Ellis et al. (1996) and Candek-Potokar et al. (1998).

Conclusions

Generally, the results of this study suggest that pigs can be slaughtered at heavier weights without compromising carcass quality and meat quality. However, given the lower lean proportion found in the fast growing genotypes used in this study, the increase in slaughter weight should be combined with appropriate genetics in order to avoid economical losses.

ANALYSIS OF THE RELATIONSHIP BETWEEN DNA POLYMORPHISMS IN CANDIDATE GENES AND BEEF TENDERNESS

Costello, S.[1], O'Doherty, E.[1], Mullen, A.M.[1], Kim, K.-S.[3], Ernst, C.W.[3] and Sweeney, T.[2]

Background

The factors underlying meat quality, while poorly understood, have a molecular basis, which are responsive to nutrition, environment and animal breeding. Major progress is being made worldwide in identifying variations in DNA (polymorphisms) which are related to genes influencing meat quality, growth and carcass yield. Some of these polymorphisms may have the potential to serve as markers of meat quality. These include polymorphisms in the calpain I and II and growth hormone genes. The calpain family are postulated to affect meat quality by initiating muscle protein degradation. Exons 9 and 14 of the calpain I gene were found to contain single nucleotide polymorphisms (SNPs), predicted to alter the protein sequence of calpain I. Analysis of these polymorphisms with Warner Bratzler shear force (WBSF) values showed that a relationship existed between the alleles containing the SNP and decreased meat tenderness (Page et al., 2002). A restriction fragment length polymorphism (RFLP) in the calpain II gene has also been identified (Zhang et al., 1996), which may have an effect on meat quality. Growth hormone has proven to be the major regulator of postnatal growth and metabolism in mammals and thus affects growth rate, body composition, health, milk production, and aging by modulating the expression of many genes. PCR-RFLP analysis was used to identify a polymorphism in intron 3 of the bovine growth hormone gene (Zhang *et al.,* 1993). A population of Piedmontese cattle was genotyped for this growth polymorphism and an association was found between WBSF at day 11 post-mortem and the polymorphic allele of bovine growth hormone (Di Stasio *et al.,* 2003).

Objective

The objective of this study was to evaluate the association of polymorphisms in bovine Calpain I exon 9 and 14, Calpain II and Growth Hormone genes with tenderness in Irish bovine *M.longissimus dorsi*.

Materials and methods

Genomic DNA was isolated from 25mg of *M. longissismus dorsi* muscles (n=284) on which quality attributes were also characterised, using the QIAamp® DNA minikit. Tenderness was measured by WBSF (Shackelford, 1991). Compositional analysis was conducted to determine any variation in intramuscular fat, protein and moisture levels. Sarcomere lengths were determined according to the laser diffraction method (Cross *et al.,* 1980). Polymerase Chain Reaction (PCR) was performed using primers specific for calpain I exon 9 and 14 (Costello et al., in preparation), calpain II (Zhang et al., 1996) and growth hormone genes (Zhang et al., 1993). Restriction digests were carried out using the restriction enzymes *Btg*I (calpain I exon 9), *DpnII* (caplain I exon 14) *HhaI* (calpain II) and *Msp*I (growth hormone). Digests were analysed on agarose gels using electrophoresis (Figure 1).

Associations between the four polymorphisms and WBSF day 14 values were tested using the GLM procedure of SAS. Association analysis was performed between the observed genotypes and WBSF at day 14 post-mortem. In a controlled data set, confounding factors were excluded, in particular animals with extreme values of sarcomere length and intramuscular fat (IMF). For sarcomere length, cut off points of 1.4µm and 1.85µm were employed. Samples with percentage of IMF greater than 5% were also removed from the sample set.

Results and discussion

A significant association was observed between the calpain I exon 9 genotypes and WBSF in both the controlled ($P = 0.0333$) and uncontrolled ($P = 0.0033$) data-sets (Tables 1 and 2). Animals with the

GA genotype exhibited decreased WBSF when compared to animals with the GG genotype. No association was observed between WBSF and calpain I exon 14 genotypes in either sample set. The V to I transition occurred in domain III of the protein, representing a conservative substitution of non-polar amino acids with no apparent function in terms of calpain enzyme activity. In contrast the G to A transition, which occurs in domain II of the protein, which has been identified as the proteolysis domain, thus this polymorphism could alter calpain I enzyme activity.

No significant association was observed between the growth hormone or calpain II polymorphisms, and WBSF. Di Stasio *et al.,* (2003) observed a significant association between the C allele of growth hormone and WBSF at day 11, but cautioned that the statistical model used to calculate the effect could lead to biased estimates of single gene effects, and that the highly unbalanced genotype distribution observed was undesirable for association analysis. However, our observed genotypic and allelic frequencies indicate that there is a higher frequency of C alleles over D alleles in general. Low frequencies for the D allele have previously been observed across Northern European breeds (Lagziel *et al.,* 2000), suggesting difficulties in finding a "balanced" genotype distribution in the Irish national herd.

Conclusions

It was found that the calpain 1 exon 9 genotypes had a statistically significant association with WBSF such that animals with the GA genotype exhibited decreased WBSF and increased tenderness, when compared to animals with the GG genotype. This observation concurs with that of earlier studies (Page *et al.,* 2002), strongly suggesting that this polymorphism is a functional marker for increased beef tenderness. None of the other genotypes examined were observed to have an effect on tenderness.

Note: Genotypes were assigned according to published literature. Genotypes for calpain I exon 9 and exon 14 refer to the coded amino acid (ie Exon 9: G refers to the amino acid glycine, A refers to alanine; exon 14: V refers to valine, I refers to isoleucine). Genotypes for calpain II and growth hormone were arbitrarily assigned.

FEEDING PROTEIN DEFICIENT DIETS DURING THE GROWER PHASE INCREASES INTRAMUSCULAR FAT DEPOSITION AND IMPROVES EATING QUALITY OF PORK

D'Souza D.N.[1], Dunshea F.R.[2], Pethick D.W.[3], Pluske J.R.[3], Mullan B.P.[1]

Background

The Australian pork industry has implemented significant changes to its production systems to produce leaner and 'healthier' pork. This has seen the introduction of leaner genetic lines, improved feed formulations, and the use of metabolic modifiers to improve carcass leanness. The gains in 'carcass leanness' have resulted in reduced intramuscular fat (IM fat) levels or marbling, and the perception is that pork is now tougher, less moist and has reduced flavour. Recent studies have shown that IM fat levels in male and female pigs are as low as 1% in some genotypes while in others, levels can vary between <1% to 4% (Channon *et al*., 2001).

Cisneros *et al*. (1996) investigated the use of nutrition to improve the quality of pork and reported that reducing the protein to energy ratio of the finisher phase increased IM fat deposition, but was also associated with a corresponding increase in carcass fat and decreased feed conversion. However, results from a recent pilot experiment (D'Souza *et al*., 2003) indicated that feeding individually housed pigs grower diets with 15% reduced protein to energy ratio, and grower and finisher diets restricted in Vit A improved the IM fat levels in the *Longissimus* muscle from 1.3% to 2%. Also, the improvements in IM fat did not negatively affect the subcutaneous fat levels of the pigs. The highest IM fat levels (2.7%) were obtained when pigs were fed a 30% reduced protein to energy ratio diet. However, this increase was accompanied by a negative impact on growth performance and increased subcutaneous fat.

Objectives

The objectives of this experiment was to (i) determine if feeding pigs either a grower diet with 15% reduced protein to energy ratio, or grower and finisher diets restricted in Vit A increased IM fat in pigs under commercial conditions without affecting growth performance and carcass quality, and (ii) to determine if nutritionally increased IM fat in pigs resulted in improved eating quality of pork.

Methods

A total of 63 Large White x Landrace x Duroc crossbred female pigs of similar age were used in this experiment. At approximately 14-16 days of age the pigs were transported to the Department of Agriculture, WA, Research Unit, Medina, and group housed in an environmentally controlled weaner room for three weeks (15-20kg LW), after which they were moved to a naturally ventilated experimental grower/finisher shed. The pigs were group-housed (7 pigs per pen). The pigs were stratified on a weight basis and randomly allocated to one of the 3 diet treatments. The dietary treatments were (i) Control (commercial grower and finisher diets), (ii) 15% reduced protein to energy ratio during the grower growth phase (commercial diet during the finisher growth phase), and (iii) Vit A restricted diet during the grower and finisher growth phase (commercial finisher diet without any added Vit A). All pigs had *ad libitum* access to feed, and water via nipple drinkers. At 23 weeks of age, the pigs were transported to a commercial abattoir and slaughtered according to standard commercial procedures.

Carcass weight and depth of backfat (Hennessy probe) were measured on the hot carcass as per commercial practice. Intramuscular fat in the *Longissimus thoracis* was chemically determined using the method of direct soxhlet extraction of fat by a solvent (hexane) and expressed as the weight percentage of wet muscle tissue (AOAC, 1990). The pH of the *Longissimus thoracis* muscle between the 12th and 13th rib was determined at 24h (pH_u) post-slaughter using a portable pH/temperature meter (Jenco Electronic Ltd, Model 6009) fitted with a polypropylene spear-type gel electrode (Ionode IJ42S, Brisbane, QLD) and a

temperature probe. Drip loss from the *Longissimus* muscle was measured using the filter paper method (Honikel, 1987). Surface lightness (L^*) of the *Longissimus* muscle was measured using a Minolta Chromameter CR-400, using D_{65} lighting, a 2^o standard observer and a measuring aperture of 8mm, standardised to a white tile. Loin samples were also used to measure cook loss and shear force. Shear force of the cooked sample was determined using a Warner Bratzler shear blade fitted to an Instron Universal Testing Machine.

One hundred and fifty boneless *Longissimus thoracis* steaks were used for the sensory analysis in this study. The steaks were individually vacuum packaged and frozen approximately 24 hours post-slaughter. Ten pigs per treatment were used. Five steaks per loin (12cm portion between the 10th and the 14th rib, 2 cm thick) were used. Thirty-two boar taint free *Longissimus* steaks (20mm thickness) were also collected for use as "warm-up steaks" during the cooking of pork samples. The steaks were thawed and cooked according to a standard protocol. The pork steaks were cooked using a Silex flat-plate grill for approximately five minutes to a standardised degree of doneness (medium/well-done, 190°C until an internal temperature of 75°C was reached). The cooking method ensured that steaks were not contaminated with flavour components from other steaks being tested concurrently. The cooked steaks were rested for 2 min, cut into half (width-ways) and immediately presented to consumers for evaluation. Consumers assessed the steaks for odour, tenderness, juiciness, flavour and overall acceptance using a line scale where 1 = dislike extremely to 100 = like extremely. The consumer taste panel were also asked to grade the pork into one of 5 quality grades where, 1 = unsatisfactory, 2 = below average, 3 = average, 4 = above average, 5 = premium

Results and Discussion

The results indicate that there was no significant difference ($P>0.005$) in carcass weight and carcass dressing % between the dietary treatments. There were no significant differences ($P>0.05$) in P2 backfat depth between the dietary treatments. The results indicate that pigs fed the 15% reduced protein:energy diet had significantly higher ($P<0.05$) IM fat levels (1.8%) compared to pigs fed the control (1.4%) and the Vit A restricted diets (1.5%). These results are in contrast to that reported by D'Souza *et al*. (2003) where pigs fed either the 15% reduced protein to energy ratio diet, or the vitamin A restricted diet had significantly higher IM fat levels compared to pigs fed the control diets.

It has been hypothesised that the effect of Vit A on IM fat deposition is mediated by retinoic acid, a derivative of Vit A, which regulates the adipogenic differentiation of fibroblasts, inhibiting the terminal differentiation of intramuscular adipose tissue in cattle (Kuri-Harcuch, 1982). It has also been proposed that retinoic acid regulates growth hormone gene expression (Bedo *et al*., 1989), which in turn decreases fat deposition and marbling in steers (Dalke *et al*., 1992). The results from the previous study by D'Souza *et al*. (2003) indicated that feeding pigs a Vit A restricted diet during the grower and finisher phase significantly lowered liver Vit A levels compared to the pigs fed a control diet. Hence it is possible that the Vit A levels in the Vit A restricted pigs in this experiment were not depleted sufficiently to result in increased IM fat levels. A similar variable response to Vit A restricted diet has been observed in cattle. Vitamin A depletion was found to be dependant Vit A levels at birth of the new born calf (in turn dependant on its the mother's Vit A levels) and hence time taken to deplete the Vit A levels sufficiently to increase IM fat levels was significantly different (D. Pethick, Personal communication).

Pork from the 15% reduced protein:energy treatment had significantly lower ($P=0.010$) ultimate muscle pH, was paler ($P=0.004$) (higher L*) and had a higher ($P=0.006$) b* value (yellowness-blueness) compared to pork from the control treatment group. There was no significant difference ($P>0.05$) in surface exudate, cook loss % and shear force of pork between the dietary treatments. The sensory pork quality results indicate that there was no significant difference ($P>0.05$) in aroma and flavour of pork from the different dietary treatments, although pork from pigs fed the 15% reduced protein:energy diet tended to have better flavour ($P=0.098$) scores compared to pigs fed the Vit A restricted diet. Pork from pigs fed the 15% reduced protein:energy diet was considered to have the best ($P=0.001$) juiciness, tenderness, and overall acceptability, followed by pork from the control treatment, while pork from the Vit A restricted diet was least preferred. Although significantly higher ($P=0.004$), consumers rated the pork from pigs fed the 15% reduced protein:energy diet with the same quality grade (ie Grade 3) compared to pork from control pigs.

Threshold levels of IM fat required for optimal eating quality have been reported to be about 2.5 % (Bejerholm and Barton Gade, 1986). While the IM fat levels in the 15% reduced protein to energy diet group in this experiment were below the threshold levels required for optimal eating quality, the pork was considered to have better juiciness, tenderness and overall acceptability compared to pigs fed the control and the Vit A restricted diet. However, the quality grade assigned by the consumer panel in this experiment suggests that consumers still class the eating quality of pork from the 15% reduced protein to energy diet treatment as having average eating quality and being similar to pork from the control diet treatment. This suggests that the IM fat levels needs to be near or above the threshold of 2.5% to significantly improve the eating quality of pork to a higher quality grade (ie quality grade 4 or 5).

Conclusions

The results from this experiment indicate that feeding pigs a 15% reduced protein to energy ratio diet significantly increased IM fat levels compared to pigs fed a control diet and pigs fed a Vit A restricted diet during the grower and finisher growth phase. Pork from pigs fed the 15% reduced protein to energy ratio diet were found to have better tenderness, juiciness and overall acceptability scores compared to pork from the control and Vit A restricted diet treatments.

Background

Climate conditions may affect significantly the quality of meat post mortem. Pigs are particularly sensitive to high tempertures (Lengerken and Hennebach, 1980; Church and Wood, 1992). Ludvigsen, according to Briskey (1964) has found pale, soft and exudative (PSE) muscle incidence to be higher in warmer periods. Patricia Barton-Gade (1971), in Denmark, found more PSE meat in summer and autumn, than in winter. Krzecio et al. (2001), were investigating different HAL genotypes in different seasons and pointed to higher incidence of PSE meat in spring-summer compared to autumn-winter. However, Schepper (1971), in Germany, found PSE and DFD meat incidences to be higher in autumn and winter than in spring and summer. Danica Manojlović and Rahelić (1978) found almost two times higher incidence of PSE meat in the period when the climare factors are changing, e.g. spring and autumn than in summer and winter. Okanović et al. (1992) showed that the highest incidence of PSE meat, regarding total mass of ham, is in spring.

Objectives

The objective of this study was to investigate the influence of seasons on quality of halves and meat of three-race pigs determining the incidence of different quality *M. semimembranosus* (RFN, RSE, PSE, DFD) on the basis of technological parameters: pH_i, pH_u, WHC and L* and our criteria for quality estimation (Tomović, 2002; Natalija Džinić et al., 2003, 2004)).

Materials and methods

The investigations included 43 pigs of three-race hybrids, from the crosbreeding program performed at a farm in Serbia and Montenegro. The pigs were slaughtered and investigated in autumn (n=14), winter (n=13), and spring (n=16). The pigs were fed standard feed during fattening, and heads of approximately uniform age and mass were transported to the slaughterhouse. After a night rest, the pigs were stunned, debleeded and processed by the standard technological procedure.

Meat yield (%) was determined by partial dissection method (Walstra and Merkus, 1996) of cooled left halves.

The pH_i was determined on right halves 45 min post mortem, and pH_u 24 hrs p.m. in *M. semimembranosus* (MSM), caudo-medial part, using the pH-meter ULTRA X, type UX 390, Gronert (Germany) INGOLD penetrating electrode.

Samples (200 – 300 g) taken from the caudo-cranial part (MSM) were used 24 hrs p.m. for the determination of colour, water holding capacity (WHC), marbleness and chemical composition. The color was determined sensorily (1 – very pale; 7 – very dark) and with MOM Color 100 and the color characteristics were expressed in CIE L*a*b* system (Robertson, 1977). WHC was determined by compression method and expressed as % of bound water (Grau and Hamm, 1953). Marbleness was determined sensorily, applying the analytical descriptive test (1 – without marbleness; 10 – very expressed marbleness).

The content of moisture, proteins, free fat and total ash was determined by standard methods (AOAC, 1999).

The incidence of different MSM quality in different seasons was determined on the basis of parameters and criteria for MSM quality: PSE: pH_i<5,8, pH_u<5,4, WHC<50%, L*>55; RSE: pH_i=5,8-6,0, pH_u=5,85-6,2; WHC=50-60, L*=50-55; RFN: pH_i>6,0, pH_u=5,4-5,85, WHC=60-70, L*=45-50; DFD: pH_u>6,2, WHC>70, L*<45).

Results and discussion

Significantly higher meat yield (P≤0,01) was found in halves of hybrids in spring (55,83%), compared with meat yield in halves of hybrids in winter (55,06%). However, it was not significantly higher in halves in autumn (55,32%) (P>0,05).

Table 1. Meat yield in halves determined in different seasons by partial dissection

Characteristic	Season			t – test		
	Autumn	Winter	Spring	A – W	A – S	W – S
Mass of halves (kg)	38,28±1,77	40,77±1,88	36,67±2,49	*	NS	NS
Meat yield in halves (kg)	21,18±1,6	22,77±1,41	20,43±1,32	**	NS	**
Meat yield in halves (%)	55,32±2,33	55,06±3,40	55,83±2,61	**	NS	**

NSP>0,05 *P≤0,05 ** P≤0,01

The investigation of technological characteristics (Table 2) showed that the average pH_i (6,27) and pH_u (5,63) measured in MSM of three-race hybrids were significantly higher (P≤0,01) in autumn compared with the same parameters in winter (6,08 and 5,53), but not in spring. The average pH_i values of MSM respond to the values of muscles which are potentially of normal quality (pH_i>6,0) (Tomović, 2002). WHC (%) of MSM in autumn was significantly higher (P≤0,01) compared with values determined in winter, but not compared with results in spring. The lowest WHC value (39,18%) was found in winter. On the basis of criterion for WHC, all investigated MSM are of PSE quality, on the average (WHC<50%).

Table 2. Effect of seasons on technological quality of *M. semimembranosus*

Characteristic	Season			t – test		
	Autumn	Winter	Spring	A – W	A – S	W – S
pH_i	6,27±0,22	6,08±0,24	6,06±0,31	**	NS	**
pH_u	5,63±0,11	5,53±0,07	5,53±0,15	**	NS	**
WHC (%)	44,55±7,9	39,18±6,73	41,64±7,27	**	NS	**
Marbleness	4,44±1,44	3,00±1,07	3,33±0,98	**	NS	*
Colour (sensory)	3,57±0,77	2,99±0,52	3,54±0,75	**	NS	**
L^*	53,15±2,49	51,39±2,49	51,02±3,41	**	**	NS

b*	13,81±1,26	8,97±1,02	7,33±1,87	**	**	NS
Moisture (g/100g)	76,09±0,36	75,92±0,41	75,56±0,71	**	*	**
Protein (g/100g)	21,65±0,35	22,14±0,39	22,35±0,44	**	**	**
Free fat (g/100g)	1,12±0,26	0,72±0,22	0,85±0,31	**	*	**
Total ash (g/100g)	1,18±0,05	1,24±0,22	1,24±0,2	**	NS	NS

The color – lightness L* – of MSM was also determined (Table 2). It was found that the investigated MSM were significantly lighter in autumn (L*=53,15) compared to winter (51,39%) and spring (L*=51,02). According to our criteria for L*, the investigated MSM were of PSE characteristics, on the average, in all investigated seasons. The moisture content of MSM in autumn was significantly (P≤0,05) and highly significantly (P≤0,01) higher (76,09) compared to winter, e.g. spring. The sensory assesment showed that the

average color of MSM was significantly lighter (P≤0,01) in autumn (3,57), compared to winter, however not significantly lighter compared to spring. The average grade for marbleness of MSM in winter (3,0) was significantly lower (P≤0,01) and (P≤0,05) compared to autumn, e.g. spring. The differences in protein content of MSM in different seasons are significant (P≤0,01), however, it was also found that the protein content was higher than 21% in all MSM samples. This is an important finding, since this aim has to be fulfilled in contemporary breeding of pigs (Vidović, 1999).

The analysis of average technological quality of MSM of three race hybrids, in different seasons, confirmed that the seasons affect the quality of meat.

On the basis of criterion for pH_i, it was found (Table 3), that the highest potential incidence of PSE characteristics of MSM was in spring, 31,25%, and significantly lower in autumn (7,7%). Further, on the basis of criterion for pH_u, all investigated MSM were of RFN quality in winter, 7,2% of MSM were of RSE quality in autumn, and 6,7% of MSM were of DFD characteristics in spring. According to criterion for L*, it was found that the highest incidence of PSE characteristics in MSM was in spring (50%), and the highest incidence of RSE characteristics of MSM, 64,3%, was found in autumn.The obtained results further show that according to criterion for WHC, all MSM in winter were of PSE quality, e.g. 81,2% and 71,6% in spring and autumn, respectively.

Table 3. Effect of seasons on incidence of different meat quality of *M. semimembranosus* in halves of three race hybrids

Parameters	Quality	Season		
		Autumn	Winter	Spring
pH_i	PSE (%)	0	7,7	31,25
	RSE (%)	21,4	23,1	12,5
	RFN (%)	78,6	69,2	56,25
pH_u	PSE (%)	0	0	0
	RSE (%)	7,2	0	0
	RFN (%)	92,8	100	93,3
	DFD (%)	0	0	6,7
L*	PSE (%)	28,6	15,4	50,0
	RSE (%)	64,3	46,2	37,5
	RFN (%)	7,1	30,7	12,50
	DFD (%)	0	7,7	0,0
WHC	PSE (%)	71,6	100	81,2
	RSE (%)	21,3	0	12,5
	RFN (%)	7,1	0	6,3
	DFD (%)	0	0	0

Conclusions

The highest average meat yield in halves of three-race hybrids was found in spring (55,83%), and the lowest in winter (55,06%) (P≤0,01). The investigated MSM, in all seasons, were on the average of PSE and RSE quality regarding criteria for WHC e.g. color L*, respectively. The highest incidence of normal quality 100% (according to criterion for pH_u) and 30,7% (criterion for L*) was in winter. The incidence of MSM of normal (RFN) quality was 7,1%, according to criteria for color L* and WHC in autumn. In spring, 12,5% and 6,3% of MSM were of normal quality, according to criteria for color L* and WHC, respectively. Accrding to criterion for color L*, the highest incidence of PSE quality (50%) was found in spring. According to criterion for WHC, 100%, 81,2% and 71,6% of MSM was of PSE quality, from carcasses of pigs slaughtered in winter, spring and winter, respectively.

MECHANICAL STIMULATION OF C2C12 CELLS INCREASES M-CALPAIN EXPRESSION, FOCAL ADHESION PLAQUE PROTEIN DEGRADATION AND CELL DIFFERENTIATION

Alberto Grossi and Moira A. Lawson

Department of Food Science, Royal Veterinary and Agricultural University, Frederiksberg C, Denmark

Background

The process of muscle growth is a central issue in the business of producing animals for meat. At the most fundamental level, the process of muscle development and growth is a complex sequence of events whereby muscle cells respond to a number of stimuli in order to form organised muscle tissue. Increase in muscle mass is greatly influenced by the rate of skeletal muscle protein synthesis, a process that can be altered by mechanical forces. Stretch- or load-induced signaling is now beginning to be understood as a factor which affects the mass and phenotype of muscles as well as the expression of a number of proteins within muscle cells (Carsen *et al.,* 1996; Winchester *et al.,* 1991). Use of magnetic field to produce mechanical forces to stimulate cell populations has been well documented (Glogauer *et al.,* 1998). Magnetic field stimulation has been shown to affect transcription of specific gene sequences, protein synthesis, the immune system and increase in Ca^{2+} influx (Tatsumi *et al*, 2002).

The past 10 years has seen a dramatic increase in the understanding of how proteolytic enzymes such as calpains can affect the growth of muscle (Goll et al, 1992). In vivo studies have shown that m-calpain is necessary for myoblast fusion leading to the formation of muscle fibres (Barnoy et al., 1998; Joffroy et al., 2000), and that inhibition of this enzyme restricts myotube formation (Temm-Grove et al., 1999). Whether there is a link between stretch- or load induced signaling and m-calpain expression and activation is not known.

Objectives

The purpose of this study was to investigate the role of mechanical signals in m-calpain induced muscle cell fusion. The specific goal of this work was to determine whether a mechanically stimulated cell population showed differences in expression and localization of m-calpain, an enzyme required for myotube formation in vitro.

Materials and methods

C2C12 cells from ATCC (American Type Culture Collection, Manassus, VA), were maintained under a 5% CO_2 stream at 37°C, plated at 7,500 cells/cm^2 on tissue culture surfaces and grown to 75% confluence in DMEM containing 10% foetal calf serum (FCS).

For stimulation experiments, cells were incubated with laminin or fibronectin coated 1 μm Encapsulated Super-Paramagnetic Microspheres (EMI- 100/40) for 30 minutes to allow for bead attachment and then rinsed to remove unattached beads. Stimulated cultures were placed on a heating plate maintained at 37 °C under the electromagnet for a period of 6 hrs. Control cultures were kept in incubator at 37 °C during that period. Where indicated, cells were incubated for 1 h at 37°C in PBS containing a 1:100 dilution of anti-integrin blocking antibody prior to the attachment of the microspheres.

A magnetic field of 0.5 mT was generated by an electromagnet (Power Generator 0-30 Volts, 0.1-100 Hz; Elcanic A/S, Denmark). The magnet produced alternating MF at frequency of 1 Hz. Magnet was placed 10 mm over the monolayer of cells during the stimulation period. Cells lacking beads but placed under the magnetic field were used as an additional control.

For immunohistochemical analysis, cells were fixed with 4% paraformaldehyde, permeabilised with saponin and stained the indicated primary antibodies, followed by Alexa 488 secondary antibodies (Molecular Probes, Eugene Oregon). Images were obtained using a Leica DmIRB inverted microscope (Leica, DK) couples to a Coolsnap digital camera (Roper Scientific, DE). Images were obtained and analysed using the Image Pro Plus system (Image House, DK).

The activity of the enzyme creatine phosphokinase (CPK) increases as myoblasts fuse into myotubes. The level of CPK was therefore assayed as a measure of cell differentiation and myotube formation in the different culture conditions, using the CPK assay kit (Sigma, St. Louis, MO), on cell suspensions whose total protein concentration was determined using a BCA kit (Pierce, Rockford, IL), on homogenised cell suspensions.

Results and discussion

Cells mechanically stimulated with laminin coated microspheres show increased CPK activity. The activity of CPK increases as myoblasts differentiate into myotubes. When cells were stimulated with laminin coated microspheres, the CPK activity seen in the culture rose approximately 40% (Figure 1). Similar increases were not seen in any of the control cultures, whether they were exposed to the magnetic field in the absence of spheres or had the microsperes present without being exposed to the magnetic field. No differences in CPK activity were seen when cells were stimulated with fibronectin coated beads. or in cell populations that had been stimulated with fibronectin coated microspheres. These results indicate that mechanical stimulation of myoblasts through laminin but not fibronectin receptors can significantly stimulate myoblast differentiation. Additionally, the response was not due to the simple binding of spheres to ECM receptors or to the exposure of cells to a magnetic field.

Expression of m-calpain but not μ-calpain is up regulated in cells exposed to mechanical stimulation. M-calpain is thought to be an essential enzyme in the differentiation and fusion of myoblasts. Cells mechanically stimulated with laminin coated microspheres express a higher amount of m-calpain, while the expression of the related enzyme μ-calpain is unaffected by this stimulation (Figure 2). Similarly, cells mechanically stimulated with fibronectin coated spheres do not show an increase in m-calpain expression (data not shown).

Mechanical stimulation through laminin receptors causes a re-localization of m-calpain to focal adhesion, followed by a disappearance of the enzyme from these regions. In control cells, m-calpain is found throughout the cytoplasm and in small quantities at the cell surface (Figure 3a). After 30 min. of mechanical stimulation, the amount of enzyme is increased in these focal adhesions, as it is in the whole cell (Figure 3b). 3 hours later, the amount of m-calpain in the cells remains high, but less is found in the focal adhesion sites (Figure 3c). The decrease in staining may be due to autolysis of the enzyme after activation.

Mechanical stimulation via laminin receptors leads to a breakdown of paxillin in focal adhesion complexes. m-calpain is known to associate with focal adhesion complexes at the cell membrane of muscle cells and focal adhesion proteins are known substrates for this enzyme. After mechanical stimulation of C2C12 cells via the laminin receptor, staining for paxillin is not longer found in punctuate regions on the cell surface (Figure 4). Similar results have been seen when cells are stained for talin, and β1-integrin, also known substrates for m-calpain (data not shown). Previous work in our laboratory has shown that blocking m-calpain activity with specific enzyme inhibitors blocks the breakdown of focal adhesion proteins on the cell surface.

Conclusions

Muscle cells are exposed to both a chemically and mechanically active environment during differentiation. During the developmental process, myoblasts come in contact with different extracellular matrix proteins, through which mechanical signals can be generated. We have shown that mechanical signals transmitted through the C2C12 cells interaction with laminin cause an increase in cellular differentiation. At the same

time, this signaling results in not only an increase in the expression of the proteolytic enzyme m-calpain, but a resultant breakdown of focal adhesion proteins on the cell surface. This breakdown may well be due to the activation and subsequent autolysis of the enzyme in this region.

BEHAVIOR OF CHICKEN BREAST MUSCLE MYOSIN SOLUBILIZED IN NEUTRAL AND LOW IONIC STRENGTH SOLUTIONS

Hayakawa, T., Wakamatsu, J., Nishimura, T. & Hattori, A.

Meat Science Laboratory, Graduate School of Agriculture, Hokkaido University, Kita-ku, Sapporo, Hokkaido 060-8589, Japan

Background

Meat, an essential food for humans, is a very rich source of proteins and contains all essential amino acids. However, its usage is limited because it is maintained in a solid state even after cooking. If the proteins in meat could be solubilized in water or a solution of low ionic strength, utilization of meat could be extended in various ways, as a liquid diet for elderly people. We have already established a method to solubilize more than 80% of chicken breast muscle myofibrillar proteins in water (Ito *et al*., 2003). To accomplish solubilization, it is essential to maintain myofibrillar suspensions at neutral pH with L-histidine (L-His) and low ionic strength and to disrupt the high-ordered structures of myofibrils by ultrasonication. Furthermore, we have shown that myosin prepared from chicken skeletal muscle, one of the major myofibrillar proteins, is also solubilized in a solution of low ionic strength by ultrasonication (Ito *et al*., 2002). However, it has not been determined whether ultrasonication and presence of L-His are essential for solubilization of myosin in a solution of low ionic strength.

Objectives

The objective of this study was to examine the behavior of myosin solubilized in neutral and low ionic strength solutions without ultrasonication.

Materials and methods

Myosin was prepared from chicken breast muscle (Perry, 1955) and solubilized in 0.6 M KCl, pH 6.5. Myosin was dialyzed against neutral and low ionic strength solutions containing 1 mM KCl and various concentrations of L-His. Each dialyzed myosin suspension was centrifuged for 120 min at 100,000×g, and the obtained supernatant was defined as water-soluble myosin. The solubility of myosin in low ionic strength solutions was determined.

SDS-polyacrylamide gel electrophoresis (SDS-PAGE) was performed according to the method of Laemmli *et al*. Water-soluble myosin molecules stained by the method of negative staining and subjected to rotary shadowing were observed under a transmission electron microscope. Gel-formation ability of water-soluble myosin was tested by heating for 10 minutes in a water bath at 70 °C.

Results and discussion

In the presence of L-His, myosin was solubilized in neutral and low ionic strength solution without ultrasonication (Figure 1). As shown in the SDS-PAGE patterns (Figure 2), water-soluble myosin contained intact heavy chains and light chains. The solubility increased with increase in the concentration of L-His to 7 mM. However, the solubility decreased when the concentration of L-His exceeded 10 mM. This indicates that the solubility is dependent on L-His concentration. The solubility was also dependent on protein concentration of myosin. When a water-soluble myosin solution was dialyzed against a solution of physiological ionic strength, myosin molecules aggregated and were precipitated by centrifugation. Therefore, it is concluded that water-soluble myosin maintains the ability of self-assembly under physiological conditions.

Using the method of negative staining, we observed that water-soluble myosin formed a very thin filament-like structure (Figure 3A, B). This structure clearly differed from the thick filament observed under the physiological condition. Also, using the method of rotary shadowing, we confirmed the existence of myosin monomers that have two heads and a long rod as do native myosin molecules (Figure 3C). The rod of water-soluble myosin was longer than that of native myosin soluble in a solution of high ionic strength (Figure 4). These observations indicate that water-soluble myosin in neutral and low ionic strength solutions

exists in two forms, separated monomers and very thin filament-like structures. Heating could not induce any gelation of water-soluble myosin.

Conclusions

Myosin is soluble in a solution of low ionic strength in the presence of L-His without ultrasonication. In such a condition, myosin molecules exist in two forms, separated monomers and very thin filament-like structures. The rod of the separated monomer is longer than that of the native myosin molecule. These results suggest that low ionic strength and L-His cause some conformational changes in myosin molecules resulting in lengthening of its rod portion. Water-soluble myosin could not be changed into gel by heating.

Background

Selection for growth rate is currently practiced in commercial sire lines of genetic schemes for rabbit genetic improvement (BASELGA and BLASCO, 1989; LEBAS et al., 1996). Meat rabbit production is based on three-way crosses. Does are crossbred females from lines selected by litter size, whereas terminal sires come from lines selected for growth rate. Selection for growth rate decreases food conversion rate and improves efficiency, but may decrease carcass and meat quality. In rabbits only two experiments have assessed the consequences of selection for growth rate in carcass and meat quality, PILES et al. (2000) and LARZUL et al. (2003). PILES et al. (2000) comparing a control group and a group selected for growth rate, found a worse water holding capacity of the meat in the selected group and a decrease in the fat content of the carcass, but did not find clear differences in fat content of the hind leg between groups. LARZUL et al. (2003) in a divergent selection experiment on 63 days weight found that, as body weight increases, the percentage of skin decreased, carcass yield was slowly affected and perirenal fat increased. However, at present there are not studies about the influence of selection for growth rate on the sensory properties of rabbit meat.

Sensory analyses are usually performed with small samples. Until now, classical statistics has been the usual way of expressing uncertainty with meat quality analysis, whereas Bayesian analysis have been mainly applied by animal breeders to solve complicated genetic problems (see BLASCO, 2001, for a review). An advantage of the Bayesian approach trough MCMC procedures is the possibility of easy construction of all kind of confidence intervals. This allows asking questions that we could not ask within the classical inference approach, or that had complex procedures to be answered. For example, we can find intervals of the type [k, $+\infty$) having a 95% of the probability area of the marginal posterior distribution. With these intervals we know that the probability of the trait of being lower than k is a 95%. We can also find the probability of finding relevant differences for a trait between two or more treatments. This gives a high flexibility to this type of analyses.

Objectives

Our objective is to study the effect of selection for growth rate on the sensory characteristics of rabbit meat. We use a Bayesian approach.

Materials and methods

Animal material

The animals used in this experiment were originated from a synthetic line selected for growth rate between the 4th and 9th week of life (ESTANY et al., 1992), in the Animal Science Department of Universidad Politécnica de Valencia. Embryos belonging to generation 7th were frozen, thawed and implanted in does in order to produce the control group. The procedure is described by VICENTE et al. (1999). The control group was formed from the offspring of the embryos belonging to the 7th generation, to avoid the effect of cryoconservation. Selected animals belonging to 21st generation were compared with animals of the control group. Control (C) and selected (S) groups were contemporary. Forty animals per group were slaughtered at 9-weeks-old. Animals were slaughtered at the abattoir on the farm, thus they did not suffer stress due to transport. No fasting was practiced. At 24 hours post-mortem the *Longissimus dorsi* muscles were dissected and vacuum packed and frozen at –20ºC until they were required for sensory analysis.

Sensory evaluation
A quantitative descriptive analysis (STONE et al., 1974) was performed by four trained tasters of rabbit meat in 20 sessions. The parameters evaluated were: intensity of rabbit flavour (IRF), aniseed odour (AO), aniseed flavour (AF), liver flavour (LF), tenderness (T), juiciness (J), fibrousness (F). The sensory analysis was carried out on samples of the *Longissimus dorsi* muscle following a complete block design (STEEL and TORRIE, 1980). Samples were vacuum packed and cooked in a water bath at 80ºC for 1 hour. Samples were cut into four pieces and distributed in such way to the panellist to eliminate any location effect within the loin.

Statistical analysis
As panellists had different ranges when scoring sensory traits, variables were transformed dividing by the standard deviation of each panellist, as recommended by (BROCKHOFF et al., 1996). The model used included, group (with two levels, S and C corresponding to selection and control groups respectively), panellist (four panellists), session (20 levels), muscle location (four zones) and sex effects. A Bayesian analysis was performed. Bounded flat priors were used for all unknowns. Data were assumed to be normally distributed. Marginal posterior distributions of all unknowns were estimated by using Gibbs Sampling. After some exploratory analyses we used one chain of 10,000 samples, with a burning period of 2,000, thus marginal posterior distributions were estimated with 8,000 samples each one. Convergence was tested for each chain using the Z criterion of Geweke. Details of the procedure can be found in SORENSEN and GIANOLA (2002).

In sensory analyses, it is difficult to determine what a relevant difference is, thus instead of assessing the differences between the selected and control populations, the ratio of the selection and control effects is analyzed. This is easily made from the results of the Gibbs sampling chains and allows expressing the superiority of the selected over the control population (or conversely the superiority of the control over the selected population) in percentage.

Results and discussion
Features of the estimated marginal posterior distributions of the sensory properties are presented in tables 1 and 2. Monte Carlo standard errors were very small. The Geweke test did not detect lack of convergence in any case. Posterior distributions of sensory properties were symmetrical. This is reflected in the similar values for means and medians, and in the symmetrical high posterior density interval around the mean.

Table 1 shows the features of the marginal posterior distributions of the ratio of the group effects, selection/control (S/C). When S/C >1, we consider that selected and control groups are different if the probability of S/C > 1 is more than 0.95 (*P>1* in table 1 more than 0.95). When S/C <1 we consider that selected and control groups are different if the probability of S/C < 1 is more than 0.95; i.e., when *P>1* in table 1 is less than 0.05. According to the values of *P>1* in table 1, there is a difference between selected and control groups for intensity of rabbit flavour (IRF), aniseed odour (AO), aniseed flavour (AF) and liver flavour (LF). Conversely, no differences were found in tenderness (T), juiciness (J) and fibrousness (F) between groups.

Selected group had a 3% higher value of IRF than control group, with a HPD(95%) from 1.00% to 1.07%. We consider that a relevant difference appears when one group is at least a 10% higher than the other one with a probability higher than 0.95 (Pr: probability of relevance). Although a selection effect appeared for IRF, this effect was not relevant, since the probability that the selected group being at least a 10% higher than the control group was only 0.01.

Conversely, a relevant effect of selection on aniseed odour (AO) and aniseed flavour (AF) appeared (Pr=1), with lower values for selected animals. By calculating the interval $(-\infty, k]$ of the marginal posterior distribution containing a 95% of the probability, we can assess the maximum value that the ratio S/C can have with a probability of 0.95. This value was a 0.69 and a 0.63 for AO and AF, respectively, which means that the probability of the selected group being higher than a 69% and a 63% of the control group respectively is only 0.05. These sensory attributes have been previously described in rabbit meat by OLIVER et al. (1997) and HERNANDEZ et al. (2000). The greater intensity of these attributes could provide positive

aromatic notes. In these sense, we could consider that selection for growth rate has a negative effect for aroma characteristics, although it is not clear that these differences could be detected by consumers.

An effect of selection for growth rate on liver flavour is also shown in table 1, being a 23% higher the selected group than the control, with a HPD (95%) from 1.03 to 1.44. This attribute is a common descriptor in meat flavour and it has been described previously in beef (FONT et al., 1995). OLIVER et al. (1997) and HERNANDEZ et al. (2000) reported the same descriptor in rabbit meat. These authors considered that an increase of liver flavour could have a negative effect on consumer acceptability. However, the probability that the selected group being at least a 10% higher than the control group was only 0.88, lower than 0.95 that it is minimum value that we have considered relevant.

Table 2 shows the features of the marginal posterior distributions of the ratio of the group effects, males/females (M/F). According to the values of *P>1* in table 2, there is a difference between males and females groups for intensity of rabbit flavour (IRF), with a 4% higher in males than in females. However, this difference was not relevant, since the probability that the selected group being at least a 10% higher than the control group was only 0.01. No differences were found for the rest of the characteristics evaluated.

Table 1. Sensory properties of rabbit meat. Features of the marginal posterior distributions of the ratio of the group effects, selection/control (S/C).

S/C	Mean	Median	HPD(95%)	*P>1*	Pr	k_1	k_2	MCse	Z

F	1.02	1.02	0.95, 1.09	0.70	0.01	1.08	0.96	0.0003	1.18

IRF: intensity of rabbit flavour. AO: aniseed odour. AF: aniseed flavour. LF: liver flavour. T: tenderness. J: juiciness. F: fibrousness.
HPD (95%): high posterior density interval at a 95% of probability. *P>1*: Probability of S/C > 1. Pr: Probability of relevance, the probability that one group being at least a 10% higher than the other group. k_1: limit of the interval $(-\infty,k_1]$ containing a probability of 95%. k_2: limit of the interval $[k_2,+\infty)$ containing a probability of 95%. MCse: Monte Carlo Standard error. Z: Z-score of the Geweke test.

Table 2. Sensory properties of rabbit meat. Features of the marginal posterior distributions of the ratio of the group effects, males/females (M/F).

M/F	Mean	Median	HPD(95%)	*P>1*	k_1	k_2	MCse	Z
IRF	1.04	1.04	1.00, 1.07	0.98	1.07	1.01	0.0002	-0.81
AO	1.03	1.02	0.83, 1.22	0.42	1.20	0.87	0.0010	0.14
AF	1.11	1.10	0.87, 1.37	0.80	1.34	0.91	0.0016	-0.56
LF	0.98	0.98	0.81, 1.14	0.40	1.13	0.84	0.0009	1.12
T	0.97	0.97	0.93, 1.01	0.09	1.01	0.94	0.0003	-1.54
J	0.97	0.91	0.91, 1.03	0.16	1.02	0.92	0.0003	-0.21
F	1.04	1.04	0.97, 1.10	0.84	1.09	0.98	0.0003	-0.47

IRF: intensity of rabbit flavour. AO: aniseed odour. AF: aniseed flavour. LF: liver flavour. T: tenderness. J: juiciness. F: fibrousness.
HPD (95%): high posterior density interval at a 95% of probability. *P>1*: Probability of S/C > 1. k_1: limit of the interval $(-\infty,k_1]$ containing a probability of 95%. k_2: limit of the interval $[k_2,+\infty)$ containing a probability of 95%. MCse: Monte Carlo Standard error. Z: Z-score of the Geweke test.

Conclusions

Selection for growth rate has not affected the main characteristics of meat rabbit, like tenderness and juiciness, but it has a negative effect for some flavor characteristics.

EFFECT OF ORGANIC RAISING AND BREED CROSS ON CARCASS AND TECHNOLOGICAL MEAT QUALITY OF GROWING/FINISHING PIGS

Anke Heyer[1], Kristina Andersson[2] and Kerstin Lundström[1]

[1]Department of Food Science, [2]Department of Animal Nutrition and Management, Swedish University of Agricultural Sciences, PO Box 7051, SE-750 07 Uppsala, Sweden

Background

The promotion of organic pig production is an EU-wide political goal. However, expansion of organic pig production is slow, possibly due to insufficient certitude about final product quality, such as carcass and meat quality. Carcass and technological meat quality traits of outdoor raised pigs are widely discussed in literature. Further, the breed cross may affect carcass and meat quality traits and therefore interact differently in indoor and outdoor housing systems.

Objectives

The aim of this study was to compare organic and conventional production systems of growing/finishing pigs with regard to their carcass and technological meat quality. Further, the influence of two different types of breed crosses on these quality traits was investigated.

Materials and methods

During two years, 280 growing/finishing pigs were raised to approximately 107 kg live weight in four different production systems; they were equally distributed to housing system (outdoor/indoor), breed cross (D*LW/L*LW) and gender (castrates/females). Outdoor pigs were fed *ad libitum*, with either an organic diet diluted with 20% alfalfa roughage throughout (org.dil.) or with first the diluted diet and thereafter this organic diet undiluted (org. dil./org. undil.). In two indoor treatments, pigs were fed restrictively with either the undiluted organic diet (org. undil.) or a conventional diet (conv.).

Hot carcass weight and back fat thickness over the middle of *M. longissimus dorsi* (LD) were recorded. Lean meat content was estimated as [lean meat percentage = -49.781 + (0.899* ham in carcass) + (0.612* meat and bone in ham) + (0.651*loin in carcass) + (0.252*meat and bone in loin) + 0.249 (for females)] (Hansson, pers. comm.). Ultimate pH (portable pH-meter equipped with a combination gel electrode SE104, Knick, Berlin, Germany, calibrated to chilling room temperature), internal reflectance (FOP, 900 nm; TBL Fibre Optics Group Ltd., Leeds, UK) and surface reflectance (Minolta Chroma Meter CR 300, DP-301, Osaka, Japan) were measured on LD. Drip loss was determined on a 2-cm-thick slice, taken from LD directly in front of the last rib towards the forepart, stored in a plastic bag and hanging on a thread at 4°C for 48 h. Thawing loss was determined as the difference between the weight of fresh and thawed 300-g piece of LD after frozen storage at -20°C. On the same piece of meat, cooking loss was determined as the weight difference before and after cooking in a water bath at 70°C during 90 min. Maximal Warner-Bratzler (WB) shear force and total WB-work were measured on 8 strings (10x10x50 mm), sheared across the fibre direction of cooked LD (speed: 55 mm/min, TA-HDI texture Analyser; Stable Micro Systems, Surrey, UK).

Statistical analyses were performed with the MIXED procedure in SAS (SAS Institute Inc., Cary, N.C., USA, version 8.02) with treatment, breed cross and gender as fixed factors. Sire within breed cross and dam within breed cross and sire were treated as random.

Results and discussion

Carcass quality

From both years, average carcass weight of indoor raised pigs was higher compared with outdoor raised pigs (Table 1). The lower dressing percentage of outdoor pigs might depend on the higher gut filling, because the diluted diet contained more indigestible fibre than the undiluted diet; moreover, the outdoor pigs had access to pasture. Lean meat content is often reported to be higher in outdoor raised pigs, compared with indoor pigs, when receiving identical diets (Stern et al., 2003). In our study, outdoor pigs fed the diluted organic diet

had significantly higher lean meat content (year 2), probably due to the lower energy content of the diet, and consequently lower daily weight gain. The higher energy requirement of outdoor pigs due to their higher agility could not be covered by the diluted diet, even when given *ad libitum*. The uniformity between indoor raised pigs in dressing percentage, lean meat content and back fat thickness indicates that an organic diet can give carcass quality results comparable with those from a conventional diet.

Between breed crosses, no differences in carcass quality could be observed (Table 2). This is not in accordance with other studies, where higher back fat in Duroc breed crosses compared with Large White breed crosses have been reported (Enfält et al., 1997).

Technological meat quality

Technological meat quality traits, such as pH, internal and surface reflectance, WB shear forces and water-holding capacity, in terms of drip, thawing and cooking losses, differed only in some cases between the production systems (Table 1). However, pH values of both muscles did not differ between the treatments, whereas FOP_{BF} values were higher in outdoor pigs, compared with indoor pigs. The pH and FOP values seemed not to be related to each other, which might indicate that these values depend less on production system than on e.g. slaughter conditions. Meat in LD was paler (higher L* values) in indoor raised pigs (year 1), which could be a consequence of the higher FOP values in that muscle. However, Lindahl et al. (2001) stated, that L* values depended mostly on pigment content and myoglobin forms than on internal reflectance. In our study, water-holding capacity was not affected by production system, which might partly be explained by the consistent pH_{LD}. Shear forces in meat from indoor and outdoor raised pigs are widely investigated with various results. Olsson et al. (2003) found significantly higher, whereas Stern et al. (2003) found lower WB shear forces for outdoor pigs. In our study, WB shear forces were mostly unaffected; solely year 2, outdoor raised pigs had lower maximal shear force, compared with indoor raised pigs, given the organic diet.

Generally, pH, FOP and colour values did not differ between Duroc and Landrace breed crosses, whereas water-holding capacity was higher and WB shear force values were lower (year 1) for the Duroc breed crosses (Table 2). This is in accordance with Blanchard et al. (1999), who reported a decrease in shear force with increasing proportion of Duroc in the final breed cross.

Conclusions

It can be concluded that the production system influenced mainly carcass composition and, to a lesser extent, technological meat quality. Indoor raised pigs fed either organic or conventional diet did not differ in carcass and meat quality traits. Breed cross did not influence carcass traits and colour, pH and FOP values. Indications of higher water-holding capacity and lower WB shear force for D*LW pigs could be found.

EFFECTS OF EXOGENOUS PROTEASE EFFECTORS ON CALPAINS ACTIVITY AND ULTRASTRUCTURAL CHANGES OF BEEF

Ming Huang, Guanghong Zhou and Xingliang Xu
Department of Food Science and Technology Nanjing Agricultural University Nanjing China 210095

Background

Beef tenderness increases gradually during postmortem aging, and as a result, the improved palatability. This is an established phenomenon which has long been discovered, however, to date, which factors contribute to this process and how the tenderization is initiated is an unresolved problem.

Koohmaraie and others(Koohmaraie et al.1996, Dransfield 1999) suggested that postmortem meat tenderization is primarily the result of calpain(especially μ -calpain)-mediated degradation of key myofibrillar and cytoskeletal proteins which can cause weakening of the muscle structure, and therefore, meat becomes tender. On the contrary, Takahashi et al. (1999) supposed that with the postmortem time extended, the concentration of calcium ion in muscle sarcoplasm increased, and the calcium alone could lead to the degradation of myofibrillar proteins and the improved meat tenderness, and that calpain was considered to be inactive due to the low concentration of sarcoplasmic calcium ions, and therefore, has little contribution to the tenderization of meat throughout postmortem aging. Consequently, in order to control and regulate meat tenderization, it is indispensable to elucidate the mechanism of meat aging.

Objectives

The purpose of this study was to, through injection treatments, investigate the role of calcium or calpains in beef aging *in situ*.

Materials and methods

Sampling procedures and treatment of muscle samples

Three 2.5 years old Chinese yellow cattle (Luxi×Limusin with liveweight 500±20kg) were slaughtered according to standard slaughtering practices. After being chilled for 20h, one strip loins were sampled per cattle, and was divided into 21 steaks. After being trimmed of all external fat and connective tissue, the steaks(25±3g) were randomly assigned to seven sample groups, which were injected (10%raw weight) distilled water(control),200mM$CaCl_2$, 200mMEGTA, 200mM$ZnCl_2$, 0.2mg/ml Leupeptin ,0.2mg/ml Leupeptin plus 1%TritonX-100 and 1%TritonX-100 respectively. Then the samples were vacuum packaged individually, and stored at 4℃ for 3, 8, 16 days respectively.

Casein Zymography

Casein Zymography was based on the protocol described by Veiseth et al.(2001) with minor modifications. At each storage time, 300mg of muscle were homogenized in 3vol of extraction buffer (100mMTris,10mMEDTA,0.05%2-mercaptoethanol[MCE],pH8.3) using hand operated homogenizer.The homogenate was centrifuged at 10,000×g_{max} for 20min, and the volume of the supernate was measured and used for casein zymography. Hammersten Casein(0.2%, wt/vol) was incorporaed in 12% separating gels(80:1 ratio of acrylamide to bisacrylamide, 375mM Tris-HCl, pH8.8), and 4% stacking gels(80:1, 125mMTris-HCl, pH6.8) without Hammersten Casein was used. TEMED and ammonium persulfate were used to catalyse the polymerisation. Sample buffer(150mM Tris-HCl, pH6.8, 20% glycerol, 0.8%MCE, 0.02% bromophenol blue) was added to supernate (4:1 ratio of buffer to supernate). The gels(1mm) were prerun at 100V for 15 min, 4℃, with a running buffer containing 25mMTris-HCl, 0.05%MCE,192mM glycine, and 1mMEDTA (pH8.3) before samples were loaded into the wells. The gels were run at 100V for 15h, 4℃, removed, and incubated at room temperature (RT) in 50mMTris-HCl, 0.05%MCE and 4mM $CaCl_2$(pH7.5) with slow shaking for 1h, then followed by 16h incubation in the same buffer at RT, before staining for 1h with Coomassie blue and destaining with 20% methanol and 7%acetic acid.

Muscle ultrastructure

At 3, 8, and 16 days storage periods, samples were cut parallel to muscle fibre and fixed by immersion in cold 2.5% glutaraldehyde in phosphate buffer (pH7.3), postfixed in 1% osmium. dehydrated in ethanol, embedded in Epon812 resin. For all samples, thin sections of the same thickness were cut parallel to the

fibres. Sections were stained with uranyl acetate and lead citrate, and then examined using a JEM-100CX-Ⅱ transmission electron microscope(TEM).

Results and discussion

Effects of injection treatment on calpain activity

Results presented in Figure1 indicate that the μ-calpain activity treated by distilled water, EGTA and TritionX-100 respectively declined quickly with aging time and after 16 days storage, μ-calpain activity could not be detected at all by Casein zymography. In contrast, μ-calpain activity in samples injected with $ZnCl_2$, Leupeptin, and Leupeptin plus TritionX-100 respectively can still be detected up to 16 days postmortem. As compared to μ-calpain activity , m-calpain activity did not changed dramatically at a 16 days storage period in all treatments except for $CaCl_2$ injected group in which both μ-calpain and m-calpain activity almost lost completely even after 3 days storage. Two or more band showing activity also appeared in figure 1. Calpain system occurring in animal skeletal muscle cells has three major components ie. μ-calpain, m-calapin and their specific inhibitor calpastatin. A unique property of the calpains is that, when exposed to sufficient calcium, they undergo autolysis, which initially reduces the 80kDa subunit of calpain to 78 or 76kDa, and the 28kDa subunit to 18kDa (Geensink et al.2000). Further autolysis leads to more extensive degradation of large subnunit and loss of proteolytic activity. Znic chloride, Leupeptin are exogenous inhibitor of calpains, the activity of μ-calpain in muscles incorporated into these two components, therefore, declined more slower compared to other treated groups. Calpains quickly lost activity in $CaCl_2$ injected group, which demonstrated that sufficient calcium can activate calpains and then calpains themselves lose activity through autolysis. Two or more active bands of μ-calpain supported the calpain autolysis theory. Except for $CaCl_2$ treated samples, the activity of m-calpain did not change greatly, which indicated that under the condition of this experiment, m-calpain kept inactivity due to low level of calcium, and hence, is not a potential contributor to beef tenderization.

Effects of injection treatment on beef ultrastructure

These experiments conducted demonstrated that injected treatments had great influence on beef ultrastructural changes (Fig.2). Myofibrils kept intact at d3 postmortem (Fig.2 A). At d16, some breaks in myofibrils appeared in control groups (Fig.2 B). While in Leupeptin treated samples, even after 16 days of storage, there was not any significant changes occurred for myofibrils (Fig.2 C). By contrast, myofibrillar breaks was readily perceived at d3 in $CaCl_2$ treated group (Fig.2 D). It has been well documented that muscle fiber changes were mainly caused by the degradation of key myofibrillar proteins, especially, titin, nebulin desmin etc. (Koohmaeaie 1996). When calpains were inhibited by Leupeptin, muscle ultrastructural changes were also inhibited, while, when calpains were activated by calcium, muscle ultrastructural changes quickly happened, which is consistent with calpain hypothesis. In agreement with Taylor et al.(1995), another change that occured in muscle during postmortem tenderization was the fracture in the I band adjacent to the Z line(Fig.2 E), not in the middle of Z line as suggested by other reporters.

Conclusions

Calpain, especially μ-calpain is the most important factor responsible for meat tenderization, while calcium may has indirect influence on meat aging by activating calpains.

EFFECTS OF POSTMORTEM PH/TEMPERATURE DECLINE ON CHANGES IN FREE AMINO ACIDS DURING AGEING IN PIG LONGISSIMUS MUSCLE

Hwang, I.H., Park, B.Y., Kim, J.H., Cho, S.H., Kim, H.J., Kim, D. H., Lee, J.M
National Livestock Research Institute, 564 Omockchun-dong, Suwon, Korea

Background

Structural and cytoplasmic proteins of meats are exposed to proteolytic actions of endogenous proteolysis during ageing and result in polypeptides. The degradation of products consequently generate small peptide and free amino acids by subsequent actions of peptidases and aminopeptidases, respectively (Toldra et al., 2000). It has been well documented that interaction between pH and temperature during rigor development directly affects the incidence of PSE meats (Henckel et al, 2000). Moya et al. (2001) showed that changes in free amino acids during ageing varied between PSE, RFN, RSE, and DFD in pork. These changes are related to aminopeptidases activity under a particular class of pork (Toldra and Flores, 2000). The results mirrored that pH/temperature window during the onset of rigor can have an effect on changes in free amino acids during ageing. Lawrie (1991) noted that the accumulation of some free amino acids could result in an undesirable flavor and decrease in the water-holding capacity. However, free amino acids are of great importance in eating quality due to their specific tastes (Nishimura and Kato, 1988). Their subsequent degradation generates volatile compounds (Toldra, 1998; Hernandez-Jover et al., 1996).

Objective

To determine the effects of pH/temperature profile during rigor development on changes in the concentration of free amino acids for 7 days at 1°C.

Materials and methods

Animals, experimental design, and treatment. A total of 20 male pigs weighing an average of 118 kg (10 head of 194-day-old Yorkshire and 10 head of 201-day-old Landrace) were sampled from the National Livestock Research Institute (NLRI) feeding program. The pigs were conventionally transported to the NLRI abattoir, approximately 65 km away, with minimum transit stress, and kept off feed but with access to water, a day before they were slaughtered. To generate a large range of declines in pH and temperature, researchers placed the pigs in a -3°C chiller (five of each breed), or in a 5°C chiller (for the rest of the five of each breed) until the following day. All pigs were conventionally slaughtered over two consecutive days with an electronic stunner (230 volts for 2.5 sec).

pH, temperature, sampling, and objective quality measurements. Muscle temperature was logged at a 5-min interval from approximately 30 min after stunning for 24 hours (Thermo Recorder, TR-50C, Japan) by using thermocouples inserted into the geometrical center of the muscle between the 3rd and 4th lumbar vertebrae. The pH was measured by using a portable needle-tipped combination electrode (NWKbinar pH-K21, Germany) inserted into the center of the muscle between the 3rd and 4th lumbar vertebrae at a 15-min interval from approximately 30 min postmortem, until the muscle was judged to have reached the ultimate pH. Another measurement was made the following day, approximately 24 h postmortem.

The day after slaughter, *m. longissimus* muscles (from the 7th thoracic vertebrae to the last lumbar vertebrae) were removed, cut into three portions, vacuum-packed, and randomly assigned to one of three ageing periods (1, 3, and 7 d). These were used to get the objective measurements of WB-shear force, meat color, drip loss, and cooking loss. The samples were held at 1°C for the relevant ageing period.

For amino acid analysis, approximately 2 g of muscle tissue were taken at the end of the lumbar vertebrae by using a home-made biopsy sampler during breeding (i.e., 0 h), 4, 12, and 24 h postmortem. Similar amounts of muscle tissues were also sampled at 3 and 7 days postmortem from the WB-shear force block. Muscle tissue was frozen in liquid nitrogen immediately after sampling, powdered in liquid nitrogen by using a mortar-based homogenizer (Warning, Dynamics Corp., USA), and stored at -70°C until analysis. WB-shear force, meat color, and cooking loss were determined according to the procedures of Hwang et al. (2004).

Free amino acids. Level of free amino acids was determined at 1 and 7 d postmortem, largely according to the method reported by Moya et al. (2001), but with minor modification. Briefly, one (1) gram of liquid

nitrogen powdered sample was homogenized in 0.01N HCl with a polytron (3x15 sec) at 4C and centrifuged at 10000g for 20 min. About 300 uL of supernatant was filtered and deproteinised for 30 min at room temperature after mixing with 690 uL of acetonitrile and 10 uL of internal standard (L-Citrulline, 250 pmol/uL). Samples were centrifuged at 10000g for 15 min and 16 primary amino acids were determined by online derivatization using o-phthalaldhyde (OPA). Amount of free amino acids were analyzed by using the Agilent 1100 HPLC system (Agilent Tech, Waldbronm, Germany) at diode array UV detector (338 nm, 10 nm band wide) with ZORBAX Eclipse-AAA C18 column (4.6x150 mm, 5 um, Agilent Tech, Waldbronm, Germany). Separation for each sample was completed in 20 min at 40C. A gradient mobile phase between 40 mM Na_2HPO_4, pH 7.8 and acetonitril-methanol-water (45:45:10, v/v) was used and expressed as pmol. The effects of breed and ageing time on objective meat quality and free amino acid contentrations were examined by applying a general linear model (SAS, 1997), where the effects were tested against residual error.

Results and discussion

The temperature treatments (ie., -3°C and 5°C) did not affect pH/temperature profile in longissimus muscle during rigor development, but the experiment design resulted in wide ranges in pH (6.0-6.9 at 3 h pm) and temperature (20-29°C, data not shown). An average sarcomere length of 1.74 µm without any treatment effect indicated that there was no muscle shortening despite the temperature of 0.6 to 36°C with a pH of 6.2 (Table 1). The pH/temperature profile did not significantly differ between breeds, but slow rate in pH decline was noticeable in this study (ie. 6.2 at 4 h pm), with a normal ultimate pH of approximately 5.4 (data not shown). The result was not clearly understood as our previous data showed a pH of ca. 6.1 at 3 h by applying the same procedure (Hwang et al., 2004). But it might be in part related to a delayed transit time with extreme traffic jam. Landrace showed significantly ($P<0.05$) lower WB-shear force and higher hunter L* value than Yorkshire, but there was no correlation between breed and ageing time.

It has been well documented that proteolysis takes place in structural and cytoplasmic protein during ageing, and this significantly is affected by pH/temperature decline during rigor development (Dransfield, 1994; Hwang and Thompson, 2001). The latter study showed a significantly faster reduction in u-calpain activity when muscle had a rapid pH decline with slow pH decline, resulting in early exhaustion of the calpain and slow ageing rate. Despite activities of exopeptidases (ie, dipeptidylpeptidases and aminopeptidases) significantly varying between pig breeds (Armero et al., 1999) and muscles (Cronet and Bousset, 1999), the result of Toldra and Flores (2000) implied that pH/temperature profile at early postmortem might affect the rate and extent of aminopeptidase activities. These consequently affect changes in free amino acids during ageing.

In the current study, two amino acids (Gly and Cyc) out of 16 primary amino acids were significantly ($P<0.05$) affected by breed, where landrace had higher concentrations (Table 1). While concentration of all examined amino acids (except Met) increased over 7 days, the interaction between breed and ageing was not detectable. To examine the effects of pH/temperature profile during rigor development on changes in free amino acids for 7 d, the amino acid concentrations at 0 day (sampled during bleeding) were subtracted from those at the 7th day, and estimated the levels as a function of muscle temperature at pH 6.2 (Tehmph62). Tehmph62 has been used as an important threshold, because it could be an indirect indication of cold and heat shortening (Pearson & Young, 1989), denaturation of myofibril and sarcoplasmic proteins (Offer & Cousins, 1992), and proteolytic and/or autolytic activity of µ-calpain (Dransfield, 1994).

Tempph62 had simple correlation coefficients (r) of -0.9 and –0.93 with pH at 2 and 4 h; respectively, and of 0.4 and 0.5 with temperature at 2 and 4 h , respectively. Tempph62 did not affect changes in extractable concentrations for His, Tyr, Cyc, Gly, Iso, Ala. On the other hand, Tempph62 had significant curvelinear effects on eight amino acids (Asp, Glu, Leu, Lys, Val, Thr, Ser, Arg), varying in magnitude, while it showed only a linear effect on Met and Phe (Figure 1). Although the curvelinear effect was relatively weak for most amino acids, as seen in figure 1, there was a clear tendency of free amino acids to have higher concentration when muscle temperature at pH 6.2 (say during rigor development) was low. Aminopeptidase activities were not determined. However, an early study (Toldra and Flores, 2000) reported that Alanyl had a significantly lower activity in PSE meat than in DFD meat at 2 h pm. Alanyl, arginyl, and leucyl in PSE meat had significantly lower activities than those in DFD meat. Although, in our data set , changes in Ala were not affected by Tempph62, the results implied that pH/temperature interaction during rigor development not only affected the rate of proteolysis (Hwang et al., 2004), but also affected subsequent release of free amino acids.

Conclusion

Prelimarily data of current study show that pH/temperature significantly affect the release of free amino acids during ageing, with higher levels at a lower temperature and pH of 6.2. However, some amino acids are not affected by declines in pH and temperature. This may have a relation to taste development during ageing and cooking.

Background

Fish and shellfish are kept in cold storage after capture and are generally consumed within several days, but the muscle freshness deteriorates even under cold storage. Because Japanese people like fresh slices of raw fish, consumers are interested in the freshness and the muscle texture is an especially important factor for freshness. The muscle structure is known to deteriorate during the 1st day of cold storage, affecting the muscle texture before rigor mortis occurs (Toyohara and Shimizu 1988, Ando *et al.*1991). Such a muscle-softening phenomenon in post-mortem is thought to be caused about by proteolysis of the muscle structure. Several proteases have been studied as being causative factor for fish muscle softening such as cathepsins B, D, H and L (Yamashita 1994), calpain (Tsuchiya *et al.* 1992) and matrix metalloproteinase (Kubota *et al.* 2000). Because of the low level of protease activities in ordinary fish muscle, the material in most of these studies was drawn from particular meat that has an unusually soft texture and extremely high protease activity such as jellied meat from Japanese flounder and matured semelparity fish. In addition, anadromous and amphidromous fish die certainly after spawning and the death is thought to be programmed as apoptosis. If the soft muscle texture at the spawning stage is also programmed as part of apoptosis, there are some possibilities that caspase, a key protease of apoptosis (Yamashita 2003), relates to post-mortem muscle softening.

Objectives

In order to demonstrate involvement of protease in the post-mortem softening in ordinary fish muscle, we have developed an *in situ* perfusion technique, which introduced other chemicals into blood vessels in fish muscle. In the present study, using the *in situ* perfusion technique, protease inhibitors were perfused to identify the type of proteases that led to post-mortem muscle softening in fish, tilapia and yellowtail.

Materials and methods

***In situ* perfusion:** Tilapia *Oreochromis niloticus* and Yellowtail *Seriola quinqueradiata* were obtained from a private fish farm and reared for several months before use. Fish were anesthetized with 200 ppm MS222 (Tricaine methanesulfonate, Acros Organics, NJ, USA) and a cannula connected to a hypodermic syringe that was filled with physiological saline (0.7489% NaCl, 0.1294% KCl, 0.199% $CaCl_2$) was inserted into the bulbus arteriosus. A polyethylene tube (1.5 mm in diameter, 10 cm long) was inserted into the ventricle to bring the venous blood out of the fish body, so that it prevented the circulation of the venous blood and helped the physiological saline perfusion. Soon after the operation, the color of the fish gills changed to white from red and the color of the fluid from the polyethylene tube became clear about 10 min later. Finally after approximately 30 min, the liver color was observed to become whitish (Fig. 2).

Eosin perfusion: Eosin (Wako Pure Chemical Industries, Osaka, Japan) was dissolved in physiological saline to obtain a 10% solution and this solution was perfused into tilapia (359 - 404 g, n = 2) using the *in situ* perfusion technique. After the perfusion of 40 mL of eosin solution (about

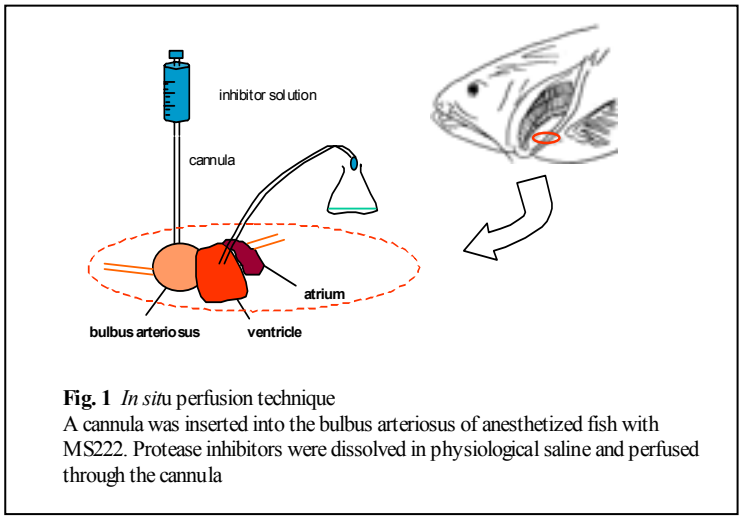

Fig. 1 *In situ* perfusion technique
A cannula was inserted into the bulbus arteriosus of anesthetized fish with MS222. Protease inhibitors were dissolved in physiological saline and perfused through the cannula

40 min), the cannula was removed and the upper dorsal muscle was dissected. The muscle section was observed under a fluorescence stereoscopic microscope (R-400; Edge Scientific Instruments, CA, USA) using ultraviolet light to confirm the occurrence of fluorescence from the eosin.

[^{35}S]-methionine perfusion: [^{35}S]-methionine (Amersham Biosciences, NJ, USA) was dissolved in physiological saline to obtain a 1,000 Bq/mL solution. After the perfusion of 25 mL [^{35}S]-methionine solution into the tilapia (448±71 g, n = 3), fish were individually dissected to obtain four samples of dorsal muscle and one liver sample. Each 1 g-tissue sample was dissolved in 0.1 M NaOH and mixed with scintillation cocktail (PICO-FLOUR 40, Packard Instrument, CT, USA), and the radioactivity was measured using a liquid scintillation analyzer (TRY-CARB 200CA, Packard Instrument).

Protease inhibitor perfusion: Each protease inhibitor, leupeptin (Peptide Institute, Osaka, Japan; 1 mg/mL, a serine and cysteine protease inhibitor), chymostatin (Peptide Institute, 1 mg/mL, a serine protease inhibitor), benzyloxycarbonyl-Val-Ala-Asp-fluoromethylketone (Z-VAD-fmk, Peptide Institute, 1 mg/mL, a caspase inhibitor), and E-64 (Peptide Institute; 1 mg/mL, a cysteine protease inhibitor) was dissolved in physiological saline. *o*-phenanthroline (Aldrich Chemical, WI, USA, 1 mM, a metalloprotease inhibitor) was dissolved in a small volume of methanol and diluted with physiological saline. These inhibitor solutions and physiological saline as the control sample were perfused into fish for 60 min. Every fish was perfused with at least 30 mL perfusion solution. Each experimental group consisted of ten tilapias (867±195 g) or six yellowtails (608±84 g). The cannula was removed and the upper dorsal muscle was sliced to give 1-cm-width strips. The sample slices were wrapped in plastic film wrap individually and kept in a 4 °C refrigerator until each measurement time. The breaking strength of the slices as a parameter of muscle toughness was measured using a rheometer (NRM-20002J, Hudoh, Tokyo, Japan) equipped with a cylindrical plunger of 3 mm diameter. The plunger was applied at the interspace between the myocomma membranes at the cut surface of the dorsal muscle. Measurements were taken at five points for each strip and the average value was calculated. Because in our unpublished experiment of tilapia, E-64 was found not to be effective to prevent muscle softening, E-64 was not used for tilapia perfusion.

Results and discussion

***In situ* perfusion**: Approximately 30 min after the perfusion of 10 mL physiological saline, the color of the fluid from the polyethylene tube became clear in the case of a 200-g tilapia (Fig. 2). This technique excludes the effect of blood fluid in fish muscle, in which factors inducing muscle softening may exist (Ando *et al.* 1999), and is able to examine the effectiveness in muscle components than in blood fluid.

Fig. 2 Color change of the fluid from the ventricle. The tilapia was anesthetized with MS222 and physiological saline was perfused by a cannula inserted into the bulbus arteriosus (A). Finally after approximately 30 min (B), the liver color was observed to become whitish.

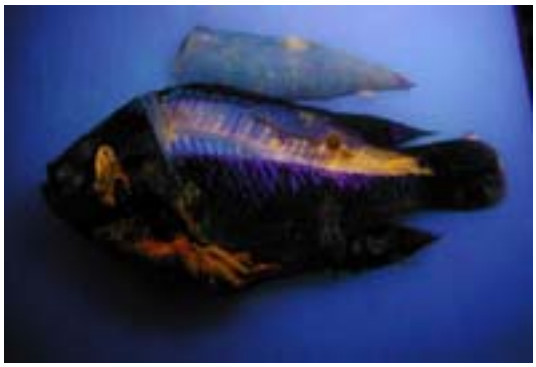

Fig. 3 Fluorescence in the whole body of the eosin-perfused tilapia. Tilapia was anesthetized with MS222 and eosin was perfused by a cannula inserted into the bulbus arteriosus. Orange fluorescence of eosin was observed in the muscle, gill, liver and intestine under ultraviolet light.

Eosin perfusion: Eosin was used for visible confirmation of the *in situ* perfusion technique. Visible fluorescence was observed in the solution from the polyethylene tube, which confirmed the occurrence of eosin, approximately 3 min after the start of the eosin perfusion. Eosin perfusion into the interior organs was confirmed under ultraviolet rays after the upper lateral muscle was removed. Visible fluorescence was observed in the gill, liver, intestine, and dorsal muscle of the eosin treated tilapia (Fig. 3). Eosin perfusion in the blood vessel of the dorsal muscle was confirmed under a fluorescence stereoscopic microscope with ultraviolet rays, and was not observed in the control muscle sample (Ishida *et al*.2003).

[^{35}S]- methionine perfusion: ^{35}S-methionine was used as a marker substance for quantitative analysis. The radioactivity measured in the ^{35}S-methionine perfused tilapia showed that this solution was taken into the dorsal muscle and liver at a rate of 7.8 μL/g and 70.2 μL/g, respectively. As the liver received the radioactive substance much more than the dorsal muscle did, the difference between the two organs possibly depended on the blood circulating volume. From these results of the eosin and [^{35}S]-methionine perfusion experiments, this perfusion technique was concluded to be suitable to introduce chemical substances into fish muscle and was applied to protease inhibitor perfusion in the further experiments.

Protease inhibitor perfusion into tilapia: Figure 4 shows the breaking strength of the tilapia in each inhibitor group. At the beginning of storage (0 h), the breaking strength of all the inhibitor-perfused tilapia was 144 - 197 gw with a large variance. At 23 h storage, significant difference was found in the leupeptin (140±36 gw, P = 0.0140) and Z-VAD-fmk (139±36 gw, P = 0.0162) - perfused tilapia, whereas no remarkable effect was seen in the chymostatin-perfused fish (104±25 gw). At 50.5 h storage, the breaking strength was 86 - 98 gw and statistic difference was not seen between the inhibitor-perfused tilapia. On the other hand, those of *o*-phenanthroline-perfused fish at even 0 h was significantly different from other inhibitors by analysis of variance. Then all the *o*-phenanthroline-perfused experiments were not analyzed statistically (23 h, 106±20 gw, 50.5 h, 86±11 gw) and were not able to be compared with the Kubota *et al*. (2001) that showed involvement of metalloprotease in muscle softening.

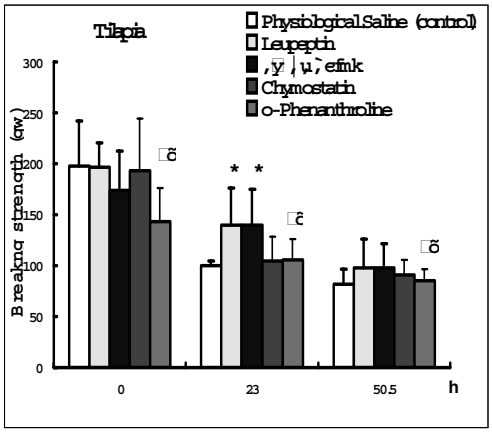

Fig.4 The breaking strength of the tilapia muscle stored under 4°C after the perfusion of the four types of protease inhibitors (leupeptin, Z-VAD-fmk, chymostatin and o-phenanthroline) into the replicate samples (n = 10). Vertical bars represent standard deviation.

* The breaking strength at 23 h storage of leupeptin and Z-VAD-fmk were significantly different by analysis of variance.
† The effect of o-phenanthroline at 23 and 50.5 h were not analyzed statistically, because the breaking strength of o-phenanthroline at 0 h was significantly different from other inhibitor groups by analysis of variance.

Protease inhibitor perfusion into yellowtail: Figure 5 shows the breaking strength of the yellowtail in each inhibitor group. At the beginning of storage (0 h), the breaking strength of all the inhibitor-perfused yellowtail was 191 - 235 gw with a large variance. The E-64 perfused yellowtail was slightly different at 9 h (199±31 gw, P = 0.1102) and significantly different at 46 h (143±13 gw, P = 0.0412) from other perfused fish.

Conclusions

In tilapia, leupeptin (serine and cysteine protease inhibitor) was effective to prevent the muscle softening and it is suggested that trypsin-like protease is the most probable candidate for causative protease of muscle softening. In addition, caspase-3 (Yabu *et al*. 2001) activity was induced in tilapia muscle after death and apoptosis might occur in muscle cells. In yellowtail, E-64 (cysteine protease inhibitor) was effective and cysteine protease was thought to be causative protease in muscle softening. These findings also showed that proteolysis was the one of causative factors for post-mortem muscle softening.

Acknowledgment

This work was supported in part by a grant of the Fisheries Agency, the Ministry of Agriculture, Forestry and Fisheries of Japan.

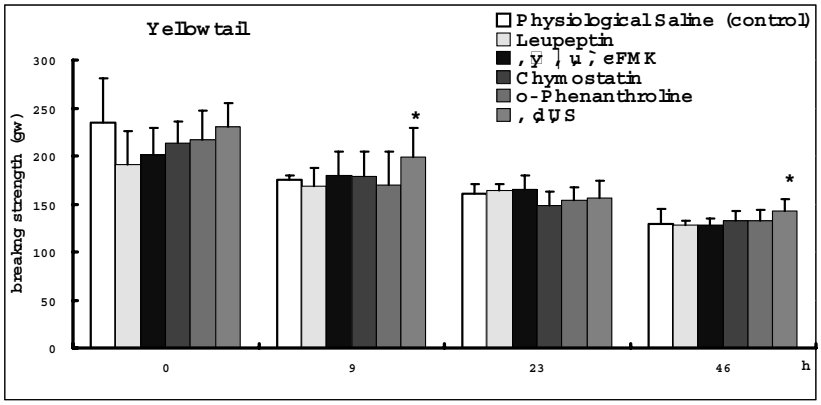

Fig.5 The breaking strength of the yellowtail muscle stored under 4° C after the perfusion of the five types of protease inhibitors (leupeptin, Z-VAD-fmk, chymostatin, o-phenanthroline and E-64) into the replicate samples (n = 6). Vertical bars represent standard deviation.

* The breaking strength of E-64 perfused fish at 9 h and 23 h were different by analysis of variance.

EFFECT OF FREEZE-THAW PROCESS ON MYOGLOBIN OXIDATION OF PORK LOIN DURING COLD STORAGE

Jin-Yeon Jeong, Han-Sul Yang, Sang-Hun Moon, Gu-Boo Park, and Seon-Tea Joo
Division of Applied Life Science, Gyeongsang National University, Jinju, Kyeongnam 660-701, Korea.

Background and Objective

Although frozen storage is an important preservation method for muscle foods, quality deterioration cannot be avoid during freezing because of the formation of ice crystals, distorting the tissue structure, mechanical damage and denaturation of protein. Especially, the rapid meat color deterioration has been often observed in thawed meat compared to fresh meat at a commercial meat market. Myoglobin (Mb) oxidation is a major nonmicrobial factor responsible for the quality deterioration of fresh meat, and it is commonly assumed that lipid oxidation is closely related to Mb oxidation. Recently, we observed the formation of MetMb without lipid oxidation in thawed pork chop steak. During retail display, the rate of Mb oxidation is related to many factors, and physical and biochemical factors influence the displayable life of meat. Enzymes and other components are released during freezing and thawing. The release of mitochondrial enzymes such as β-hydroxyacyl CoA-dehydrogenase (HADH) into sarcoplasm have been reported (Gottesmann and Hamm, 1984; Chen et al., 1988; Toldra et al., 1991). Decker and Welch (1990) also reported that the rate of iron release from ferritin was influenced by temperature in muscle foods. In this research, we hypothesized that HADH activity could be partially responsible for the observed formation of MetMb without lipid oxidation in thawed pork loin during cold storage. The objective of this study was to determine whether HADH activity increased by freeze-thaw process could impact myoglobin oxidation without lipid oxidation in pork loin during cold storage.

Materials and methods

Commercial 10 pork loins were selected randomly at 24h postmortem, and the longissimus lumborum was used to make steaks (3 cm thickness). The steaks of each loin were packaged in a polyethylene bag, and samples were subjected to fresh group (Control), one cycle freeze-thaw group (Treatment 1) and two cycles freeze-thaw group (Treatment 2), respectively. All freeze-thaw samples were kept at -65℃ for 12 hours for freezing and stored at 4℃ for 12 hours for thawing. After thawing, samples were stored at 4℃ for 7 days to measure meat color (CIE L*a*b*), percentage of MetMb, thiobarbituric acid reactive substance (TBARS) value and HADH activity at 0, 3 and 7 days of storage.
Meat color (CIE L*a*b*) was measured by using a Minolta Chromameter (Minolta CR 301; Tokyo, Japan). Seven random readings were made from the surface of samples. Myoglobin was extracted from meat samples with phosphate buffer of pH 6.8. Samples were homogenized, centrifuged and filtered to obtain the absorbance of the resulting supernatant solution at 572, 565, 545, and 525 nm, respectively. Lipid oxidation was measured by TBARS value. Five grams of meat was weighed into a 50ml test tube and homogenized with 15 ml of deionized distilled. One ml of homogenate was transferred to a disposable test tube, and butylated hydroxyanisole (50, 10%) and thiobarbituric acid/trichloroacetic acid (TBA/TCA) (2 ml) were added, and then incubated in a boiling water bath for 15 min. The absorbance at 531 nm was used for TBARS value as milligrams of malondialdehyde per kilogram of meat. HADH activity was measured according to the method of Fernandez et al. (1999). Extract was obtained from meat sample by immersion in two volumes (4-6ml) of 0.1M phosphate buffer, pH 6.0, at room temperature. The HADH released in the extracts was assayed by mixing in a methacrylate disposable semi-micro spectrophotometer cell (10mm light path length, nominal working volume 1.5ml), 34 extract, 70 ethylenediaminetetraacetic acid (EDTA; 34.4ml) and 880 phosphate buffer (0.1M, pH 6.0). The mixture was kept at room temperature for 3 min and 20 NADH (1.5mM) and 20 acetoactyl-CoA (5.9mM) were added. The HADH activity was determined by measuring immediately the absorbance of the mixtures at 340nm.

Results and discussion

Sampes of control showed significantly ($p<0.05$) higher CIE a* value compared to those of treatments at 7 days of cold storage. Moreover the a* value of Treatment 1 was higher than that of Treatment 2. On the

contrary, MetMb percentages of Treatments were significantly ($p<0.05$) higher than those of control at 3 and 7 days of cold storage. Treatment 2 showed significantly ($p<0.05$) higher MetMb percentage compared to Treatment 1 at 3 days of storage. There were no significant ($p>0.05$) differences in TBARS values between control and treatments during cold storage. However there were significant ($p<0.05$) differences in HADH activity between control and treatments at 3 days of cold storage. Samples of treatments showed higher HADH activity compared to those of control. There was no significant ($p>0.05$) difference in HADH activity between Treatment 1 and Treatment 2.

These results suggested that the freeze-thaw process could accelerate meat color deterioration, i.e. decreased redness and increased MetMb percentage in pork loin during cold storage. However the freeze-thaw process did not affect on lipid oxidation of pork. This implied that autoxidation of Mb in freeze-thaw pork loin was influenced by somehow except lipid oxidation products. It could be possible that the freeze-thaw process leads to a local concentration effect of metal ions that might accelerate Mb oxidation. The rate of iron release from ferritin could be influenced by temperature in muscle foods (Decker and Welch, 1990). It could be also possible that the thawing process likely makes for a lower solubility of oxygen in the tissue that would lead to decreased OxyMb. The damage to cellular and sub-cellular compartments form physical disruption by ice crystals during freezing and thawing could release enzymes into sarcoplasm, and the enzymes could potentially be involved in MetMb formation in thawed meat finally. In this research, we confirmed the increasing of HADH activity by freeze-thaw process. HADH is involved in generation of NADH that has MetMb reductase activity in mitochondira intermembrane space. Because NAD^+ (Nicotinamide adenine dinucleotide) could not generate NADH (Reduced Nicotinamide adenine dinucleotide) effectively with presence of HADH, MetMb reductase activity might be reduced by increased HADH activity in postmortem muscles. Therefore, results suggested that the rapid Mb oxidation without lipid oxidation could be affected by partially the increased HADH activity during freezing and thawing of pork loin.

Conclusions

Freeze-thaw process of pork loin accelerated color deterioration during cold storage. The oxidation of Mb was not related to lipid oxidation. It was suggested that released HADH into sarcoplasmic from mitochondria could be involved in the autoxidation of Mb in freeze-thaw pork loin.

Background

It is well known that muscle is converted to meat as food during postmortem aging. Due to the increase of peptides and free amino acids during postmortem aging, meat taste is improved. During postmortem aging, a peptide APPPPAEVHEVHEEVH derived from troponin T (TnT) was found not only to contribute to improvement of taste (sour-suppressing) but also to be useful as a conditioning indicator in meat (Okumura et al., 2003). However, the details of TnT degradation and the relationship between TnT degradation and muscle tenderization remain poorly understood.

Objectives

The objectives of this study were to determine N-terminal amino acid sequences of TnT degradation fragments during postmortem aging and to clarify the involvement of calpain in the degradation.

Materials and methods

Preparation of myofibrillar proteins

In all steps of myofibrillar proteins preparation from porcine longissimus thoracis muscle (LT), samples were kept on ice. The meat samples were minced and homogenized with 0.04M Tris-HCl buffer (pH 7.4) containing 0.16M KCl. The precipitate obtained was washed and centrifuged three times in 0.16M KCl for 15min at 3,000 x g. After centrifugation, pellet was suspended in 0.16M KCl containing 5mM NaN_3. Finally, the solubilized myofibrillar proteins was filtered by nyron net to remove connective tissue.

Hydrolysis of myofibrillar proteins by m-calpain

m-Calpain from rabbit skeletal muscle was purchased from Sigma (Germany). Myofibrillar proteins were prepared from LT stored for 2 days after slaughter. Myofibrillar proteins (2.5mg) were hydrolyzed with m-calpain (125U) at 30°C for 180 min in 50mM acetate buffer (pH 6.2) containing $CaCl_2$ (5mM) and 2-mercaptoethanol (0.1%). The portion of this mixture (200 μl) was taken after 0, 10, 30, 60, and 180 min and added with 30mM Tris-HCl (pH6.8) buffer (100 μl) containing 60% glycerol, 3% SDS, 3% 2-mercaptoethanol, and 0.03% bromophenol blue to stop the reaction.

SDS-PAGE and electroblotting

All steps of SDS-PAGE and western blot analysis were performed at room temperature. The solubilized myofibrillar proteins (300 μg) were loaded onto 55mm-wide lane of SDS-PAGE gels. The 12.5% gel was run in 25mM Tris buffer containing 192mM glycine and 0.1% SDS at a constant current (14mA) for 2 hr 45 min. Prestained Precision Protein Standard (Bio-Rad, Hercules, CA) was used as the marker.

Western blot analysis

After SDS-PAGE, the gel was soaked in a transfer buffer (25mM Tris, 192mM glycine, 15% methanol, 0.05% SDS). Then, the proteins on the gel were transferred to a polyvinylidenedifluoride (PVDF) membrane (Immobilon-P_{SQ} Millpore, Bedford, MA) in the same transfer buffer. The current was set at 3mA/cm^2-membrane for 90 min. The electroblotted membrane was then blocked by blocking buffer (PBS containing 1% BSA and 0.1% Tween-20) for 30 min. After blocking, the membrane was incubated for 30 min with anti-fTnT polyclonal goat antibodies raised against a peptide corresponding to the internal region of human fTnT (Santa Cruz Biotechnology, Inc., Santa Cruz, CA). The primary antibodies were used at a 1:100 dilution in an antibody buffer (PBS containing 0.1% BSA and 0.01% Tween-20). After three washes with 0.1% Tween-20/PBS for 5 min each and being blocked with blocking buffer for 30 min, the membrane was incubated with

biotin-conjugated anti-goat secondary antibodies (Santa Cruz Biotechnology). The secondary antibodies were used at a 1:500 dilution in the antibody buffer for 30 min. After three washes, the membrane was incubated with avidin-DH and biotin-conjugated HRP (VECTORSTAIN® ABC-PO kit, Vector Laboratories, Burlingame, CA) according to the manufacturer's protocol. After three washes, the membrane was finally stained with a DAB substrate kit (Vector Laboratories).

Determination of N-terminal amino acid sequence of proteins

The electroblotted proteins on PVDF membrane were stained with Coomassie Brilliant Blue R-250 (CBB; Bio-Rad). The bands of interest were excised, and then the N-terminal amino acid sequences were analyzed by a G1000A Protein Sequencer (Hewlett Packard, Palo Alto, CA).

Results and discussion

The results of Western blot analysis revealed that multiple degradation products of TnT were generated in porcine LT during postmortem aging (Fig. 1) and by calpain hydrolysis (Fig. 2). Before aging and hydrolysis, four fTnT bands were detected molecular masses of around 37 kDa. These bands were thought to be intact TnT isoforms. These bands were decreased with aging and by calpain hydrolysis, and their degraded fragments with molecular masses of around 30 kDa increased. At 7 days postmortem, anti-fTnT-positive six bands were detected, and three of six bands were determined their N-terminal sequences with molecular masses of approximately 29, 28, and 27 kDa. The N-terminal amino acid sequences of 29, 28, and 27 kDa bands were EVHEPEEKPRPKLTAP, EKPRPKLTAPKIPEG, and APKIPEGEKVDF, respectively. After calpain hydrolysis, five anti-fTnT-positive bands were detected and three of five bands were determined their N-terminal amino acid sequences with molecular masses of approximately 30, 29, and 27 kDa. The N-terminal amino acid sequences of 30, 29, and 27 kDa bands were APPPPAEV, EVHEPEEK, and APK, respectively.

In our previous study, we have determined the amino acid sequences of porcine fTnT isoforms deduced from the DNA sequences (accession nos. AB176595- AB176602 in DDBJ/EMBL/GenBank nucleotide sequence databases). The number of amino acid residues of the fast and slow TnT isoforms were 270 (fTnT1), 265 (fTnT2), 259 (fTnT3), 249 (fTnT4), 261 (sTnT1), and 250 (sTnT2). The N-terminal sequence EVHEPEEK was found only in fTnT2 and fTnT3 (Fig. 3). As shown in Fig. 4, the cleavage sites His_{37}-Glu_{38} (a1 and b2) and Thr_{51}-Ala_{52} (a3 and b3) were cleaved after postmortem aging as well as by calpain hydrolysis. On the while, Glu_{43}-Glu_{44} (a2) was cleaved only after postmortem aging, and Glu_{21}-Ala_{22} (b1) was cleaved only by calpain hydrolysis. These results suggested that His_{37}-Glu_{38} and Thr_{51}-Ala_{52} were cleaved by calpain hydrolysis in postmortem aging, while Glu_{43}-Glu_{44} was by another proteinases hydrolysis, such as cathepsins. Recently, we found the sour-suppressing peptide APPPPAEVHEVHEEVH from postmortem aged pork (Okumura et al., 2003). From the results in the present study (Fig. 4), the sour-suppressing peptide would be produced by calpain hydrolysis at Glu_{21}-Ala_{22} and His_{37}-Glu_{38} sites. Howevere, APPPPAEVHEVHEEVH sequence was not detected from the N-terminal sequences of TnT fragments in postmortem aged porcine meat. The following thing is a probable reason; in postmortem aged pork, several proteinases, such as calpains and cathepsins, were involved in TnT degradation and, as a result, the peptide was liberated from TnT. On the while, in postmortem aged beef, the sequence APPPPAEVHEVHEEVH was determined from 32.1 kDa fragment (Muroya et al., 2004). These results indicated the ratio of proteinases might be different in porcine and bovine.

In this study, we clarirfied effect of calpain on TnT degradation. Howevere, the involvement of other proteinases such as cathepsins in the TnT degradation needs to be also clarified.

Conclusion

It is highly possible that a peptide APPPPAEVHEVHEEVH is derived from TnT by calpain during postmortem aging.

Background

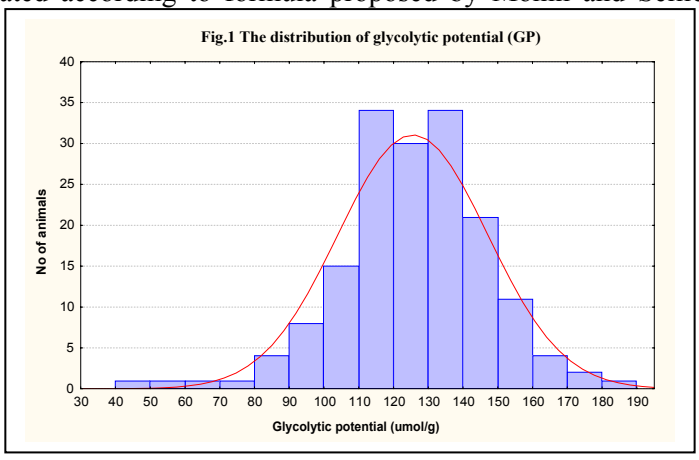
Pork quality traits are composite, being affected by major genes (RYR1 RN) and the candidates e.g. mapped on 2 chromosome calpastatine gene – an endogenous inhibitor of calpain (Koćwin-Podsiadła et al. 1995, Przybylski et al.1995, Sellier 1998, Sensky et al. 1999).

Objectives

The present study was conducted to estimate the polymorphism of calpastatin (*CAST*) gene identified with *Hinf*I, *Msp*I and *Rsa*I restriction endonucleases, and the effect of RN$^-$ gene (determined on the basis of glycolytic potential), on meat quality traits.

Materials and methods

The investigations were carried out on 169 fatteners of three genetic groups: Landrace (41), Landrace x Duroc (67) and Landrace x Yorkshire (61), obtained from F_0 animals, imported from Denmark. The animals were kept under the same environmental conditions and fed a full bath feed. The animals were slaughtered at the live weight about 110 kg (hot carcass weight 85 kg), 4-5 hours after transportation, using the electrical stunning method and recumbent bleeding out. Immediately after slaughter blood samples were collected in EDTA-coated tubes for subsequent DNA analysis for the RYR1 and *CAST* genotype. The RYR1 genotypes were established according to Fuji et al. (1991). The polymorphism of *CAST* gene was identified with *Hinf*I, *Msp*I and *Rsa*I restriction endonucleases, according to Ernst et al. (1998). At 45 min *post mortem* the samples from *Longissimus lumborum* (LL) muscle were collected into tubes with 0,5 M PCA for determination of glycogen (Darympale and Hamm, 1973) and lactate (Bergmayer, 1974). On the basis of them, the glycolytic potential (GP) was calculated according to formula proposed by Monin and Sellier (1985). The RN genotypes were identified on the basis of glycolytic potential (GP) and its bimodal distribution: rn^+rn^+ (GP≤130µmol/g) RN$^-$/? (GP>130µmol/g) (Fig.1). The pH was measured directly in the tissue of *Longissimus lumborum* muscle, using a pH-meter Master produced by Dramiński (Poland). The electrical conductivity was evaluated using a LF-Star apparatus, produced by Matthaus (Germany). The lightness (L*) of the muscle tissue was measured 24 hours *post mortem* using a Minolta CR-310 apparatus (Japan) in CIE L*a*b* colour system. The drip loss at 48, 96 and 144 hours after slaughter was evaluated in accordance with the method of Prange et al. (1977). The shear force was determined in (144h) on cooked meat slices, using an Instron 1140 apparatus with Warner-Bratzler device. The data was analysed, using a two-way analysis of variance in a non-orthogonal scheme. The significance of differences between means of groups for the investigated traits, was calculated using Tukey's test.

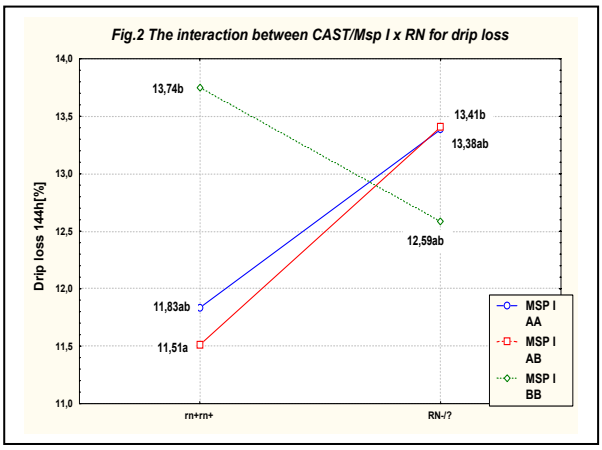


Results and discussion

The high muscle glycolytic potential (GP>130µmol/g) has an effect on pH decline (at 24, 48 and 96 hours after slaughter), and higher meat lightness [Tab.1]. The low pH_u is connected with a higher drip loss from pork meat (Kauffman et al. 1993, Bertram et al. 2000). The deeper glycogenolysis (as the effect of RN$^-$ allele), affected fluid loss from fresh meat during *post mortem* storage, giving higher (about 0,7 percent points) drip loss in 48 hours after slaughter. Josell et al. (2003) suggested, that high amount of glycogen, the most important substrate for ATP regeneration, might contribute to hinder muscle contraction in RN$^-$ carriers, while Deng et al. (2002) showed, that the low water-holding capacity of meat from RN$^-$ carriers, was caused by high degree of denaturation of proteins. The tenderness (expressed by shear force) has been shown to be related to RN gene, which is in agreement with studies by different authors (Lundstrom et al. 1994, Enfalt et al. 1997, Josell et al. 2003).

In table 1 showed the effect of calpastatin gene (regardless RN$^-$ gene) on analysed meat quality traits. The AA genotype at the *CAST/Hinf*I locus affected the initial pH, given (in comparison to animals with AB and BB genotypes) lower at about 0,15 units pH_{35} and 0,22-0,25 units pH_3. In contradiction to this experiment, in the investigations of Koćwin-Podsiadła et al. (2003), carried out on fatteners differentiated by RYR1 gene, the faster pH_{35} decline, in group of fatteners with BB genotype at *CAST/Hinf*I locus, was noted. There was no effect of GP (RN gene) on drip loss measured in 96 and 144 hours *post mortem* but the influence of *CAST/Hinf*I gene on fluid loss, was noted. It should suggest that *CAST/Hinf*I genotype is connected with a later drip loss from fresh meat during storage. The AA animals compared with AB and BB porkers at the *CAST/Hinf*I locus given about 4 pp. higher drip loss measured in 96 and 144 hours *post mortem*. During the storage from 48 to 144 hours after slaughter, a highest fluid loss has been shown from fresh meat of AA genotype porkers at the *CAST/Hinf*I locus (8, 5 and 6 pp. respectively for AA, AB and BB genotype at the *CAST/Hinf*I locus).

In contrast, the BB genotype porkers at *CAST/Rsa*I locus (compared with AA and AB animals) affected fluid loss, given about 2 pp. higher drip loss measured in 144 hours *post mortem*. During the storage from 48 to 144 hours after slaughter, a highest fluid loss has been shown from fresh meat of BB genotype porkers at the *CAST/Rsa*I locus (8, 6 and 5 pp. respectively for BB, AA and AB genotype at the *CAST/Rsa*I locus).



It should the mention that both genotypes with highest drip loss (AA at *CAST/Hinf*I and BB at *CAST/Rsa*I) had a lowest percentage share in analysed population of fatteners (8,88 and 6,51% respectively).

The AA genotype at the *CAST/Msp*I affected the glycolytic changes in *Longissimus lumborum* muscle, given about 0,05 units higher pH at 24 and 144 hours after slaughter. The effect of calpastatin gene (*CAST/Msp*I and *CAST/Rsa*I) on meat quality traits, in the investigations of Emnet et al. (2000), was not found.

In this experiment, the interaction was found between RN gene and *CAST/Msp*I for a drip loss measured in 144 hours after slaughter (Fig.2). The AA genotype at the *CAST/Msp*I locus was differed by RN gene, given 1,9 pp. lower drip loss (144h) in non-carriers of RN gene. Among non-carriers of RN$^-$ gene, were two groups related *CAST/Msp*I genotype and differed by drip loss measured in 144 hours *post mortem*. The AB animals compared with BB porkers at the *CAST/Msp*I given 2,23 pp. lower drip loss from *Longissimus lumborum* muscle.

Conclusions

Meat from RN$^-$ carriers, compared to meat from non-carriers had higher glycogen content, lower ultimate pH and higher meat lightness (L*) and drip loss (48h).

The highest fluid loss from fresh meat during storage in a group of porkers with AA genotype at the *CAST/Hinf*I and BB genotype at the *CAST/Rsa*I locus, was noted. The frequency of mentioned above genotypes with highest drip loss was lowest in analysed population and reached 8,88 and 6,51% respectively.

In this experiment, we also found the interaction between RN gene and *CAST/Msp*I for a drip loss evaluated in 144 hours after slaughter. The non-carriers of RN$^-$ gene, but with AB genotype at the *CAST/Msp*I locucs

porkers compared with BB genotype animals at the same locus of *CAST* and RN, given 2,23 pp. lower drip loss (144h after slaughter) during storage of fresh *Longissimus lumborum* muscle samples.

[3]INRA, Station de Recherches sur la Viande, 63122 Saint Genes Champanelle, Theix, France

Background

Post mortem proteolysis of myofibrillar proteins is associated with activity of the calpain system (-μ and -m calpain) and their inhibitor calpastatin (Sensky et al. 1999, Hao et. al 2000). Calcium channel activity is regulated by domain L of calpastatin (Hao et al. 2000). Ca^{2+} level in sceletal muscle is also regulated by *RYR1* gene. Activity of calpastatin (as endogenous inhibitor of calpain) in sceletal muscle is highly related to rate of meat tenderization and protein turnover after slaughter (Goll et al. 1998). Thus, *CAST* represents an excellent candidate gene for studying variation in pork quality (Ernst et al. 1998).

Objectives

The aim of this study is analysis of the effect of polymorphism of *RYR1*and calpastatin (*CAST*) genes for some meat quality traits taking into consideration group of meatiness. An effect of interactions between variants of *RYR1* and *CAST* gene and group of meatiness for investigated meat quality traits was also analysed.

Materials and methods

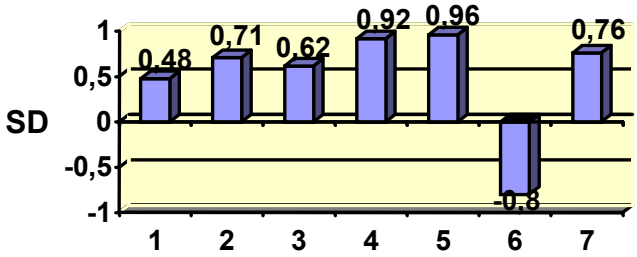
Investigations were carried out on 201 fatteners being crosses of [(Polish Large White x Polish Landrace) x (Duroc x Pietrain)] (77), [(Landrace x Yorkshire) x (Duroc x Pietrain)] (40) and [(Polish Large White x Polish Landrace) x (Hampshire x Pietrain)] (84). The animals were kept in similar environmental conditions, fed balanced mixtures and slaughtered using electrical stunning ("Inarco" system) at 4-5 hours after transportation on the distance 300 km. Immediately after slaughter blood samples were collected in EDTA-coated tubes for subsequent DNA analysis for the *RYR1* and *CAST* genotype.
Average warm carcass weight of analysed animals was 78.40±0,54 kg (mean value ± se). Carcasses belonged to three groups of meatiness: I ≤50.0; II from 50.1 to 55 and III >55 percent of meat in carcass respectively. Average meatiness of carcasses analysed population of fatteners was 51.28±0.40 %. In each group was similar number of gilts and castrates.
The following meat quality characteristics immediately after slaughter were determined: pH of *Longissimus Lumborum* (*LL*) muscle tissue (immediately in carcass - pH_{35}) and in water homogenate of muscle tissue (pH_{45}); R_1 expressed as IMP/ATP ratio at 45 min *post mortem* according to Honikel and Fischer (1977). At 24 h *post mortem* pH, meat lightness (measured with Minolta CR310 Chroma Meter in CIE L*a*b* system), water holding capacity (WHC) according to Grau and Hamm (1952) and Pohja and Niniivaara (1957) modification and losses of weight of meat in cooking process were determined. Drip loss from muscle tissue at 48 and 96 h after slaughter was determined according to Prange et al. (1977). Besides, analysis of protein, water and dry matter content in *LL* muscle tissue were determined. Meat lightness and pH_{24} in *Semimembranosus (SM)* muscle were also executed. At 45 min *post mortem* samples from *Longissimus Lumborum* muscle were collected into tubes with 0.5 M PCA for determination of glycogen (Dalrymple and Hamm 1973) and lactate (Bergmeyer, 1974). On the basis of them the glycolytic potential (GP) was calculated according to formula proposed by Monin and Sellier (1985).
The *RYR1* genotypes were established according to Fujii et al. (1991). Polymorphism of *CAST* gene was identified with *Msp*I endonuclease according to Ernst et al. (1998).
Statistical elaboration of the data was executed using three-way non-orthogonal ANOVA. Statistical model comprised: *RYR1* and *CAST* genes polymorphism, group of meatiness and their interactions:
Detailed comparison of average values of analysed groups was made using Tukey' test.

Results and discussion

In analysed population of animals a highly significant influence of *RYR1* genotype on pH value measured at 35 min *post mortem* immediately in *Longissimus lumborum* muscle (pH_{35}) as well as at 45 min *post mortem* in water homogenate of muscle tissue (pH_{45}) and on lightness of *LL* muscle ($P \leq 0.01$) was observed. The *RYR1* gene polymorphism affected also lactate level in *LL* muscle tissue, R_1 value, WHC and drip loss in both terms of measurements ($P \leq 0.05$). It should be stressed that analysed animals were of *CC* and *CT* genotype of the *RYR1* locus. Most profitable values of above mentioned parameters in stress resistant (*CC*) group of fatteners were noted.

A significant influence of *CAST* gene polymorphism identified with *Msp*I enzyme (*CAST/Msp*I) was noted for R_1 coefficient value, drip loss from muscle tissue at 48 and 96 h *post mortem* ($P \leq 0.01$) and for lactate level, WHC and protein and water content ($P \leq 0.05$).

Fig. 1. Differences between mean values of meat quality traits of animals with AA and BB genotypes at the CAST/MspI locus, expressed in SD units of the traits



1-Lactate level; 2-R_1; 3-WHC; 4-drip loss at 48h; 5-drip loss at 96h; 6-% of protein; 7-% of water in LL muscle

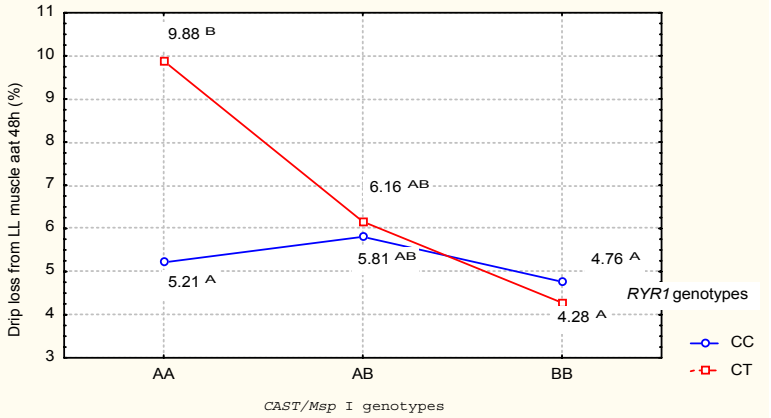
We have observed that animals with *BB* genotype at this locus were characterised by most profitable values of all these traits. High and significant influence of *CAST/Msp*I gene on drip loss from muscle tissue obtained in these investigations is especially interesting, taking into consideration important problem concerning a high variation of this trait (from 2 to 16%) signalised by several authors (Honkavaara 1997, Bertram et al. 2000, Schäfer et al. 2002).

Among analysed meat quality traits affected by *CAST* genotype, differences between average phenotypic values of *AA* and *BB* homozygotes in relation to *CAST/MspI* locus were close to 1 SD unit for drip loss at 48 h as well as at 96 h *post mortem* (0,92 and 0,96 SD respectively) (Fig. 1).

This indicates that *CAST/Msp*I genotype has an effect close to the major effect for drip loss from *LL* muscle tissue.

Statistically significant interaction between *RYR1* and *CAST/Msp*I loci was noted for: drip loss at 48 h post mortem ($P \leq 0.01$) (Fig. 2), and pH_{24} of *LL* muscle ($P \leq 0.05$) (Fig. 3). Value of drip loss at 48 h *post mortem* was differentiated between *CC* and *CT* animals at *RYR1* locus being *AA* homozygotes at *CAST/Msp*I locus. Among animals of *CT* genotype at *RYR1* locus carrying *AA* or *BB* genotypes at *CAST/Msp*I locus drip loss at 48 h *post mortem* differed significantly (9,88 and 4,28% respectively). Conducted additionally one-way ANOVA analysis showed that animals with *AA*/*CT* genotype at *CAST/MspI* and *RYR1* loci, respectively, showed significantly highest drip loss at 48 h *post mortem* (9,88 %), higher drip loss at 96 h and R_1 value, worse WHC and protein content than *BB/CT* animals, whereas meatiness of these two groups did not statistically differ.

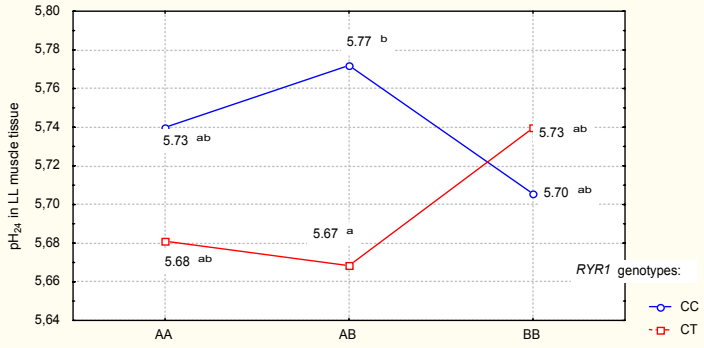
Fig. 2. Interactive effect of *CAST/Msp*I and *RYR1* genotypes for drip loss from LL muscle at 48h



Explanations: A,B mean values showed at the plot, signed by different capital letter differ significantly at P<

It is known that animals with *TT* or *CT* genotype at the *RYR1* locus show higher level of Ca^{2+} ions released from cells as a result of defective functioning of calcium channels under stress conditions. Next, proteolytic activity of calpain system (calpains and their inhibitor - calpastatin) is significantly dependent on Ca^{2+} ions level. One should suppose that different variants of calpastatin conditioned by polymorphism of *CAST* gene could have different sensibility to level of Ca^{2+} ions, and the same different activity stopping proteolytic activity of calpain. This may explain the differences in drip loss and pH values noted between fatteners with the same *RYR1* genotype but differentiated by *CAST/Msp*I genotypes.

Fig. 3. Interactive effect of *Cast/Msp* I and *RYR1* genotypes for pH_{24} in LL muscle tissue



Explanations: a, b mean values showed at the plot, signed by different small letter differ significantly at P<=0.05

Investigations carried out by Koćwin-Podsiadła et al. (2003) in similar scheme but only on (Polish Large White x Polish Landrace) x (Hampshire x Pietrain) crossbreeds showed significant interaction between *RYR1* and *CAST/Hinf*I genotypes for drip loss from *Longissimus Lumborum* muscle at 48 h *post mortem*.

Ciobanu et al. (2002) confirmed the effect of polymorphism of *CAST* gene identified with *Hpy*188I and *Pvu*II restriction enzymes on drip loss.

The polymorphisms of the *CAST* gene genotyped in this study were located in intron 7 and it is difficult to conclude their effect on calpastatin level or activity. The effect of analysed mutations on meat quality traits may be due to the linkage to any other mutation within the coding or regulatory regions of the *CAST* gene being the causal mutation.

Conclusions

In analysed fatteners' population highly significant influence of *RYR1* gene polymorphism on pH_{35}, pH_{45}, R_1 values that are basis of PSE meat classification and also on lactate level in *Longissimus Lumborum* muscle was noted.

Fatteners with *BB* genotype at the *Cast/Msp*I locus by lower lactate level (7.59 µmol/g), R_1 value (0.05), WHC (0.93 cm^2), drip loss at 48 h (3.03%) and at 96 h *post mortem* (3.36%) values, lower water content (1.31%) and also by about 0.5% higher protein content were characterized in comparison to fatteners with *AA* genotype at this locus. Relationships between polymorphism at the *CAST* locus and some meat quality traits, especially the high effect of *CAST/Msp*I polymorphism on drip loss of muscle tissue at 48 h as well as at 96 h *post mortem* (0,92 and 0,96 SD respectively) suggest that effect of the *CAST* gene is close to a major effect for this trait.

Interactions between genotypes *CAST/Msp*I and *RYR1* indicate that quality of meat influenced by *RYR1* genotype may be modifying by simultaneous influence of genotype as regards *CAST* locus. The polymorphism at the *CAST/Msp*I locus was closely related with drip loss from LL muscle tissue at 48 h among animals with *CT* genotype at the *RYR1* locus (with similar meat content in carcass) whereas this relationship among stress resistant (*CC*) animals was not confirm.

Obtained interesting results indicate that relationships between polymorphism of *CAST* gene and meat quality of pigs should be further investigated.

POST-MORTEM PROTEOLYSIS IN FRESH PORK: ROLE OF THE LYSOSOMAL ENZYME SYSTEM AND OF THE CALPAIN SYSTEM

Kristensen, L.[a], Therkildsen, M.[b], Oksbjerg N.[b], Ertbjerg, P.[a]

[a]Royal Veterinary and Agricultural University, Department of Food Science, Rolighedsvej 30, DK-1958, Frederiksberg C, Denmark. [b]Danish Institute of Agricultural Sciences, Department of Animal Product Quality, PO Box 50, DK-8830 Tjele, Denmark.

Background

It is well known that the tenderness of meat increases during storage and it is generally believed to be caused by an enzymatic degradation of muscle proteins post mortem (PM). Two enzyme systems have continually been suggested as possible candidates for the proteolytic degradation PM. Several studies have suggested the lysosomal cathepsins to be involved in the tenderization process (Dutson, 1983; Etherington et al., 1987; Mikami et al., 1987; O'Halloran et al., 1997; Ouali et al., 1987). Cathepsins are able to degrade a wide spectrum of muscle proteins and have a pH optimum close to normal ultimate pH in meat which makes lysosomal enzymes good candidates for catalysing PM proteolysis and meat tenderization. In the last decade much work has implicated a major role of the calpain system for tenderization of beef and lamb. In beef the initial at-slaughter levels of the calpain system have been found to be related to the PM tenderization process and ultimate tenderness (Shackelford et al., 1991; Whipple et al., 1990; Zamora et al., 1996) and the calpain system has also been suggested to be primarily responsible for PM protein degradation and tenderness development during refrigerated storage leaving little or no importance of the lysosomal enzyme system (Hopkins and Thompson, 2002; Koohmaraie, 1996; Taylor, 2003). In pork, sparse data exists on the relationship between the initial level of enzyme activity and PM protein degradation and tenderness. However, a recent study on pork suggests that both enzyme systems could play a role (Ertbjerg et al., 1999a).

Objectives

The intentions of the present paper are to report data related to PM proteolysis in fresh pork and discuss the mechanisms of PM proteolysis and to what extent calpains and cathepsins are involved in this.

Materials and methods

Nine litters of three female pigs and three male pigs were allocated to three diet groups. Diets composition, slaughter procedure and sampling procedure were as described in Therkildsen et al. (2004). Briefly, samples for m-calpain, μ-calpain, calpastatin, cathepsin B+L, cathepsin B, β-glucuronidase and cystatin were taken 15 min after slaughter and frozen in liquid nitrogen. Temperature decline in the carcasses were measured over 24 h PM by inserting a temperature logger 10 min PM at left side LD at last rib. Samples for myofibrillar fragmentation index (MFI) were taken day 1, day 2 and day 4 PM. Calpastatin, m-calpain, μ-calpain and MFI were determined as described (Kristensen et al., 2002). Lysosomal enzyme activity and cystatin activity were done as described in Kristensen (2003). The data were tested for normal distribution using the Shapiro-Wilk test within the UNIVARIATE procedure of SAS (SAS Inst. Inc., 1999 - 2000). Variables not satisfying the requirement of a normal distribution were transformed. The effects of diet and sex were removed from all variables using the GLM procedure of SAS. Multiple linear regression models were obtained by the REG procedure of SAS using stepwise regression. A P-value of 0.15 was used to introduce and keep variables in the models.

Results

The effects of diet, sex and the interaction have consequently been removed from all data before modeling. Multiple linear regressions models were obtained using the MFI values as dependent variables and the at-slaughter activities of μ-calpain, calpastatin, cathepsin B, cystatin and the temperature decline from 60 minutes until 180 minutes PM as independent variables (Table 1). Calpastatin correlated to m-calpain ($r = 0.37$; $P = 0.009$), β-glucuronidase and cathepsin B+L to cathepsin B ($r = 0.63, 0.68$; $P = < 0.001$ & < 0.001) and μ-calpain, cathepsin B, cystatin, and temperature decline to pH45 ($R = -0.30, 0.37, 0.33, -0.50$; $P = 0.03$,

0.01, 0.02, < 0.001). To fulfill the requirement of non-covarying independent variables m-calpain, cathepsin B+L, β-glucuronidase and pH45 were excluded from the models. Modeling MFI values resulted in highly significant models explaining almost 50 % of the variation (Table 1). Calpastatin had the highest explainable power followed by cathepsin B in the models obtained for MFI values day 1 and 2 PM. At 4 days PM cathepsin B had the highest explainable power followed by calpastatin. Cystatin activity and temperature decline were included in all three models.

Table 1. Multiple linear regression models on MFI-values 1, 2 and 4 days PM.

MFI day 1		MFI day 2		MFI day 4	
Variable	Partial R^2	Variable	Partial R^2	Variable	Partial R^2
Calpastatin	0.18	Calpastatin	0.24	Cathepsin B	0.24
Cathepsin B	0.10	Cathepsin B	0.18	Calpastatin	0.15
$T_{decline}$	0.04	Cystatin	0.04	$T_{decline}$	0.04
Cystatin	0.04	$T_{decline}$	0.03	Cystatin	0.03
µ-calpain	0.03				
Model R^2	0.46		0.48		0.46
P-value	< 0.001		< 0.001		< 0.001

Discussion

The tenderization of meat is mainly caused by proteolytic degradation of muscle proteins PM. The fragmentation of myofibrils has for long been associated with tenderness development of meat (Davey and Gilbert, 1969; Møller et al., 1973) and a method to measure it has been termed MFI (Olson and Parrish, 1977). The calpain system has been suggested as the primary catalyst of the PM tenderization process in beef (Huff-Lonergan et al., 1996; Koohmaraie et al., 1986) and has also been linked to the tenderization process in pork (Ertbjerg et al., 1999a; Kristensen et al., 2002; Kristensen et al., 2003). Likewise indicators of lysosomal proteolysis PM have been linked to tenderisation in beef (Calkins et al., 1987; Ertbjerg et al., 1999b; Shackelford et al., 1991). Ouali (1992) argued that the changes in the structure of meat PM caused by proteolysis only can be explained by a synergistic action between lysosomal enzymes and the calpain system. To test this, multiple linear regression models were developed using MFI as dependent variables and the at-slaughter activity of both the calpain system and indicators of the lysosomal enzymes as independent variables (Table 1). The models obtained at all time points clearly showed that calpastatin and cathepsin B explained more of the variation in MFI collectively than each of them did in isolation, suggesting that calpastatin and cathepsin B have a co-operative action in PM proteolysis. If the calpastatin activity and the activity of cathepsin B are taken as representatives of the calpain system and of the lysosomal system, respectively, the results presented in Table 1 strongly suggest a role for both enzyme systems in PM proteolysis of pork as proposed by (Ouali, 1992).

There has been some debate regarding the involvement of the calpain system and lysosomal system in PM proteolysis and tenderization of meat, and some researchers have argued against the importance of the lysosomal system and favored the importance of the calpain system (Hopkins and Thompson, 2002; Koohmaraie, 1996; Taylor, 2003). Koohmaraie (1996) argued that no role can be assigned to the lysosomal enzymes until it is clearly confirmed that the enzymes are released from the lysosomal system during PM storage. The lysosomal proteases are encapsulated within the lysosomal system and therefore have no direct access to the myofibrillar proteins in the living animal. However, several papers report an increased activity of free lysosomal enzymes during PM storage, indicating a release from the lysosomal system after slaughter. Dutson and Lawrie (1974) observed a two fold increase in the free activity of β-glucuconidase in beef 24 hours PM which increased to three fold after 5 days storage. Ertbjerg et al. (1999b) also observed an increase of free β-glucuconidase activity and in addition an increase of the free activity of cathepsin B+L in beef during storage for 21 days. Release of cathepsin C and β-glucuconidase was also observed in lamb PM (Dutson et al., 1980). Using electron microscopy of rabbit muscle stained with anti-cathepsin D (Kubo et al., 2002) observed a gradual diffusion of cathepsin D from the lysosomes to the myofibrils during storage for 14 days. Almost all cathepsin D were released from the lysosomes and absorbed onto the myofibrils after 14 days storage. These results signify that lysosomal enzymes are released during PM storage of meat and are therefore likely to contribute to PM proteolysis. Also a significant part of the total activity of cathepsin B and cathepsin B+L can be measured in drip (Purslow et al., 2000; Kristensen, 2003). The only way cathepsin activity can be measured in drip is via a release from the lysosomal system. An other major argument against

a role for the lysosomal enzymes in muscle proteolysis during PM storage has been that no adequate explanation is provided for lack of actin and myosin degradation PM, as cathepsins can degrade myosin and actin in vitro and neither are degraded during PM storage of meat (Hopkins and Thompson, 2002; Koohmaraie, 1996; Taylor, 2003). However, degradation of both myosin and actin has recently been reported during PM storage of meat (Berge et al., 2001; Ertbjerg et al., 1999b; Lametsch et al., 2002).
The information revealed above suggest that both the lysosomal system and the calpain system significantly contribute to PM proteolysis and tenderization of meat, which is in accordance with several other studies (Dutson, 1983; O'Halloran et al., 1997; Ouali, 1992; Ouali and Valin, 1981). Ouali (1992) studied how structural changes, biochemical changes and proteolysis were affected by tenderization of beef and rabbit. The effects of tenderization were compared to the effects of incubating purified myofibrils with either lysosomal proteases or calpains. Ouali (1992) concluded that the observed changes in beef and rabbit during tenderization only can be explained by a synergistic effect of both enzyme systems. It was further suggested that the calpain system primarily is responsible for changes occurring early PM and the lysosomal system primarily responsible for changes occurring later PM. The involvement of both enzyme systems in PM proteolysis is supported by the results presented in **Table 1**. The at-slaughter activity of a representative of the lysosomal system (cathepsin B) and of the calpain system (calpastatin) were used to model the MFI values obtained from pork 1, 2 and 4 days PM. Both enzyme systems were important contributors to the three models obtained. However, calpastatin had the highest partial correlation coefficient at 1 and 2 days PM and cathepsin B the highest at 4 days PM, which fit well into the suggested time dependency of the two enzyme systems (Ouali, 1992).

Conclusions

Taken together the results presented in this paper and previous studies suggest that both the calpain system and the lysosomal enzyme system are involved in PM protein degradation in pork, and that a co-operative mode of action is a likely mechanism.

Background

Preslaughter stress is generally thought to be of influence on meat quality parameters, mostly with a negative effect. However, the results of published experiments are not unequivocal. Genotype, transportation, lairage time, season of the year, environmental conditions and many other factors are also of effect on meat quality. One problem is to evaluate the effective level of stress on the animal. Heart rate can be used as one indication.

Although tenderness is mostly taken into account in beef investigations, it is also an essential parameter for pig meat quality. Tenderness of meat develops by the proteolytic action of the calpain/calpastatin system on different interfilament proteins, loosening the myofibrillar structure. Calpain is activated by Ca^{2+}, indicating the role of the intracellular Ca^{2+} concentration on the tenderness. The effect of Ca^{2+} is manifested by several investigations injecting Ca^{2+} (Kerth et al, 1995), marinating meat in Ca^{2+} containing solutions (Young et al., 1995) or inducing Ca^{2+} release by high pressure (Okamoto et al., 1995). Generally, a disturbed regulation of the intracellular Ca^{2+} concentration results in inferior meat quality parameters pH, drip, and colour, but on the other hand an increased Ca^{2+} concentration may activate the protease calpain, tenderising the meat. So, it seems worthwhile to investigate the relationships between Ca^{2+} transport, meat quality and tenderness.

Objectives

The objective of this study was to elucidate the impact of different kinds of stress (nose snare, electrical goad, control) just before slaughter on the development of meat quality. Especially the effect of the SR-Ca^{2+} transport in post mortem muscle samples on the development of tenderness was of interest. To estimate the reaction of the used kinds of stress on the pigs, the heart rate was determined.

Materials and methods

Animals and stress

Thirty female German Landrace pigs were used. The pigs were produced and raised in single boxes in an experimental unit of the institute up to a live weight of 105 – 115 kg. The animals of this experimental unit are free of the mutation of the calcium release channel (CRC).

The evening before slaughter the three heaviest pigs were transported to the slaughter facility of the institute. The heart rate was measured for about half an hour before slaughter by using a Polar Heart Rate Monitor.

About 5 min before the slaughter one pig was gently driven into the stunning pen and stunned electrically. The second pig was also driven into the stunning box but received an additional stress by the application of a nose snare for 5 min. The third pig was stressed for five minutes before slaughter by using an electrical goad according to D`Souza et al. (1999). Immediately following the stress just before stunning a biopsy (shot biopsy device) was taken. The stunning and the following procedures were identical for all pigs. Immediately following exsanguination a muscle sample (0 h sample) of the *longissimus* muscle between the 13th and 15th rib was removed by shot biopsy. Also, at 45 min p.m. and at 4 h p.m. samples were taken.

Sample preparation and Ca^{2+} uptake determination

About 0.5 g of muscle tissue were homogenised and the Ca^{2+} uptake of the muscle homogenate was determined as described by Küchenmeister (1999a). A part of the homogenate was stored at -70° C and later used for protein determination and different biochemical investigations. The calcium release channel was manipulated as described earlier (Küchenmeister et al., 1999a).

Meat quality measurements
Meat quality parameters of the *longissimus* muscle were measured by standard procedures (Küchenmeister et al., 1999b). The R-value as an indication for p.m. energy metabolism was determined on 45 min samples (Honickel et al., 1977). For determination of tenderness, two slices of *longissimus* muscle (13th-15th rib) were sampled 24 h p.m. One slice was used for tenderness determination on this sampling day and the second slice was stored at about 5° C for 6 days and then the tenderness was determined using a Texture Analyser with Warner-Bratzler accessories.

Results and discussion

The effect of the applied stress on the pigs is not easy to evaluate. One parameter to indicate the stress is the heart rate (HR). Figure 1 shows that the HR of the control animals (no additional stress) increased slowly in the course of the gentle movement (start about 5 min before slaughter) from the lairage box to the stunning from about 100 beats per minute (bpm) to 175 bpm. The nose snare stress started 5 min before slaughter after gently moving the pig into the stunning pan (with increasing heart rate comparable to the control animals). So, the heart rate started at about 175 bpm (comparable to Control). Surprisingly, however, the heart rate decreased in the time course of snare use down to 100 bpm, although the pigs were shrieking and pulling. This phenomenon is in agreement with earlier investigations (Geverink et al., 2002), but a plausible explanation is missing. The use of the electrical goad not only increased the HR in a short time interval up to 200 bpm, but also the pigs were running to avoid the electrical shock. So, this seems to be an effective stress.
These different levels of stress are reflected on the meat quality parameters (Tab. 1). There were no significant differences between control and nose snare pigs. However, the use of the electrical goad resulted in significant lower pH45 values and a brighter colour. Also, the drip loss and conductivity 24 h p.m. were highest in the goad group. Figure 2 shows the pH in the time course p.m. Four h p.m. the pH values were almost identical. However, the use of the goad resulted in lower values already immediately after slaughter and 45 min p.m., indicating an increased energy consumption and glycolysis p.m. by the application of the goad. This is verified by a higher R-value (IMP/ATP) 45 min. p.m.
The Ca^{2+} uptake of the sarcoplasmic reticulum (SR) of the homogenate (Tab. 2) shows generally lower values in the goad group, although not always significantly different from the other groups. The uptake 45 min p.m. was significantly lower following goad stress (independent of the state of the calcium release channel: basic or closed), but there were no differences between control and nose snare. As expected, the uptake decreased in the time course p.m. The rate of decrease was higher with basic CRC, compared to closed CRC. While the level of decrease with closed CRC indicates deterioration of SR-ATPase and SR membranes, the rate with basic CRC implies an opening effect on the CRC. A very fast and significant decrease of uptake between biopsy and 0 h samples with basic CRC was the result of applying goad stress. A reduced SR Ca^{2+} transport is supposed to increase the intracellular Ca^{2+} concentration compared to undisturbed Ca^{2+} regulation.
Our hypothesis, that a reduced Ca^{2+} uptake will be of effect on the tenderness by activation of calpains because of a higher intracellular Ca^{2+} concentration could not be verified. The tenderness, determined at 24 h p.m. samples, was not different between experimental groups (Fig. 3). This also applies for samples stored for six days before tenderness measurement. The shear values were significantly reduced after the storage of the loin chops compared to the 24 h p.m. measurements, however, the increase in tenderness was not influenced by the kind of stress. The rate of glycolysis affects the extend of the tenderisation at least in beef. A low glycolytic rate p.m. results in high shear force, whereas a high glycolytic rate leads to lower shear values (O´Halloran et al., 1997), probably related to lower or higher intracellular Ca^{2+} concentrations, respectively.

Conclusions

The immobilisation by a nose snare seems to have a very limited stress effect, indicated by decreasing HR and no significant effects on meat quality and Ca^{2+} transport. The use of an electrical goad had a major effect on all measured parameters: Heart rate, Ca^{2+} transport, meat quality, except tenderness. A reduced Ca^{2+} transport, induced by the high goad stress resulted as expected in inferior meat quality.

However, the hypothesis, that a reduced Ca^{2+} transport implies a higher intracellular Ca^{2+} concentration resulting in more tender meat could not be verified. Altogether, a stress before slaughter has to have a high level to be of significant influence on meat quality.

DOES THE ACTIVITY OF GLYCOGEN DEBRANCHING ENZYME LIMIT THE RATE OF THE GLYCOLYSIS?

Kylä-Puhju, M., Ruusunen, M. and Puolanne, E.
Department of Food Technology, PO Box 66, FIN-00014 University of Helsinki, Finland

Background

In living muscle glycogen provides local fuel storage for short-term energy consumption. After slaughter glycogen degradation to lactate causes *post mortem* pH to decline in muscles. The rate and the extent of the pH decrease affects several meat quality traits. The complete degradation of glycogen is achieved by two enzymes: glycogen phosphorylase (phosphorylase) and glycogen debranching enzyme (GDE) (Brown and Brown, 1966). Mammalian GDE is a monomeric protein containing two independent catalytic activities: a glycan transferase (EC2.4.1.25) (transferase), and amylo-1,6-glucosidase (EC3.2.1.33) (glucosidase).

Phosphorylase catalyses the sequential phosphorolysis of the outer chains of the glycogen molecule until it reaches the fourth glucose unit from the branch point of the molecule (Walker and Whelan, 1960). Glycogen with four glucose units in every branch is called the limit dextrin state. The outer layer of limit dextrin has symmetric structure and it is converted back to an asymmetric structure by the transferase activity of GDE. This occurs by transferring a maltotriosyl group from the side chain to the main chain. The glucosidase hydrolyses the remaining glucosyl branch, producing free glucose. The debranched dextrin formed has long outer chains which are again susceptible to further degradation by phosphorylase (Brown and Brown, 1966; Nelson, Kolb and Larner, 1969; Nelson and Larner, 1970).

Yurovitzky and Milman (1975) suggested that the rate of glycogenolysis is limited by the activity of GDE. Furthermore, Immonen (2000) showed that *post mortem* glycogenolysis may stop even if there is glycogen left in the muscle and speculated that GDE may play a role in this process. However, there is very little information available about the activity of GDE in meat production animals.

Objectives

The aim of the present study was to investigate the activity of GDE in relation to temperature in porcine light *longissimus dorsi* (LD) muscle and dark *masseter* (M) muscle. If temperature affects the activity of GDE, it may influence the rate of *post mortem* glycogenolysis and glycolysis and thus the ultimate pH of meat. The method for determining the activity of GDE used in the present study measures activities of both the transferase and the glucosidase, not the individual activities of the enzyme.

Materials and methods

Muscle samples (LD and M) from 10 pigs were obtained from a commercial abattoir. The LD sample was dissected from the last rib about 35 min after stunning. The samples were frozen and stored in liquid nitrogen. The analyses were performed within two days after sampling. The activity of GDE was first determined in the muscles of four animals at temperatures 4, 15, 25, 35, 39 and 42 °C and was further determined at higher temperatures (39, 42, 50 and 60 °C) in six additional animals.

The activity of GDE was determined using the method of Nelson, Palmer and Larner (1970) with minor modifications. The method follows the change in the iodine-complex spectrum of glycogen phosphorylase limit dextrin (limit dextrin), a natural substrate for GDE. In the present study the assay solution contained only 0.1 ml 1% limit dextrin and 0.020 ml 0.5 M sodium maleate (A24979, Sigma-Aldrich). The pH of the reaction mixture was adjusted to 6.3 ± 0.05 and then incubated at 4, 15, 25, 35, 39, 42, 50 or 60 °C before the reaction was started by adding 0.08 ml meat extract. The meat extract was prepared daily, using 2.5 ml buffer which contained 0.05% $KHCO_3$ and 0.004 M EDTA (pH approx. 7.8 at 25 °C) per 1 g wet weight muscle. The mixture was homogenised (Ultra-Turrax T25, Janke and Kunkel, Germany) and centrifuged (Sorvall Instruments RC5C) 10 min, 10 °C and 30000 G and the supernatant was used in the measurements.

The reaction was stopped in a boiling-water bath followed by immersion in an ice bath. The reaction times were 1, 1.5 and 2.5 min for LD muscle and 1, 2.5 and 4.0 min for M muscle. Iodine reagent (2.6 ml) was added to the stopped reaction mixture and the absorbance (525 nm) recorded after 20 min. The iodine reagent was prepared according to Nelson et al. (1970). The pH value (6.3) and the reaction times used for determining the temperature-activity profiles of GDE in both muscles were determined in preliminary experiments. Method blanks (zero time controls) were prepared by denaturing the meat extract protein in the boiling-water bath before adding the other reagents.

The conversion of limit dextrin to glycogen was ensured from the absorption spectra between 375 - 800 nm. Samples and the method blank were diluted 5-fold with additional iodine reagent. All the absorbance and absorption spectra measurements were obtained with a Lambda 2 spectrometer (Perkin Elmer, Ueberlinger, Germany).

Phosphorylase limit dextrin was synthesised in our laboratory according to the method of Werries, Franz and Geisemeyer (1990) as it is not available commercially. Commercially available phosphorylase *a* was passed through a column of ω-aminobutyl agarose (Werries et al. 1990). The activity of purified, dried phosphorylase *a* was measured spectrophotometrically according to Bass, Brdiczka, Eyer, Hofer and Pette (1969). Purified phosphorylase a was added to 350 mg glycogen (bovine liver, G0885, Sigma-Aldrich) in 5 ml 0.05 M phosphate buffer (pH 6.8). In the present study the solution also contained 0.1 mM 5'AMP (01930, Fluga). The solution was dialysed at 37 °C against 150 ml of the same buffer. The digest was mixed with trichloroacetic acid (final concentration 10% v/v), dialysed against water and centrifuged for 10 min at 1000 G. The limit dextrin formed was precipitated with 4 volumes of ethanol, centrifuged (5 min, 1000 G), washed twice with ethanol and dried.

Statistical analysis was performed with the Statistical Analysis System version 8.02 (SAS, 1990). The mixed procedure with Bonferroni adjustment was applied when calculating the least squares means of the variables in the temperature-activity profiles of GDE. The curves were fitted using SAS/insight and the curves were plotted with Microsoft Excell 97 SR-2 (XY(scatter), polynomial trendline). The temperature values for maximum enzymatic activity were read from the curves if possible.

Results and discussion

In both muscles the activity of GDE was higher ($P < 0.001$) at the temperatures found in the carcass just after slaughter (39 °C and 42 °C) than at temperatures found during cooling (4 °C and 15 °C) (Figure 1). In M muscle significant ($P < 0.01$) difference was also shown in activity of GDE between temperatures of 39 °C and 25 °C. The temperature-activity profiles indicated that GDE was more active in light LD muscle than in dark M muscle.

In LD muscle the optimum temperature for GDE activity was 39 °C. The activity began rapidly to fall when the temperature decreased to below 35 °C, and the enzyme was practically inactive at temperatures below 15 °C. The other glycogen degrading enzyme, phosphorylase, is also most active at normal body temperatures (Cori, Cori and Green, 1943).

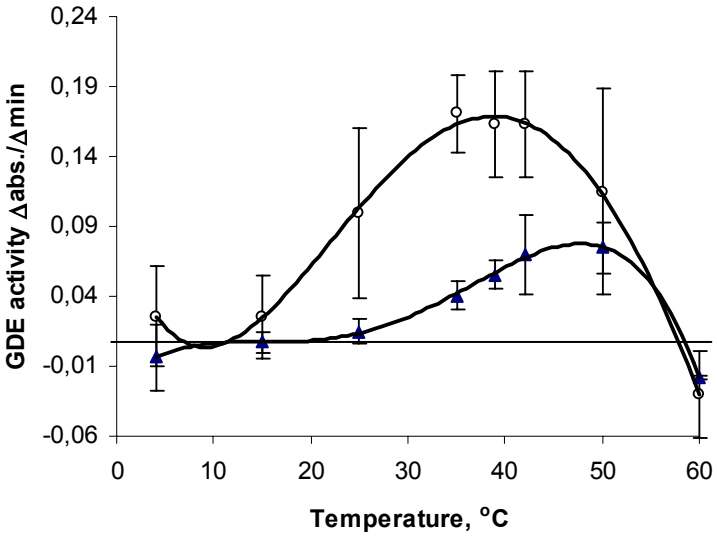

Figure 1. The activity of GDE in porcine *longissimus dorsi* (o) and *masseter* (▲) muscles in relation to temperature.

For *masseter* muscle the optimum temperature for GDE was near 50 °C and the decrease in activity began before the temperature had decreased to below the body temperature (38.5±0.65 °C; Hannon, Bossone and Wade, 1990). The decrease in activity of LD muscle GDE did not begin until the temperature had decreased to below 35 °C. Nelson and Watts (1974) have showed that the temperature optimum for rabbit muscle GDE activity is near 50 °C and that the activity sharply decreases when the temperature decreases to 20 °C which is consistent with the results of the present study. It seems that the activity of GDE does not block rapid glycolysis and pH decrease when the temperature is high since the enzyme remains activity even at temperatures above 45 °C. This may be important in pale soft and exudative (PSE) meat, where the pH decreases rapidly at high temperatures. Rapid cooling could decrease GDE activity and thus the rate of glycolysis, so reducing the formation of PSE meat.

We assume that the decrease in the activity of GDE caused by the temperature decrease also takes place in carcasses after slaughter. During the normal chilling procedure used in Finland, the core temperature of porcine LD muscle decreases to below 35 °C in about 1 h *post mortem*. At that time the pH has decreased to about 6.3 and the glycogen (assumed concentration at the time of slaughter has been normal or high) is still in a state which is susceptible for the degradation of phosphorylase. The temperature decrease of the muscles goes on due to cooling of the carcass and, therefore, when the activity of GDE is needed to continue glycogenolysis and glycolysis, its activity is not maximal. Thus, the decrease in the activity of GDE may delay the rate of glycogenolysis and glycolysis *post mortem*.

In dark M muscle, the decrease in the activity of GDE and in the rate of glycogenolysis was faster than in the light LD muscle. This is supported by the findings that M muscle temperature decreases faster and that even a slight decrease in temperature significantly reduces the activity of GDE. Mélendez-Hevia et al. (1993) have estimated that at most 34.6% of glycogen molecule is directly susceptible to the degradation of phosphorylase. We estimated that this amount is enough to cause pH to decrease from 7.0 to about 6 in dark porcine M muscle *post mortem*. After that the activity of GDE is needed so that glycogenolysis can continue. However, the ultimate pH of M muscle does not usually decrease to below 6, which may be due to the temperature decrease in M muscle during cooling which inhibits the activity of GDE and leads to delayed glycogenolysis and thus to high ultimate pH. It is not known in which state the glycogen molecules are, in other words, how many glucose units are in the outer layer of the glycogen molecule at the moment of slaughter. Also is unclear, are all the glycogen molecules within a muscle in the same state.

Beecher, Briskey and Hoekstra (1965) showed that *post mortem* glycolysis is faster at 37 °C than at 4 °C both in light and dark parts of porcine *semitendinosus* muscle. Their results showed that the glycolytic and glycogenolytic enzymes remained active at low temperatures but were slower. The present study showed that

the activity of GDE was very slow at low temperatures (below 15° C). Beecher et al. (1965) found no significant differences between the ultimate pH values of the light parts of *semitendinosus* muscle held at 37 °C or at 4 °C, while the ultimate pH of the dark part of the *semitendinosus* muscle was significantly lower in muscles held at 37 °C than at 4 °C. This is also consistent with our results where the light LD muscle GDE also showed activity at temperatures below 25 °C but the dark M muscle enzyme did not. Thus, the decrease in the activity of GDE due to temperature decrease may stop the glycolysis earlier in dark M muscle than in light LD muscle.

Conclusions

It can be concluded that GDE is more active in porcine light LD muscle than in dark M muscle. In both muscles, the *post mortem* decrease in temperature strongly reduces the activity of GDE, which may in turn regulate the rate of glycolysis. The eventual impact of activity of GDE on PSE pork and cold shortening in beef warrants further study.

EFFECTS OF DIETARY VITAMIN E AND VITAMIN C SUPPLEMENTATION ON LEVEL OF ALPHA –TOCOPHEROL AND L-ASCORBIC ACID IN MUSCLE AND ON THE ANTIOXIDATIVE STATUS AND MEAT QUALITY OF PIGS

R. Lahučký, I. Bahelka, K. Novotná, K. Vašíčková
Research Institute of Animal Production, 94992 Nitra, Slovak Republic

Background

Vitamin E and C are primary antioxidants in biological systems and break the chain of lipid peroxidation. Many studies suggest that vitamin C and vitamin E act synergistically (Gay 1998). Previous studies evaluating the efficiency of relatively high levels of vitamin have been inconsistent in producing a growth or feed efficiency response. By Mahan et al. (1994) was used a stable source of vitamin C (magnesium-L-ascorbyl-2-phosphate) in pig feeding experiment. Another stable source of vitamin C (L-ascorbyl-2-polyphosphate, Rovimix® Stay-C® 25, Roche) was used by de Rodas et al. (1998) and Sahin et al. (2002). Data from pig experiment introduced by Kremer et al. (1999) suggest that vitamin C supplementation before slaughter can improve parameters of meat quality.

Objectives

The objective of this study was to evaluate further the effects of vitamins E and C supplementation on level of α–tocopherol and ascorbic acid and lipid peroxidation status in fresh and chill-stored meat and on some quality parameters

Materials and methods

Thirty Slovak White Meaty pigs were used in this experiment. Control group (n = 10) and two experimental groups were homozygotes, negative on malignant hyperthermia (defined by DNA based test). Control group was fed with a diet supplemented with basal level α–tocopherol (Table 1). Experimental groups received a supplemental (Table 1) level α–tocopherol (500 mg/kg), (group E, n = 10) and a supplemental level α – tocopherol (500 mg/kg) and ascorbic acid (200 mg/kg), (group EC, n = 10) for 30 days before slaughter. Vitamin E (ROVIMIX® E-50 SD, stable source of vitamin E in feed) and vitamin C (ROVIMIX® STAY-C® 35) were provided by a commercial company (Roche, Germany). Animals were slaughtered at average live weight of 110 kg. The sample of longissimus dorsi (part lumborum, LD) muscle was used immediately (24 h) and the remaining samples were wrapped in aluminium film and stored in a refrigerator at 4°C for 5 days. The concentration of vitamin E (α–tocopherol) of the samples (fresh, cooked, frozen) was measured by HPLC and vitamin C (ascorbic acid) with 2,4-dinitrophenylhydrazin as a color reagent was estimated. Lipid oxidation in samples (fresh and 5 days chill-stored) and the stability of the skeletal muscle (fresh samples) lipids against stimulated (by Fe^{2+}/ascorbate) lipid peroxidation were assessed by the 2-thiobarbituric acid method (TBARS) and expressed in terms of malondyaldehyde (MDA, mg/kg tissue) as described earlier (Lahucky et al., 2001). The pH value of the carcass (m. longissimus – between 13th and 14th rib) 45 min post mortem, electrical conductivity 3 h, color by Miniscan 24 h, total water, protein and intramuscular fat were also measured (Lahucky et al., 2001) . Drip loss analyses were made according to Honikel (1998). Shear force was determined in cooked samples (internal temperature 80°C, used also for further analyses) with Warner-Bratzler (W-B) apparatus. Statistical analyses were calculated as mean values and standard deviations and differences were evaluated by t-test.

Results and discussion

The supplementation of vitamin E (α–tocopheryl acetate) to pigs increased about 2 folds the α–tocopherol levels (Fig 1) of fresh (24 h) and 5 days chill-stored meat. The levels of α–tocopherol in longissimus dorsi muscle are higher or comparable with previously reported results (Honikel et al., 1998, Lahucky et al., 2000, 2001). Dietary supplementation of vitamin C increased fresh meat vitamin C concentrations (Fig 2) and in some extense in stored meat ($P<0.05$). The values of the moisture, crude protein and intramuscular fat (Table 2) were not influenced by dietary treatments. Improvement in pH value ($P=0.06$) after vitamin C and vitamin E supplementation (group E + C, Table 3) can support data from one experiment (Kremer et al.,

1999). They suggest that adding sodium oxalate or vitamin C to final meal given to pigs before slaughter resulted in higher early post-mortem pH, but further studies on glycolysis and glycogen metabolism would be useful as vitamin C is known as precursor of oxalic acid and sodium oxalate inhibits a key glycolytic enzyme, pyruvate kinase.

A tendency of improving drip loss (lower value) in longissimus dorsi in 24 h post mortem of normal on malignant hyperthermia pigs supplemented with vitamin E (Table 3) and significant lower ($P<0.05$) value in pigs supplemented with vitamin E and vitamin C (group E + C) were received. It seems that adding a high level of vitamin E and/or vitamin C to the diet will reduce drip loss in some situations, but perhaps not in all situations and genetic background (occurrence of mutation on ryanodine receptor gene, malignant hyperthermia status) of experimental pigs could influence the results as was also discussed earlier (Lahucky et al., 2000). Dietary levels of vitamin E (group E) and vitamin E and vitamin C (group E + C) did not substantially affect the development of lipid oxidation (Fig 3) in the fresh meat (24 h), but significant differences ($P<0.05$) we mainly received in chill-stored (5 days) between control vs. supplemented pigs (group E and group EC). Whereas the MDA of the control were increasing during 30 min of incubation, the increase was significantly ($P<0.05$) lower in supplemented groups. Significant differences ($P<0.05$) we also received between vitamin E vs. vitamin E + C group (Fig 4).

Conclusions

Dietary supplementation of vitamin E (500 mg α–tocopheryl acetate/kg feed) and vitamin C (200 mg/kg feed) to grow-finishing pigs increases the concentrations of α–tocopherol and ascorbic acid in meat (longissimus dorsi). Supplementation vitamin E and vitamin C improves meat quality parameters (drip loss, pH), but results can be influenced by genetic background of animals (occurrence of mutation on ryanodine receptor gene, malignant hyperthermia status). Lipid oxidation measured as TBARS (MDA) and antioxidative capacity (Fe^{2+}/ascorbate induced) of meat can be positively influenced by supplementation of vitamin E to grow-finishing pigs.

[2] Dept. Animal Production, Fac. vet. Med., University of Liège, Sart Tilman B43b, BE-4000 Liège, Belgium

Background

Pork quality is dependent on various genetic and environmental factors from whose halothane genotype and pre-slaughter factors such as fasting time, transport, abattoir lairage are recognized of great importance for final meat quality. However, most of our present knowledge is based on studies investigating the influence of a single or at the most two factors (Rosenvold and Andersen, 2003). It is therefore necessary to understand how different production or slaughter factors influence pork quality in actual practical conditions. This approach could subsequently be used in the control of the quality of pork products.

Objectives

The objectives of this study were to evaluate technological and organoleptic properties of pork meat representative of different Belgian production systems and to determine the contribution of significant factors to meat quality variability, in particular the halothane genotype, fasting time, lairage time and slaughtering plant.

Materials and methods

A total of 521 pigs were used in five Belgian commercial slaughtering plants over a 1 ½ year period. 79% of pigs belonged to four different quality production systems. The remaining 21% were randomly sampled in standard production. In the slaughterline, pH_1 and electrical conductivity (PQM_1) were measured 45 minutes *post mortem* in the *longissimus dorsi* muscle at the level of the two last thoracic vertebrae. The weight of 'white offals' (entire intestinal tractus) was measured with a hanging electronic scale (Kern HCB 20K50). Hot carcass weight of all pigs was determined just before chilling. One 2.5 cm thick cut of the *longissimus dorsi* muscle was removed 24 hours *post mortem* in order to measure the ultimate pH (pHu), ultimate electrical conductivity (PQMu), water holding capacity (WHC), color (CIE $L^*a^*b^*$) and tenderness (WBPSF). The pH was measured by using an inserting combined pH electrode (Ingold ref 104063123) on a Knick 913 pH-meter. Electrical conductivity was assessed with a Pork Quality Meter (Intek). The Labscan II device (Hunterlab) was used to objectively measure CIE L^* (brightness) and a^* and b^* (color) parameters. The water holding capacity was estimated as drip loss and cooking loss. Drip loss was assessed as the percentage weight loss after 4 days storage in a plastic bag at 2°C ; cooking loss was measured as the percentage weight loss after cooking in an open plastic bag in a waterbath during 50 min at 75°C. Warner-Bratzler Peak Shear Force (WBPSF) was determined with a Lloyd LR5K universal testing machine perpendicular to the muscle fibre direction on ten 1.25 cm diameter cores obtained from heated cuts. Lairage time, calculated from the time between animals arrival at the abattoir and stunning was divided into five intervals (≤ 1, 1-2, 2-3, 3-4, >4 hours). In order to assess the fasting time, the weight of white offals was expressed as a percentage of hot carcass weight. The slaughtering plants differ in several aspects : slaughterline speed, the mean number of pigs slaughtered per week, handling treatment, stunning systems. Halothane genotype was determined with a DNA test using a polymerase chain reaction technique according to the method described by Nakajima *et al.* (1996). The data were analyzed using Statistical Analysis System (SAS Institute inc., Cary, NC, USA, 1999). Several models were adjusted to the data using General Linear Models (GLM) SAS procedure to estimate the influence of halothane genotypes -homozygote negative stress (CC), heterozygote negative stress (CT) and homozygote positive stress (TT)-, lairage time (≤ 1, 1-2, 2-3, 3-4, >4 hours) and slaughterhouses (1, 2, 3, 4, 5) on the variability of pH_1, PQM_1, pHu, PQMu, drip loss, cooking loss, CIE $L^*a^*b^*$ and WBPSF. The relative weight of white offals on hot carcass was included in the models as covariate. Least Squares Means (LSM) were computed for significant effect in the models and compared pairwise by the Student's t-test.

Results and discussion

Table 1 shows the average results for the total population. A large variation for the results of pH_1, drip loss and brightness was observed, indicating the presence of pale, soft, exudative (PSE) meat. Missing data for some parameters reduce the number of samples introduced in statistical models.

The proportion of variance explained by the GLM models (R^2) and the significance level of the effects in the models are summarized in Table 2. For all parameters -except for the pHu, cooking loss and the WBPSF- a moderate to great part of variation was explained by the model (R^2 = 0.22-0.56). Similar determination coefficients (R^2 = 0.04-0.59) were reported by Casteels *et al.* (1995) when they studied the influence of halothane genotypes, stunning method and slaughter weight on the variability of meat quality using GLM models. The halothane genotype effect was highly significant ($p<0.001$) on most meat quality traits : pH_1, PQM_1, PQMu and color parameters (CIE $L^*a^*b^*$) but not significant on pHu and cooking loss. The lairage time had a highly significant influence on PQMu, CIE b^*, drip loss but for the other parameters it had negligible or no influence. There was a highly significant effect of the slaughtering plant on pH_1, PQM_1, PQMu and color parameters (CIE $L^*a^*b^*$) and a significant influence ($p<0.01$) on the variability of drip loss and cooking loss. By contrast, the fasting time had no effect on most meat quality properties except on drip ($p<0.01$) and cooking loss ($p<0.001$). These results are in accordance with those of De Smet *et al.* (1996) whose found no effect of feed withdrawal on most meat quality traits. As indicated by the regression coefficient, an increase of offals/hot carcass weight seems to be related to an increase of drip or cooking loss.

The halothane genotype Least Squares Means and their standard errors (SE) for all parameters are listed in Table 3. Meat quality was negatively affected by the presence of the halothane gene. Drip loss differed significantly between genotypes with the TT pigs having the highest drip loss (6.8%) while that of the CC (5.5%) was the lowest and that of CT intermediate (6.1%). Cooking loss was also significantly higher in TT pigs indicating lower water holding capacity. Significant differences between CC and TT genotypes ($P< 0.05$) were observed in terms of pH_1 (6.12 *vs* 5.69), PQM_1 (4.9 *vs* 6.4) and PQMu (9.7 *vs* 12.7). The CIE L^* and b^* values (56.9% and 16.6) were significantly higher in homozygous stress positive animals (TT) comparatively to CC (55.0% and 15.8) or CT pigs (54.6% and 15.4). The higher L^* value of the TT genotypes indicated paler meat. The WBPSF was the lowest for CT pigs with no significant difference observed between the CC and TT genotypes.

The abattoir Least Squares Means and their standard errors for all parameters are listed in Table 4. The slaughterhouse 1 had lower pH_1, pHu, higher PQM_1 and CIE L^* values compared with slaughterhouses 2, 3 ,4 and 5. Cooking loss, drip loss and PQMu means were the highest for the meat originating from slaughterhouse 5. Although it would be necessary to determine the reasons for abattoirs differences, the small and old structure of the abattoir 1 with no training of the staff could partially explain the results.

Conclusions

From these results, it can be concluded that the halothane genotype is the most important factor determining organoleptic and technological properties of pork meat. A significant proportion of TT stress-susceptible pigs which can develop PSE meat was found in this Belgian study. Additional efforts to reduce halothane gene in pig population have to be realized to improve meat quality. Slaughterhouse and lairage time are significant factors influencing quality attributes of pork. The influence of the fasting time (assessed by offals/hot carcass weight) was low except on drip and cooking loss.

Further research is needed to evaluate the interaction terms slaughterhouse x genotype and lairage time x genotype and to identify slaughtering factors which could explain slaughterhouse differences in terms of meat quality.

GIANT FIBRES IN BROILER CHICKENS

Mammoli, R., Branciari, R., Ranucci,D., Miraglia, D., Cioffi, A., Avellini, P., Severini, M.

Department of Food Science, Section of Quality and Safety of Food of Animal Origin, Via San Costanzo 06126 University of Perugia, Italy

Background

Giant fibres can be described as being generally rounded in shape, bigger than the normal fibres around them, the shape of which can also be modified by them, and usually slightly separated from the surrounding fibres and localized at the borders of muscle fascicles. This is a great simplification of the problem as proven by the fact that their real origin and meaning has been the subject of discussion for over 30 years and still there is no clear answer to the question.

The issue of giant fibres was first dealt with by Cassens et al. in 1969. These authors focused their attention mainly on the frequency and on the histochemical characteristics of such fibres in the muscles of adult and growing pigs. Considering their particular staining pattern following histochemical evaluation as well as the fact that they were more frequent in muscles taken from stress-sensible pigs, these authors reached the conclusion that giant fibres may represent a pathological muscle modification. In later years other authors (Handel et al., 1986) focused their attention on giant fibres also observing them with the electron microscope which revealed, among other things, a reduced quantity of sarcoplasmic reticulum and an irregular disposition of the miofilaments inside the myofibres. This last point, as well as the lack of the characteristic myofibrillar banding pattern seen on examination of longitudinal sections, might be explained by supercontraction. These authors concluded that giant fibres might be due to a defect in single developing muscle fibres and not to degenerative changes within the muscle. A recent study by Fazarinc et al. (2002) deals with the influence of the halothane gene on the percentage of giant fibres. These authors reached the conclusion that giant fibres are glycolitic fibres which, due to the accumulation of intracellular lactate during post-mortem glycolisis, become swollen. Their appearance may also be facilitated by stress or stress susceptibility.

All of the above articles deal with pigs, but this is by no means the only animal where giant fibres can be found, as a matter of fact they have been observed in muscles of various species such as cattle and poultry. In this regard there is a paper (Remignon et al., 2000) concerning the moment, post-mortem, in which giant fibres appear in turkey muscles. These authors only found giant fibres in post-rigor (24h post-mortem) and not in pre-rigor (3 minutes post-mortem) muscles and therefore hypothesized that they are due to alterations in the developing muscle fibres that lead to structural and metabolic anomalies that give origin to their appearance during the biochemical events typical of rigor mortis.

Objectives

The purpose of this study is to evaluate the number as well as the histological and histochemical characteristics of giant fibres in various chicken muscles since literature concerning this topic is quite scarse. Furthermore the post-mortem time of appearance of giant fibres will be taken into consideration in order to compare their behaviour in chicken to that found by Remignon et al. (2000) in turkeys.

Materials and methods

A total of 11 male Ross broiler chickens were collected at the slaughterhouse just after plucking (10 minutes port-mortem) and muscle samples, parallel to fibre direction, were immediately taken from the left half of the carcasses, rolled in talcum powder, wrapped in aluminum foil, labelled, frozen and stored in liquid nitrogen until analyses were performed. The carcasses were then placed in portable coolers and taken to the laboratory where they were stored at 4°C until 24h post-mortem, when samples of the same muscles where taken from the right half of the carcasses, prepared as described above and stored in liquid nitrogen. Four muscles known, from literature and from previous studies, to have a different fibre distribution were considered: 1. *m. Pectoralis major*; 2. *m. Semimembranosus*; 3. *m.Ileotibialis lateralis*; 4. *m. Femorotibialis medius* (samples of this muscle were only taken from 5 animals). Serial cross-sections were obtained in a cryostat at -20°C and stained with hematoxylin-eosin (8µm thick) for histological evaluations and using

periodic acid schiff (PAS) (10 μm thick) for evaluation of the glycogen content. Serial, 8 μm thick, cross-sections were also processed for myofibrillar ATPase activity after acid and alkaline pre-incubation (Padykula and Herman, 1955; Guth & Samaha, 1969) and for succinate dehydrogenase (SDH) activity (Nachlas et al., 1957) or for the combination of the two (Solomon and Dunn, 1988) depending on the muscle considered. Myofibres were classified, according to the terminology introduced by Ashmore and Doerr (1971), as types βR, αR, and αW. βR fibres are stable after acid pre-incubation, labile after alkaline pre-incubation and SDH positive; both αR and αW fibres are labile after acid pre-incubation and stable after alkaline pre-incubation but while αR fibres are SDH positive, αW fibres are SDH negative.
Images were acquired and analysed, in order to determine percentages and cross sectional areas, using an image analysis system (analySIS, Soft Imaging System) implemented on a workstation equipped with a graphic card linked to a video camera placed on the microscope (Olympus BX51). Measurements were determined on about 200 fibres, from a random field in each muscle sample section stained with hematoxylin-eosin. Giant fibre percentages were calculated considering about 600 fibres from 3 random fields in order to have a better estimate of their number.
Data were statistically evaluated using Student's T test.

Results and discussion

The results concerning muscle fibre distribution of the different muscles are reported in table 1. Muscle *Pectoralis major* and muscle *Ileotibialis lateralis* are composed of mostly glycolitic fibres that have the same distribution throughout the muscle, while m. *Semimembranosus* and m. *Femorotibialis medius* are made up of various parts with a different fibre type distribution. This explains why the results are not as homogeneous for these last two muscles as they are for the first two, perhaps even a very small variation in the sampling site can determine variations in the fibre distribution.
Giant fibres did not all react in exactly the same way when they were subjected to histochemical evaluation. However, we can say that they could be classified as α type fibres as their oxidative capacity is variable yet never extremely strong, and they are more positive than α type fibres when processed for myofibrillar ATPase activity both after alkaline and after acid pre-incubation. This result is in contrast with that obtained by Chiang et al. (1995) who classified giant fibres in chicken mostly as αR and βR. Giant fibres are also always negative after PAS staining both 10 minutes and 24 hours after slaughter.
The percentage of giant fibres found in the muscle samples, 10 minutes and 24 hours post-mortem, is reported in table 2. The tables indicate that while the number of giant fibres is similar in all four muscles 10 minutes post-mortem, 24 hours post-mortem giant fibres are much more numerous in m. *Ileotibialis lateralis* and especially in m. *Pectoralis major*. The latter muscles show a significant variation in giant fibre percentage between the two sampling times ($p<0,01$) and it is interesting to notice that m. *Pectoralis major*, which has the greatest variation for this parameter, is also the muscle with the biggest difference in glycogen content between the two sampling times (table 3). This could imply that there is a link between the appearance of giant fibres and the biochemical events involving glycogen and glycolitic enzymes that take place post-mortem. This could also explain why there are usually more giant fibres in "white" muscles as seen in this experiment as well as in previous work on poultry (Chiang et al., 1995). Nonetheless, all the fibres composing these muscles are in the same condition, so it is not clear why only some of them become giant fibres. As Severini et al. (1997) suggested in a study concerning the presence of giant fibres in normal and PSE pig muscles, this could be due to a latent or very limited myopathy that could itself be accentuated by stressful conditions or by stress-susceptibility, thus explaining the higher number of these fibres sometimes seen in PSE pork. Remignon et al. (2000) in their study on turkey muscles found no giant fibres in pre-rigor muscles, while in the present study some were found. This could be due either to a species difference (chicken versus turkey) or to the small difference in sampling time (10 minutes versus 3 minutes post mortem).
Contrary to their name giant fibres are not always bigger than normal fibres. Nonetheless, on average, the mean cross sectional area of giant fibres is bigger than that of any other fibre type (tables 4 and 5).
While observing muscle samples coloured with hematoxylin-eosin, it was possible to notice that some of them contained fibres with a lower staining intensity. The evaluation and comparison of the fields containing such fibres for all of the enzymatic activities considered, proved that these fibres were always negative or only slightly positive, thus their nature and classification was not clear. These fibres resemble those found by Severini et al. (1998) in PSE pork muscle.

Conclusions

Giant fibres were more common in "white" muscles and had staining patterns similar to α type fibres. Some giant fibres also had some of the alterations usually seen in pathological muscle fibres such as an apparent hypercontraction which could explain the higher staining intensity they sometimes show. It could be said that the origin of giant fibres is connected to the biochemical events that take place during post-mortem glycolitic metabolism. There must be a reason though, that explains why only some of the fibres composing a muscle become giant fibres. This could be due to an alteration occurring in the live animal.

HOW DOES LACTATE ENHANCEMENT IMPROVE BEEF COLOR STABILITY?

Mancini, R.A., Kim, Y.H., Hunt, M.C., and Lawrence, T.E.
Department of Animal Sciences, 224 Weber Hall, Kansas State University, Manhattan, 66506, USA

Background

In both raw and cooked meat products, lactate limits discoloration by minimizing red color changes during storage and display (Brewer *et al*. 1991; Papadopoulos *et al.* 1991; Prestat *et al*. 2002; Lawrence *et al.*, 2003). However, the mechanism by which lactate improves muscle color stability is unknown.

How does lactate improve muscle color stability?
We speculate that lactate's ability to stabilize muscle color is linked to regeneration of nicotinamide adenine dinucleotide (NADH), which is necessary for metmyoglobin reduction; a reaction that promotes color stability. We believe this link between lactate and NADH regeneration is lactate dehydrogenase (LDH; Figure 1). From a meat quality standpoint, LDH may be an "overlooked" endogenous enzyme that has potential to influence color life.

Metmyoglobin reduction
Oxidation of myoglobin is inevitable; thus, maximizing metmyoglobin reduction (gain of electrons) is essential for color stability. It is widely accepted that NADH donates electrons to metmyoglobin via both enzymatic and nonenzymatic pathways (Brown and Snyder 1969; Hagler *et al*. 1979; Livingston *et al*. 1985; Renerre and Labas 1987; Stewart *et al*. 1965). However, the location of the NADH pool that provides electrons to postmortem metmyoglobin reduction is unknown (Renerre and Labas 1987).

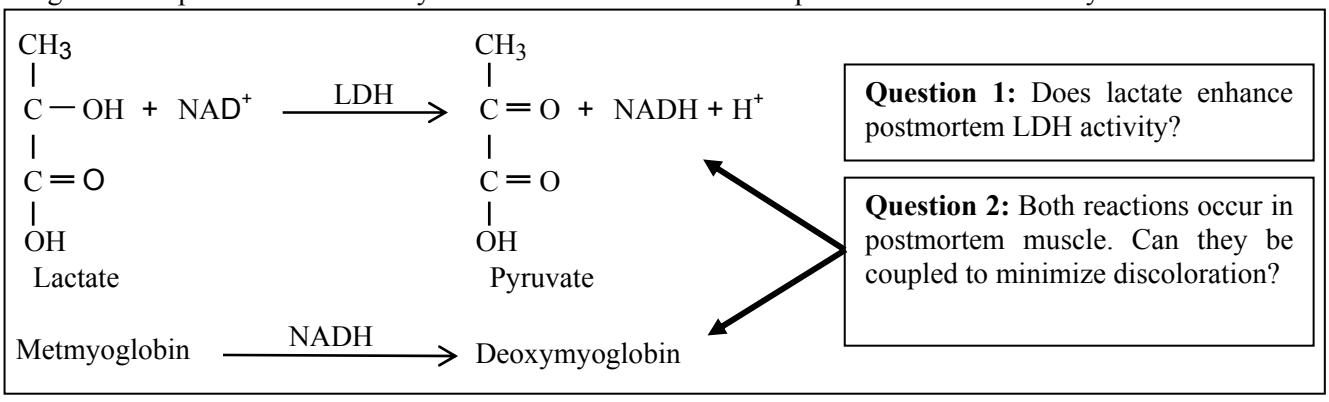
The NADH pool
Stewart *et al*. (1965) provided early speculation regarding replenishment of the NADH pool by suggesting that LDH catalyzes the production of reduced pyridine nucleotides from lactate and diphosphopyridine. These authors believed this mechanism was feasible because both lactate and LDH are abundant in postmortem muscle. However, to date, this mechanism has not been evaluated or proven.

Objectives

Hypothesis: Enhancing beef with lactate increases LDH activity, which consequently improves meat color stability by promoting metmyoglobin reduction (Figure 1).

Objective: Evaluate if enhancement of beef *longissimus* with potassium lactate increases postmortem lactate dehydrogenase and metmyoglobin reducing activity.

Figure 1: Proposed mechanism by which lactate enhancement improves beef color stability.



Materials and methods

Experiment 1: Whole loin enhancement
Five boneless beef strip loins (5 days postmortem) were divided into four equal sections. Each section within a loin was assigned randomly to one of four treatments (1 = no enhancement; 2 = enahancement with water; 3 = 1.5% potassium lactate in the finished product; 4 = 2.3% potassium lactate in the finished product). Strip loin sections were pumped at 10% of their green weight using a multineedle injector. Pumped loin sections were cut into 2.54 cm-thick steaks, overwrapped in polyvinyl chloride (PVC), and displayed for 7 days at 1ºC in open-top display cases under 1614 lux of continuous fluorescent light (3000 K). Lactate dehydrogenase activity was measured on day 1, day 3, and day 7 of display. The experimental design was a split plot where the whole plot design structure was a completely randomized block (n = 5) with a one-way treatment structure consisting of 4 treatments. Within the whole plot, loins served as blocks, and each of four loin sections were the experimental units to which enhancement treatments were applied. Steaks within a loin section (subplot experimental units) were assigned randomly to 1 of 3 display times.

Experiment 2: Model system enhancement
Eight randomly selected beef *longissimus* steaks from different animals were used in the model system. Each steak was divided into three equally sized pieces. To each piece within a steak, one of three treatments was assigned randomly (1 = nonenhanced; 2 = nonenhanced plus LDH inhibitor; and 3 = potassium lactate). Pieces assigned to treatment 3 (lactate) were injected with a syringe to a concentration of 2% lactate in the final product. Oxalate (LDH inhibitor in treatment 2) was added during quantification of LDH activity (described below). Steaks were overwrapped in PVC and stored at 4°C for 7 days. Lactate dehydrogenase activity and metmyoglobin reducing activity were measured after day 1 and day 7 of storage. The experimental design was a randomized complete block (steaks were blocks) with repeated measures. For both experiments, data were analyzed using SAS and significance is represented at $P < 0.05$.

LDH activity
Lactate dehydrogenase activity was measured using a spectrophotometric technique (Wahlefeld 1987). From each loin, a 2.0 g sample was homogenized with 0.01 M potassium buffer (pH 7.2). Homogenates were centrifuged for 30 minutes at 14,600 x *g* (4°C). In brief, β-Nicotinamide-adenine dinucleotide, Tris buffer, and L-Lactate were added to 0.1 mL of homogenized muscle supernatant. After 5 minutes of incubation at 30°C, LDH activity was measured using absorbance at 339 nm, which indicates the production of NADH via lactate oxidation (NAD reduction increases absorbance at 339 nm; L-Lactate + NAD^+ → Pyruvate + NADH + H^+). To determine activity, absorbance at 339 nm was measured at 30-second intervals for 2.5 minutes. Activity in U/L was calculated as: change in absorbance ($\Delta A/\Delta t$) x 4.21 x 10^3. For those samples assigned to treatment 2 (LDH inhibitor), oxalate was added after centrifugation to the supernatant. All assays were performed in duplicate and averaged for statistical analysis.

Metmyoglobin reducing activity
Step 1: Samples (3 x 2 x 1.27 cm^3) were submerged in 0.3% sodium nitrite. After 20 minutes, samples were blotted dry, immediately vacuum packaged, and reflectance from 400 – 700 nm was measured. Step 2: Samples were incubated at 30ºC and reflectance was measured after 2 hours. Percent metmyoglobin was determined according to AMSA (1991) and metmyoglobin reducing activity (MRA) was claculated as: (Observed decrease in metmyoglobin during incubation ÷ initial metmyoglobin concentration) x 100.

Results and discussion

Experiment 1: Whole loin enhancement
Enhancing loins with potassium lactate tended to increase LDH activity (Table 1). On day 7, both 1.5% and 2.3% lactate resulted in signifcantly more LDH activity than enhancement with only water. Using 2.3% lactate significantly increased lactate dehydrogenase activity compared to nonenhanced control loins at the end of display (day 7). Lactate dehydrogenase activity increased during display. Neither treatment influenced muscle pH (Control samples = 5.8 and lactate enhanced samples = 5.9).

Experiment 2: Model system enhancement
Compared to nonenhanced controls at the end of storage (day 7), adding 2.0% potassium lactate to beef *longissimus* significantly improved LDH and metmyoglobin reducing ability (Tables 2 and 3). However,

there was no significant difference between nonenhanced steaks and lactate-enhanced steaks early in storage (day 1). Thus, as storage time increased, the ability of potassium lactate to promote LDH and MRA activity also increased. Conversely, there was no significant change in LDH activity during storage for nonenhanced steaks. As expected, oxalate minimized LDH activity. Muscle pH was not influenced by treatment (pH = 5.9).

Lactate dehydrogenase activity in muscle has been used as an indicator of endpoint temperatures in meat products (Collins *et al*. 1991; Keeton and Morris 1996; Stadler *et al*. 1991 & 1997). However, food-safety researchers commonly measure pyruvate reduction rather than lactate oxidation, which was measured in our experiment. Nevertheless, previous work support our findings that LDH remains active postmortem.

Meat color stability is vital for maximizing consumer purchasing. Product inconsistency and central packaging have driven beef purveyors to utilize enhancement technology aimed at improving shelf life and product quality. In addition to water, salt, and phosphate, beef processors have a vested interest in color-stabilizing, antimicrobial, and palatability-enhancing ingredients such as lactate. Determining mechanisms present in postmortem muscle that support myoglobin reduction may be beneficial for developing future enhancement technologies that improve the shelf life of muscle based food products.

Conclusions

There is a lack of knowledge regarding the mechanism of lactate-induced color stability. The role of metmyoglobin reduction and NADH in meat color stability has been well documented. However, mechanisms in postmortem muscle involved in replenishing the NADH pool have received little attention. It is possible that lactate dehydrogenase is an endogenous enzyme involved in postmortem NADH production.

We conclude that enhancing beef *longissimus* with lactate can influence both postmortem LDH activity and metmyoglobin reducing ability. We speculate that LDH converted postmortem-injected lactate to pyruvate and NADH, which replenished the reducing equivalent pool of postmortem muscle and chemically reduced metmyoglobin (increased MRA). This project suggests that lactate has potential to not only benefit beef processors through improved shelf life, but also to benefit researchers by providing a better understanding of postmortem replenishment of the NADH pool.

EFFECT OF TRANSPORT TIME AND SEASON ON ASPECTS OF RABBIT MEAT QUALITY[1]

G.A. María*, G. Liste, M. Villarroel, T. Buil, C. Sañudo, J.L. Olleta and M. López
Department of Animal Production & Food Science. University of Zaragoza, 50013 Zaragoza, Spain.

Background

The events involved in the transport chain, and other related factors, may induce stress in rabbits (Jolley, 1990) and can affect aspects of meat quality (Masoero et al., 1992). Little is known about the effect of transport on rabbit meat texture or colour. Ultimate meat pH is the most commonly measured parameter in studies that consider ante-mortem effects on meat quality. However, while it is clear that even travelling short distances can reduce live weight (shrinkage), decrease glycogen reserves and increase meat temperature (Jolley, 1990), this is not always reflected in changes in ultimate pH. There may be no effect when transport is only a slight stress and the animals are in good condition. The relationship between initial muscle glycogen content and ultimate pH is only linear at very low levels of glycogen. Thus, they are not lowered enough to have a substantial effect on the ultimate pH, especially when the animals can recover during lairage. Changes in meat texture and colour with respect to ante-mortem stress have been considered, but normally the effect of transport time has been mixed with other confounding factors (e.g., breed, production system, nutrition, etc.). In Spain, transport of commercial rabbits to the abattoir is relatively short, typically less than 3 hours. Recently, a report by the Scientific Committee on Animal Health and Animal Welfare has proposed important limitations on transport time and the European Parliament has suggested decreasing all journeys for all species to less than nine hours. Although these measures may improve animal welfare, it remains unclear whether imposing them on a commercial level will also improve meat quality. This fact is even more important in commercial rabbits where little information is available.

Objectives

The aim of this study was to analyze whether transport times of up to 7 hours can have a significant effect on instrumental meat quality traits in rabbits. Due to the characteristics of the Spanish climate, with very hot summers and cold winters, replicates were performed in two seasons. We also considered the effect of position on the truck as a factor which could affect meat quality.

Materials and methods

We analysed the instrumental quality of meat from 156 rabbits that were transported by road, together with other non-target animals, for 1h or 7h in winter and summer with three replicates each. The average temperature during transport was recorded every 5 minutes with a Testo thermometer at the level of the study animals. The average temperatures were 11ºC ± 3 and 28ºC ± 2 in winter and summer, respectively. Three main effects were considered: transport time, season and position on the truck (top, middle or bottom) in a multi floor cage rolling stand (MFRS). For each season and journey time, 36 animals were selected (12 in each position). The stocking density during the transport was 360 cm^2 per animal. The cage size was 57 x 57 x 25 cm, in MFRS & Sañudo, 2001). For texture meat analyses, longissimnus dorsis muscles were vacuum packaged and frozen at –18ºC. The compression and Warner-Bratzler (WB) analyses were performed on sample slices as in Campo et al. (2000) with an Instron with 12 cages each. The total capacity of the truck was 2400 rabbits per trip. The rabbits were slaughtered after 3 h of lairage in the same MFRS. Average carcass weight was 1192.50 g (±121). Carcasses were chilled under commercial conditions at 0ºC for 24 h. The meat pH was measured at 24 h post-mortem on the lumbar region with a Crison 507 electrode. Sixteen additional rabbits were taken randomly to study the proportion of muscle, bone and fat of the carcasses by dissection in the lab. The longissimus dorsi was removed from both sides and the right side was sliced into three steaks for instrumental analysis. Water holding capacity (WHC) was measured 24 h after slaughter and expressed as press juice using the Grau and Hamm method (Cañeque 4301. Briefly, thawed steaks (internal

temperature 17-19ºC) were cut transversally to be studied either as raw or cooked meat. Texture of the raw meat was analysed using a modified compression device that avoids transversal elongation of the samples. The stress was assessed at 20% (P20), 40% (P40), 60% (P60) and 80% (P80) of the maximum compression (MS). Meat was vacuum packaged prior to cooking in a water bath at 75ºC until the internal temperature reached 70ºC. Samples (1 cm^2 cross-section) were cut with muscle fibres parallel to the longitudinal axis of the sample. Maximum load (ML) and toughness (TO) were assessed in heated meat using a Warner Bratzler device, shearing until breaking the samples (10 mm wide and 10 mm thick). The sample gauge was 10 mm, gauge length 30 mm, load cell 100 kg (minimum load level 0.001 kg), crosshead speed 150 mm /min (high extension limit 30 mm) and sampling rate 20 points/second. Meat colour was measured in the reflectance spectrum every 10 nm from 400 to 700 nm using a Minolta (2002) reflectometer-colorimeter. Measurements were taken from the surface of a slice of meat from each animal transported. Slices were freshly cut at 24 h post-mortem and measured after 24 h blooming. Each slice was placed at 4ºC on individual plastic foam trays and wrapped with an O_2 permeable film without touching the sample. The L*a*b* values were taken using the standard illuminant D65 and 10º standard observer for all measurements. The data were analysed using the least square methodology of the GLM procedure of SAS (SAS, 1988), fitting a three-way model including the fixed effect of transport time (2 levels), season (2 levels) and position on the stand cages (3 levels) plus the interaction effect.

Results and discussion

The average percentage composition of the left middle carcass was 75.31 (±2.7) muscle, 4.62 (±1.09) fat and 16.39 (±1.8) bone (n=16 animals). The significance of the main effects is presented in Table 1. The effect of position on the truck was not significant. Season and journey time had significant effects on several instrumental meat quality parameters. The interaction between time and season was only significant for Warner Bratzler variables.

The least square means for all the instrumental variables are presented in terms of season and journey time in Table 2. The parameters fell within the range of good quality meat. Similar results were found by Trocino et al. (2002) and Xicato et al. (1994) in their studies on rabbit transport. Transport time did not affect pH24, WHC or Warner Bratzler texture parameters. All the texture parameters evaluated by compression were significantly affected by journey time ($p \leq 0.001$). In general, the values were higher after short journeys. Transport time slightly affected colour parameters, and a* was significantly higher after long journeys ($p \leq 0.05$), especially in winter. Other studies (Jolley, 1990; Masoero et al. 1990 and Dal Bosco et al., 1997) have found that pH increase after longer journeys.

Season had a significant effect on all the response variables, with the exception of compression at 80% and maximum stress. The pH 24 values were significantly higher in winter than in summer, but always below 6. The same situation was observed for WHC. Some authors have found that transport affects WHC (Trocino et al., 2002; Jolley, 1990). Nevertheless this parameter could be affected by the treatment applied (Ouhayoun & Dalle Zotte, 1996). All texture variables analyzed by Warner Bratzler were higher in winter than in summer. The same situation was true for 20% compression. The colour parameters were all affected by season. Redness was higher in winter than in summer but the opposite occurred for yellowness. Lightness varied less, but the difference was still significant ($p \leq 0.05$) between long journeys, increasing for summer trips. There was a significant interaction between journey time and season for texture traits evaluated by Warner Bratzler (Figure 1). According to our results, instrumental meat quality could be affected by the multifactor stressors involved in the transport process. Values for meat colour were similar to Trocino et al. (2002), but higher than Jolley, 1990. Dal Bosco et al. (1997) found that meat from animals from short journeys had significantly higher L*.

Few studies have considered the effect of transport on instrumental measurements of meat quality in commercial rabbits. Under the controlled commercial conditions of this work, transport time of up to seven hours significantly affected the instrumental quality of rabbit meat as measured by a modified compression device, which reflects the mechanical resistance of the myofibrillar structure (P20) and connective tissue strength (P80). No differences were found in ultimate pH between transport groups, which conditioned the lack of variation in other variables such as WHC and other texture parameters assessed by Warner Bratzler shear device and the slight effect of redness.

Season affected almost all the variables, but it was not completely independent from the effect of transport time. Even when the effect of journey time was not significant (for WB variables), there was a significant interaction between transport time and season, with the worst texture values after short journeys in winter

and long journeys in summer. Independently of journey time, season did not have an effect on meat quality. In summary, transport time had an effect on instrumental meat quality in terms of compression and a slight effect on colour. Within the range of transport times analysed, there were no significant changes in pH, which is the main parameter used to judge meat quality on an industrial level. Finally, position within the multi floor cage stand did not affect instrumental meat quality.

Conclusions

The general conclusion of this study is that, even under optimum commercial conditions, rabbit meat quality could be affected by the multiple stressors involved in the transport process. Transport affected several measures of meat quality and this effect depended on the season of the year.

TRANSPORT RELATED BRUISING IN CATTLE

Midtveit, I.[1], Johansen, J.[1], Schwencke, H.[2] and Alvseike, O.[1]
[1]Norwegian Meat Research Centre, P.O. Box 396 Økern, N-0513 Oslo, Norway
[2]Norwegian Food Safety Authority, District Office of Nord-Gudbrandsdal, N-2670 Otta, Norway

Introduction

The bruising of cattle is used as an indicator for animal welfare problems during pre-slaughter handling and can reduce meat quality (1). The aim of this study was to describe the prevalence of carcass bruising in cattle observed at *post-mortem* meat inspection in a Norwegian abattoir and to assess risk factors.

Materials and methods

The study was carried out in a commercial abattoir processing approximately 20,000 cattle a year. The drivers recorded transport parameters. Carcass bruising were assessed by two official veterinarians at *post-mortem* meat inspection. Bruises were categorised according to size as small (diameter < 4 cm), medium (diameter 4 - 10 cm) or extensive (diameter > 10 cm). Only bruises adjacent to *Tuber coxae*, *Trochanter major* or *Tuber ischii* were recorded. Data on carcass conformation, fat cover and weight were obtained from the abattoir.

Carcass bruising was set as continuous response variable, and the regressor variables included both categorical and continuous variables. Descriptive statistics were performed, and ANOVA was used for hypothesis testing of risk factors. An ANOVA model was used for each bruise site and size.

Statistical analysis

The data were analysed using one-way cross tabs procedure for bruising, descriptive statistics and analysis of variance (ANOVA) procedure for hypothesis testing of the risk factors. Carcass bruising was set as response variable, and transport risk factors were set as regressors. The following model was used (2):

$$Y_i = \beta_0 + \beta_1 + ... + \beta_j + \varepsilon$$

Where i = p number of bovine carcass bruisings, j = q number of transport risk factors

No interactions were included in the model.

The model was analysed using SYSTAT Version 10 © SPSS Inc. 2000 Standard Version, Statistics – GLM – Estimate Model. Carcass bruising was set as continuous response variables, and the regressor variables both included categorical and continuous variables.

Results and discussion

Data from 84 transports comprising 1252 cattle were obtained during a period from May to August 2003. All animals were transported direct from the farms, and included The predominant breed in the region is Norwegian dairy cattle. Transport times were generally short (Table 1).

Table 1. Transport time

Transport time (hours)	
Minimum	0.25
Maximum	7.0
Mean	2.35
Median	2.0

The overall prevalence of carcasses with bruises ≥ 4 cm was 36.2 %. Table 2 summarises the recorded bruises.

Table 2. Prevalence (%) of bruises in cattle (n=1252) according to size and localisation

Bruise diameter (cm)	< 4			4 – 10			> 10		
Site of bruising	None	Unilat.	Bilat.	None	Unilat.	Bilat.	None	Unilat.	Bilat.
Tuber ischii	11.4	16.7	71.9	80.4	15.0	4.6	88.3	8.1	3.6
Trochanter major	3.7	13.4	82.9	87.3	10.3	2.4	94.5	4.4	1.1
Tuber coxae	2.1	10.9	87.0	89.9	8.8	1.3	96.7	3.0	0.3

The ANOVA identified animal category, driver, increasing transport time, increasing number of herds mixed in vehicle pen, ascending order of loading and increasing area (m^2) per animal as the primary risk factors for carcass bruising. Details from the ANOVA analysis (Table 3).

*P-value 0.01 – 0.05, **P-value 0.001 – 0.01, *** P-value < 0.001, NS (non-significant) P-value > 0,05

The low prevalence of bruising found in this study contrasts earlier findings from the UK. Jarvis and others (3) found that 97 % of carcasses observed were bruised, and that cattle from markets had more bruises than cattle transported direct from farms. Weeks and others (4) found that in cattle transported direct to abattoir 53.7 % of observed carcasses were bruised, while in cattle from markets 71.0 % were bruised. The difference in prevalence of bruising found in this study and other studies can partly be explained by differences in bruise recording system and type of lairage. All cattle in this study were lairaged in individual pens, which eliminates mounting behaviour. Cows have a higher risk for bruising than other categories of cattle. The same observation has been made in previous works by Weeks and others (4) and Wythes and others (5). This may be due to poorer muscle conformation,

reduced ability to cope with movements of the vehicle during transport, or a combination. The predominant housing system for dairy cows in the region is tie stalls, while steers mainly are kept loose in pens. Holleben and others (6) found higher bruising scores in cattle from tied housing. Transport time is found to be a risk factor for bruising, indicating that transport time is relevant in terms of animal welfare. Ascending order of loading is also identified as a risk factor, despite that transport time is shorter for cattle loaded in the end of the journey. In previous work performed by Tarrant and others (1988) stress was found to increase with pen localisation towards the tail of the truck (7). The truck design is probably of importance in this matter and should receive further investigation. The driver is showed to influence the risk of bruising. This could be explained by the fact that driving skills varies between drivers. Careful braking and cornering is important for the animals in order to avoid loss of balance (7).

Conclusion

The overall prevalence of bruising ≥ 4 cm was 36.2 %. The primary risk factors for bruising were found to be category, driver ID, transport time and number of animals mixed in vehicle pen.

ANALYSIS OF POST MORTEM PRODUCTS OF PROTEOLYSIS IN PORCINE TCA SOLUBLE EXTRACTS AND THEIR ASSOCIATION WITH TENDERNESS

O'Reilly, K. [1], Morzel, M.[2], Bouchut, C.[2], Troy, D.[1] and Mullen, A.M.[1]

1: The National Food Centre, TEAGASC, Ashtown, Dublin 15, Ireland

2: INRA, Station de Recherche sur la Viande, 63122 Saint-Genès Champanelle, France

Background

Proteolytic degradation of myofibrillar proteins has been shown to contribute to *post mortem* tenderisation with the rate and extent of proteolysis being associated with meat tenderness (Troy and Tarrant., 1987; Sentandreu et al. 2002, & Sawdy et al., 2004). Analysis of the products of proteolysis has held much interest in terms of developing diagnostic tests for meat tenderness. In the past a lot of focus has been directed to the study of products of *post mortem* proteolysis in the myofibrillar fraction of muscle. In more recent years, however, the analysis of more soluble proteolytic fragments has held much interest (Nakai et al., 1995; Mullen et al., 1998; Stoeva et al., 2000). One dimensional gel electrophoresis (1DGE) allows visualising products on the basis of molecular weight while two dimensional gel electrophoresis (2DGE) separates proteins according to their isoelectric point and molecular weight. In this manner 2DGE provides a very high resolution separation. Application of these techniques may add further definition to the pattern of proteolysis over the *post mortem* ageing process and its association with pork tenderness.

Objectives

The objective was to apply 1-DGE and 2-DGE to track *post mortem* proteolytic events and their associations with tenderness, in Trichloroacetic acid (TCA) soluble extracts from porcine *M.longissimus dorsi*.

Materials and methods

Forty pigs were slaughtered and carcasses treated conventionally in a commercial abbatoir. A sample was excised from the *M.longissimus dorsi* (striploin, LD) at 1d, 3d and 7d *post mortem*. These samples were snap frozen in liquid nitrogen and stored at –80^{o}C. The LD was excised at 1d postmortem and chops were taken for analysis of eating quality. Tenderness was measured by Warner Bratzler shear force (Shackelford et al., 1991). Compositional analysis was conducted to determine any variation in intramuscular fat, protein and moisture levels. Sarcomere lengths were determined according to the laser diffraction method (Cross *et al.,* 1980). Other quality measurements included drip loss (Honikel and Hamm, 1994), cook loss, pH rate of decline and temperature profile up to 1d postmortem.

Based on the quality analysis, carcasses which displayed extreme values of tenderness were selected while controlling for extreme values of sarcomere length and intramuscular fat. Samples were alloted to three catagories, namely tender (Class I), tough becoming tender (Class II) and tough (Class III). A representative sample from each category was selected and TCA soluble extracts were prepared for both 1DGE and 2DGE analysis. 2-D gels were produced in triplicate for each sample, according to the method described in Morzel et al. (2004) with slight modifications.
Spots were detected and quantified by the image analysis software PDQuest. Spots of interest, i.e. those more associated with the "tender" class, were defined as spots that were either specific to the class I sample, or spots that were over-expressed at least three-fold in the class I (compared to class III) on day 7.

Results and discussion

Initially 1DGE analysis was conducted on extracts (1d, 7d, 14d) from each of the classes where bands of various molecular weights were seen to increase and decrease over the ageing period (Figure 1). In the tender sample increases were observed in lower molecular weight bands (Areas 3 & 4) which were not so obvious in the tough sample. These bands may be the product of proteolysis of myofibrillar or sarcoplasmic proteins over the postmortem ageing period. Two other areas of interest were noted (Areas 1 & 2). The tough sample appeared to have a higher level of the higher molecular weight band in Area 1, compared to the

tender sample. In addition in Area 3 the bands seem to appear sooner in the tough sample. Each lane received similar protein loading, however in some instances some of the changes observed may be due to larger proteins being held back in the gel matrix. However, repeated analysis of these gels have revealed similar banding patterns.

A representative 2DGE image is presented in Figure 2. Approximately 120-160 spots were successfully detected and quantified on all gels. Spots specific to class I are squared in blue, whereas spots over-expressed in class I are squared in red. Spots are designated by their unique number attributed by PDQuest. As an example, figure 3 shows the quantity (ppm) of spot 2504 in the three samples, as affected by *post mortem* time. It is very likely that most of those potential biomarkers are protein fragments, generated by *post mortem* proteolysis.

Both 1DGE and 2DGE will be repeated on further samples. Comparisons between gels will be invaluable in the interpretation of 1D gels. Proteins of interest in both gel formats are being identified by MALDI-ToF Mass Spectroscopsy.

Conclusions

Changes in banding protein patterns were evident in 1DGE gels. 2DGE electrophoresis allowed us to propose a list of potential biomarkers of tenderness in pork meat. In order to confirm their relevance, these need to be identified by MALDI-ToF Mass Spectroscopy and quantified in a larger set of samples.

DIFFERENCE IN DEGRADATION OF TROPONIN-T ISOFORMS AMONG BOVINE MUSCLES DURING POSTMORTEM AGING

Muroya, S., Nakajima, I. and Chikuni, K.

Department of Animal Products, National Institute of Livestock and Grassland Science, Tsukuba, Ibaraki 305-0901, Japan

Background

The beef tenderization during postmortem aging, largely affected by protein degradation, differs among the muscles (Olson *et al.*, 1976; Koohmaraie *et al.*, 1988). Though the activities of Ca^{2+}-dependent protease (calpains) and the inhibitor (calpastatin) vary among different type muscles, the ratio of calpain/calpastatin does not seem to be different among the muscles examined (Olson *et al.*, 1977; Koohmaraie *et al.*, 1988; Whipple and Koohmaraie, 1992). Each muscle has specific composition of four muscle fiber types which are determined by expression pattern of myofibrillar contractile protein isoforms, such as myosin heavy chains (MyHCs) (Schiaffino and Reggiani, 1996). The extent and rate of postmortem degradation of myofibrillar proteins are presumptively affected by muscle fiber type. Olson *et al.* (1976) and Whipple and Koohmaraie (1992) reported that degradation of myofibril proteins occurs faster in bovine white (faster type) muscles (longissimus, biceps femoris, semitendinosus, or gluteus medius) than in the red (slower type) muscles (psoas major or supraspinatus). In a detail investigation of pork aging by Christensen *et al.* (2004), the extent and rate of troponin T (TnT) and desmin degradation did not depend solely on muscle fiber type determined by MyHC ATPase histochemistry. Different type muscles have different isoform composition of myofibrillar contractile proteins. The degradation pattern may be changed by the type of the isoforms, because the cleavage pattern of the isoform proteins are thought to differ, depending on the molecular structures. Actually, four recombinant isoforms of rabbit fast type TnT (fTnT) are degraded by calpain at different rates in vitro (Gomes *et al.*, 2001). Furthermore, we found that fast and slow type TnT isoforms are differently degraded in postmortem bovine LT muscle (Muroya *et al.*, 2004).

Objectives

The purpose of this study is to clarify the relationship among protein degradation patterns of muscles and the isoforms types of the protein substrates. To this end, we investigated the difference in degradation pattern of TnT isoforms among muscles with different isoform composition during beef aging.

Materials and methods

The lingual (TN), masseter (MS), diaphragm (DP), longissimus thoracis (LT) muscles for 0 d postmortem samples were excised from a Japanese black steer within 1 hr after slaughter. After overnight hanging of the carcass at 2°C, the muscle blocks were excised from the carcass. At 1, 5, and 14 d postmortem, the muscle samples were prepared from the central part of the block bagged during aging at 2°C. For western blotting analysis, myofibrils were extracted from the muscles by 0.1 M potassium phosphate buffer (pH 7.4) with 0.6 M KCl. The myofibrils were applied to SDS-PAGE using 12.5% or 15% gel, followed by transfer to polyvinylidenefluoride membrane. In the western blotting, the TnT bands were detected by using commercially-available anti fast- or slow-type polyclonal antibodies for TnT (Santa Cruz Biotechnology, Santa Cruz, CA).

Results and discussion

According to our previous analysis investigating MyHC and TnT isoform expression in bovine skeletal muscles by RT-PCR, MS and DP expressed slower type MyHC and TnT isoforms, while TN and LT expressed the faster type isoforms (Muroya *et al.*, 2002; Muroya *et al.*, 2003). According to the MyHC isoform expression pattern, TN is characterised to be slower than LT. Especially, MS exclusively expressed the slow type isoform mRNAs, which agrees with the present results of isoform-specific TnT western blotting (Figs. 1 and 2).

Eight fast- and two slow-type TnT (sTnT) isoform mRNAs were detected by RT-PCR, and the distribution of the isoforms varies among the muscles (Muroya *et al.*, 2003). The fTnT isoforms are classified into four types in SDS-PAGE by the amino acid numbers, or approximate molecular weight. The four fTnT isoform types were detected in bovine TN, MS, DP, and LT muscles, with different distribution among the muscles (Fig. 1). The DP and TN muscles expressed two sTnT isoforms, while MS and LT muscles expressed only a higher molecular weight one (Fig. 2), as we detected by RT-PCR previously.

The degradation pattern of LT muscle revealed that fTnT and sTnT isoforms are degraded differently from each other (Figs. 1 and 2). On the other hand, even though two high molecular weight fTnT and one sTnT isoforms in DP and TN muscles were the same as those expressed in LT, all of the isoforms in DP and TN did not appear to be degraded. The sTnT isoform in MS muscle appeared to be slightly degraded.

The results revealed that postmortem TnT degradation in beef varies depending on the muscle type. The degradation was observed only in LT muscle that has faster contractile properties than MS, DP, and TN muscles, suggesting that TnT proteins are degraded more easily in faster muscles than in slower muscles. This is consistent with the previous results reported by Olson *et al.* (1976) and Whipple and Koohmaraie (1992). There might be differences in activity of calpain or calpastatin and in some metabolic effect among the muscles examined. Though fTnT and sTnT isoforms are differently degraded, the difference in the rate and extent of TnT degradation among fTnT or sTnT isoforms during postmortem aging in beef is still unknown.

Conclusions

The results revealed that postmortem TnT degradation in beef differs depending on the muscle type. The degradation was observed only in LT muscle that has faster contractile properties than MS, DP, and TN muscles, suggesting that TnT proteins are degraded more easily in faster muscles than in slower muscles.

SPECIES-SPECIFIC DIFFERENCE IN INDUCING PIG ADIPOSE CONVERSION FROM THAT OF MOUSE

Nakajima, I., Muroya, S. and Chikuni K.
Meat Science Laboratory, Department of Animal Products, National Institute of Livestock and Grassland Science, Norindanchi PO Box 5, Tsukuba, Ibaraki 305-0901, Japan

Background

Subcutaneous adipose tissue in pigs represents a major source of both cost inefficiency and consumer concerns. Numerous investigations have been carried out to regulate the carcass fat for the meat quality traits through both nutritional controls and selective breeding. However, there are some difficulties to monitor adipose development in vivo studies, due to the complicated interactions of all kinds of neural and hormonal signals involved in adipocyte metabolism. Therefore, investigators have established in vitro cell culture systems as useful tools for studying adipose development.

Much of the knowledge about cellular and molecular events accompanying adipose conversion in recent years has been based on murine preadipocyte cell lines. Since no cell lines from porcine adipose tissue have been established so far, understanding the control of adipocyte differentiation in pigs is limited in either the approach of using these mouse cell lines or otherwise, primary culture systems. As a result, it can always come into question whether the data from mouse cell lines and pig primary stromal-vascular cells with cellular heterogeneity in its population, can represent the characteristics of pig adipocytes.

Objectives

We have established a preadipocyte clonal line from porcine subcutaneous tissue (PSPA) for the study of pig adipose development (Nakajima et al., 2003). The present study was designed to demonstrate whether there are species specificity in adipose conversion between mouse and pigs, by comparing the most widely studied mouse 3T3-L1 cell line and PSPA cells.

Materials and methods

Cell culture: A clonal porcine subcutaneous preadipocyte (PSPA) cell line was maintained in the preadipocyte condition by cultivation in Dulbecco's modified Eagle's medium (DMEM, 1 g/L glucose) supplemented with 10% fetal bovine serum, 1000 IU/ml penicillin, and 1 mg/ml streptomycin. Cells were passaged every 4 days, with the density of inoculation kept constant (1×10^4cells/cm^2).

For experiments, cells were plated at 2.1×10^4cells/cm^2 to obtain confluency within 3 days. After reaching confluence (day 0), adipose conversion was induced in high-glucose (4.5 g/L) DMEM containing 10% FBS, 5 μg/ml insulin, 0.25 μM dexamethasone, 33 μM biotin, 17 μM pantothenate, 5 mM octanoate. The medium was changed every other day and the cells were allowed to differentiate for 10 more days.

The mouse embryo 3T3-L1 cells were plated at a density of 0.5×10^4cells/cm^2 in growth medium for 3 days. At confluence, the medium was then shifted to high-glucose DMEM supplemented with 10% FBS, 0.5 mM of 1-methyl-3-isobutylxanthine (MIX), and 0.25 μM dexamethasone, to induce differentiation. Forty-eight hours later, this medium was replaced with 10% FBS high-glucose DMEM containing 5 μg/ml insulin for the remaining 8 days.

Triglyceride Assay: Triglyceride (TG) in the cell lysate was extracted with chloroform-methanol and quantified enzymatically using a Triglyceride G Test Wako Kit.

Extraction of mRNA and RT-PCR analysis: Messenger RNAs were isolated from PSPA cells using the QuickPrep Micro mRNA Purification Kit and then reverse transcribed using the First-Strand cDNA Synthesis Kit. The synthesized cDNA was amplified with AmpliTaq Gold by PCR using paired forward and reverse primers with the ribosomal protein L7 (RPL7) as the internal control (Venuti et al., 1995). Primer sequences were as follows: peroxisome proliferator-activated receptor (PPAR) γ2 (GGTGAAACTCTGGGA GATTCTCTTA, GGCTCTTCGTGAGGTTTGTTGTACAG); PPARγ1 (CCTTAAACGAAGAGTCATCTT TTAGCG, GGCTCTTCGTGAGGTTTGTTGTACAG); CCAAT element-binding protein α (C/EBPα, AAG TCGGTGGACAAGAACAGCAACGAGTA, ATTGTCACTGGTCAGCTCCAGCACCTT); adenovirus E2 promoter-binding factor 1 (E2F1, TGGACCTGGAAACTGACCATCAGTACCT, TCTTGGACTTCTTGGC

AATGAGCTGGATG); proliferating cell number antigen (PCNA, CTGGTGAATTTGCACGTATATGCCG AG, AGGGGTACATCTGCAGACATACTGAGTGT); thymidine kinase (TK, TCGGACCCATGTTCTCG GGAAAAAGT, ACTCCACGATGTCAGGGAAAAACTG); lipoprotein lipase (LPL, CATAGCAGCAAA ACCTTTGTGGTGATCC, TTGGTCAGACTTCCTGCAATGCCAGCA); adipocyte-specific fatty acid binding protein (aP2, TTTGCTACCAGGAAAGTGGCTGGCAT, GCAGTGACACCATTCATGACACAT TCC); stearoyl CoA desaturase 1 (SCD1, ACCGTGCCCACCACAAGTTTTCAGAAA, GCTCCAAGTGA AACCAGGATATTCTC); hormone-senstive lipase (HSL, CGCAGTGTGTCTGAAGCAGCACTGGC, AT GACCGAGTCGTCCAGCATGGGGTC); RPL7 (GCAGAACCCAAATTGGCGTTTGTCATCAG, GATG ATGCCGTATTTACCAAGAGATCGAGC).

Western blot analysis: Both nuclear proteins and cytoplasmic proteins were prepared by using the CelLytic NuCLEAR Extraction Kit. Twenty-five micrograms of nuclear protein and 50 μg of cytoplasmic protein were separated by electrophoresis through SDS-polyacrylamide 12.5% gels. After they were electrotransferred onto nitrocellulose membranes, blotting membranes were incubated with primary polyclonal antibodies specific to PPARγ, C/EBPα, PCNA, E2F1, and glycerol-3-phosphate dehydrogenase (GPDH). Secondary antibodies were horseradish perocidase-conjugated anti-rabbit, anti-mouse or anti-goat antibodies. Antigen-antibody complexes were visualized by the ECL detection system.

Results and discussion

When confluent PSPA cells were stimulated with insulin, dexamethasone biotin, pantothenate, and octanoate, growth was arrested, and the cells exhibited a marked increase in lipogenesis. However, adipose conversion was not induced upon exposure of PSPA cells to a standard hormonal mixture of 3T3-L1 cells (Student et al., 1980), and their cell numbers increased as did the preadipocytes in growth medium (Fig.1A). Also, some differences in cell behavior were observed between PSPA cells and 3T3-L1 cells (Fig.1A and B).

To investigate whether every component of the PSPA medium was equally essential to the induction of adipocytes, PSPA cells were exposed to differentiation media each of which was lacking one agent. Under these culture conditions, the absence of either octanoate or dexamethasone from the medium resulted in a marked decrease in lipid accumulation (data not shown). Furthermore, octanoate was the only factor able to induce growth arrest. Octanoate supplementation to 3T3-L1 medium dramatically improved TG accumulation of PSPA cells while accompanying growth arrest (data not shown). These data strongly suggested a correlation between the growth-inhibiting effect of octanoate and terminal differentiation. Additionally, based on the result of a dexamethasone-depleted medium in which the cell numbers were maintained as normal adipocytes, it appears that dexamethasone regulates PSPA preadipocyte differentiation through a different induction pathway from octanoate.

The expression of a number of adipogenic genes and proteins was studied by RT-PCR and Western blot analysis. Expression patterns of E2F1, PCNA and TK were consistent with the results indicated so far by means of cell numbers, and expression patterns of LPL, aP2, SCD1 and HSL consistent with TG content. The most interesting result was that the expression of those master regulators of adipocyte gene transcription, PPARγ2 and C/EBPα. The absence of octanoate from the differentiation medium expressed only PPARγ2 but not C/EBPα, and in contrast, removal of dexamethasone resulted in expression of C/EBPα but not PPARγ2 (Fig.2).

Conclusions

Species specificity in adipose conversion between mouse and pig preadipocytes has been shown as the responsiveness to inducers was not equal between these two. Hormonal cocktail of 3T3-L1 cells failed to induce adipose conversion of PSPA cells and kept on proliferating. Growth arrest by octanoate was required for PSPA cells to enter terminal differentiation. Our results can probably provide an answer as to why researchers often prefer serum-free conditions in porcine primary cultures instead of serum-containing medium (Hentges and Hausman, 1989; Surywan and Hu, 1993; Gerfault et al., 1999). This was because none of the agents added according to mouse reports were sufficient to make preadipocytes cease dividing, whereas serum-free medium readily did so. We propose that mouse is not suitable for the study of porcine adipose development.

INTERMUSCULAR VARIATION IN DEGRADATION OF HIGH MOLECULAR WEIGHT PROTEINS IN BOVINE MUSCLES DURING POSTMORTEM AGING

Neath[1], K. E., S. Muroya[2], I. Nakajima[2], Y. Kanai[1] & K. Chikuni[2]

Background

Beef tenderisation during postmortem aging differs among muscles in an individual carcass (Olson et al., 1976; Koohmaraie et al., 1988; Ilian et al., 2001). Although the sequence of postmortem metabolic events that indicate final meat tenderness remains unexplained, research has implicated the involvement of protein degradation. High molecular weight proteins, such as titin (□3,000 kDa) and nebulin (□800 kDa), are unique in size and play important roles in maintaining muscle structure, thus there is potential for degradation of these proteins to impact on meat tenderisation (Taylor et al., 1995; Huff-Lonergan et al., 1996).

The activities of Ca^{2+}-dependent proteases (calpains) and the inhibitor (calpastatin) are suggested to play an important role in protein degradation (Koohmaraie et al., 1988; Whipple and Koohmaraie, 1992; Ilian et al., 2001). Recently, the novel calpain 3 (94 kDa) isoform has been of particular interest as not only it is expressed almost exclusively in skeletal muscle, at least two binding sites for this protease are located on the titin molecule (Sorimachi et al., 1995). The expression of calpains 1, 2, and 3, and calpastatin have been shown to vary between muscles of different fibre type (Ilian et al., 2001; Jones et al., 1999). Furthermore, muscle fibre type has been suggested to have an effect on the extent and rate of postmortem degradation. Skeletal muscles can be characterized into fast and slow muscles according to the distribution of four muscle fibre types, which contract at different rates according to the expression pattern of myofibrillar protein isoforms, such as myosin heavy chains (Schiaffino and Reggiani, 1996). The degradation of myofibril proteins has been reported to occur faster in bovine white (faster) muscles, such as longissimus thoracis (LT) and semitendinosus (ST), than in red (slower) muscles, such as psoas major (PM) (Olson et al., 1976). There appears to be a complex relationship between protein degradation, muscle fibre type, and the calpain system, and their ultimate effect on meat tenderness.

Objectives

The objective of this study was to determine the effect of degradation of high molecular weight proteins on the rate of tenderisation among four bovine muscles during postmortem aging.

Materials and methods

The diaphragm (DP), psoas major (PM), longissimus thoracis (LT), and semitendinosus (ST) muscles for 0 d postmortem samples were excised from a Japanese Black steer within 1 h after slaughter. After overnight hanging of the carcass at 2˚C, the muscle blocks were excised from the carcass, bagged and aged at 2˚C. At 1, 3, 7, and 14 d postmortem, muscle samples were prepared for immediate Warner Bratzler shear force measurement (kg/cm^2), along with electrophoresis samples that were frozen at -40˚C until analysis.

For SDS-PAGE analysis, crude myofibrils were extracted from the muscles by 0.1 M potassium phosphate buffer (pH 6.8) with 0.6 M KCl and protease inhibitor cocktail (SIGMA, Saint Louis, Missouri), and analysed on the same day to avoid degradation. Myofibrils were applied to SDS-PAGE using a 3% gel without stacking gel (ATTO, Tokyo, Japan), and run at room temperature for 1 h at a constant current of 10 mA, followed by 1 h at a constant current of 20 mA. Protein bands were detected by fluorescent stain using SYPRO Ruby gel stain (Bio-rad, Hercules, CA) for 16 h overnight.

Results and discussion

There was intermuscular variation in the rate of tenderisation, as shown in Figure 1. Shear force measurement showed a faster rate of tenderisation in LT compared to ST, with PM and DP being intermediate. Although published data could not be found on the tenderisation of the diaphragm, the trend in

the rate of tenderisation of LT being higher than ST and PM is consistent with previous research (Koohmaraie et al., 1988; Ilian et al., 2001).

Figure 2 shows the degradation pattern of titin and nebulin among the four muscles. The 1,200 kDa degradation product of titin is evident in Figure 2, however T1 and T2 could not be clearly distinguished, therefore the intermuscular variation in degradation of titin could not be observed in this experiment. There was a difference in degradation of nebulin among the muscles, as intact nebulin was absent by 3 d of postmortem aging in LT compared to by 7 d in ST. The degradation of nebulin in PM and DP was observed after 1 d postmortem.

Degradation of two unidentified high molecular weight proteins was evident soon after death in this study, as can be seen in Figure 3 (band *x* and band *y*). Band *x* was present at 0 d in LT and ST muscle, and was absent by 3 d in LT and by 7 d in ST, which is a similar degradation pattern to that of nebulin in the LT and ST muscles. Band *x* was not detected in PM or DP muscles. The detection of the degradation of band *x* was due to the highly sensitive fluorescent staining, as compared to Coomassie brilliant blue which has been conventionally used in previous studies (Fritz et al., 1993; Taylor et al., 1995; Huff-Lonergan et al., 1996). Band *y* appears to be filamin, which was shown to degrade to a 240 kDa fragment (Huff-Lonergan et al., 1996). In this experiment, band *y* degradation was observed to occur from 3 d in LT, and from 7 d in ST and PM, however band *y* was not degraded in DP. In addition, a degradation fragment migrating slower than band *x* was observed from 7 d of postmortem aging in PM, with trace amounts evident also from 7 d in LT, but was not detected in ST or DP, as evident in Figure 3. This fragment may be a product of titin degradation (Taylor et al., 1995).

The degradation of myofibril proteins has been reported to occur faster in bovine white (faster) muscles, such as LT and ST, than in red (slower) muscles, such as PM (Olson et al., 1976). However, in this study, the protein degradation patterns and meat tenderisation of LT and ST were different. LT exhibited a higher postmortem tenderisation rate, and in addition, the degradation of nebulin, band *x*, and band *y* was faster in the LT muscle compared to ST. The lower tenderisation rate in ST may have been the result of relatively slower degradation of nebulin, band *x*, and band *y*. These differences may be due to intermuscular variation in the expression of calpains and calpastatin. According to Ilian et al (2001), the higher relative tenderisation rate in LT compared to ST (in ovine) and in LT compared to PM (in bovine) was due to a higher level of expression of calpain 3 in LT. These results suggest that, other than muscle fibre type, the relative proportion of calpains and calpastatin in different muscles may also influence meat tenderisation.

The diaphragm is classified as a slower type muscle (Muroya et al., 2002), and has been shown to express slow type isoforms which have different degradation patterns to fast type isoforms (unpublished data). Nebulin degradation was observed in the diaphragm, however band *x* was not present and there was no degradation of band *y*. The data suggests that the degradation of myofibrillar proteins differs among the isoform types, due to the different susceptibility to proteolysis. Thus, the difference in tenderisation rate between the diaphragm and LT may indicate that muscles with different isoform composition are tenderised at different rates.

Conclusions

The results revealed that postmortem degradation of high molecular weight proteins varies among bovine muscles of the same carcass. There appears to be a relationship between the degradation of high molecular weight proteins and meat tenderisation, with the possibility of other influencial factors such as different expression levels of calpains and calpastatin among the muscles.

EFFECT OF TRANSPORT, LAIRAGE, AND PRESLAUGHTER STRESS ON PORK MEAT QUALITY

Newman, D.J., Hambrecht, E., Berg, E.P.

Department of Animal Science, University of Missouri, Columbia 65201
Nutreco Swine Research Centre, P.O Box 220, 5830 AE Boxmeer, The Netherlands

Background

Preslaughter handling of pigs, including stockman interaction (loading, unloading, driving animals), transport, and lairage, has been designed to meet the pork industry's requirements rather than the pig's needs. Various preslaughter handling such as transport (Warris and Bevis, 1986), lairage (Brown et al, 1999), and preslaughter stress (Hambrecht et al., 2004a) can trigger a stress response and may have negative consequences for pork quality aspects such as color, water-holding capacity, and other sensory characteristics. Warris (1998) and Gispert et al. (2000) found that pigs transported for long periods of time are more likely to form dark-firm-dry pork because of exhaustion and fatigue. Bradshaw et al. (1996) found that short (≤1h) compared with long transports were more detrimental because the pigs did not recover from the stress of loading and could not adapt to the conditions of transport. The effect of lairage duration depends on factors such as environmental temperature and mixing. Aaslyng and Gade (2001) found that a lairage time of less than one hour does not allow for sufficient resting and may negatively impact both animal welfare and meat quality. However, extended lairage times of six hours and more may increase carcass damage and stress caused by fighting and prolonged periods without feed (Warriss, 1998). The negative factors associated with transport, lairage, and preslaughter stress increase the chances of economic losses to producers and packers.

Objectives

The objective of this experiment was to investigate to what extent various important preslaughter handling factors such as transport conditions, lairage duration and stress level immediately before slaughter affect muscle energy, blood-based stress indicators, and ultimate pork quality.

Materials and methods

All pigs were commercial halothane-free progeny of the Hypor pig breeding company. Pigs (n = 384) were assigned to one of eight treatments in a 2 x 2 x 2 factorial arrangement, with two types of transport [short (50 min) and smooth or long (3 h) and rough], two lairage durations [long (3 h; considered as optimal) or short (<45 min; considered as sub-optimal)] and two stress levels administered immediately before slaughter (minimal or high). Pigs were penned 12 pigs per pen at the production site. For each treatment, groups of four random pigs were removed (four pigs taken from each of 3 pens to form groups of 12) from their home pens on the production site and randomly allocated to either minimal or high preslaughter stress and either short and smooth or long and rough transport. Long and short lairage alternated between consecutive weeks. Transport duration and preslaugher stress levels were varied within the same slaughter day. Eight groups of 48 pigs were processed over a series of weeks at a commercial plant. Pigs were electrically stunned in a fully automated, head-to-heart stunning system. Blood samples were collected in a heparinized tube at exanguination for cortisol and lactate determination. A 1-g muscle sample was taken at 135 min postmortem from the longissimus muscle (LM) at the last rib and frozen in liquid nitrogen for determination of the glycolitic potential, a good approximation of in vivo muscle glycogen. At 30 min, 3 h and 24 h postmortem temperature and pH were measured in the LM adjacent to the third lumbar vertebra**.** At 23 h postmortem loins were harvested for final meat quality measurements. L* (lightness), a* (redness), and b*(yellowness) color values were assessed in the LM on a freshly cut surface after a 10 minute blooming period with a Minolta Portable Chroma Meter (Model CR 210**).** Electical conductivity was measured using the LF-Star. Water-holding capacity was measured by pressing a filter paper on a freshly cut surface and measuring the amount of absorbed moisture after 10 sec. Additionally, drip loss was determined as percentage of weight lost from a LM slice after 1, 3, and 7 d of storage lying face down on a metal grid in a closed plastic container. Data were analyzed by the mixed-model procedure (PROC MIXED) of SAS. Tests of multiple comparisons of least squares means were adjusted according to the TUKEY-KRAMER method to ensure the

overall significance level of $P < 0.05$. The model applied included the fixed effects of transport conditions, lairage duration, and stressor level, as well as their 2-way interactions, and the random effect of slaughter day nested within lairage.

Results and discussion

Stress indicators in blood

Results are presented in Table 1 and 2. High preslaughter stress increased ($P < 0.05$) plasma lactate and cortisol concentrations. The increase in plasma lactate concentrations seemed to be larger after both long vs. short transport (transport x stress interaction; $P < 0.05$) and after the short vs. long lairage (lairage x stress interaction; $P < 0.05$). Cortisol levels were increased after short transport only when followed by short lairage (transport x lairage interaction; $P < 0.05$). Lairage is meant to serve as a period of recovery for animals after transport. The larger increases in plasma cortisol and lactate in response to high stress indicate that both the long transport and the short lairage treatment were unfavorable and made the pigs more susceptible to subsequent stress. Moreover, the increase in cortisol concentration after short transport in combination with short lairage was probably due to a lack of recovery time in lairage from the stressful experience of loading, transport, and unloading. Results of the present expirement are in agreement with studies that showed that rough vs. smooth transport (Bradshaw et al., 1996), short vs. long lairage (Perez et al., 2002) and high vs. minimal stress (Hambrecht et al., 2004a) caused stress in pigs as indicated by elevated blood-based stress indicators.

Muscle glycolitic potential and pork quality

Long transport increased ($P < 0.05$) LM glycolitic potential with a concomitantly increased muscle lactate production. This is in disagreement with Leheska et al. (2003) who found a significant muscle energy depletion in response to longer transports and indicates that the transport treatment in the present study was physically not exhausting. Lairage had no effect on muscle energy stores whereas high preslaughter stress increased ($P < 0.05$) LM lactate production but overall decreased ($P < 0.05$) muscle glycolitic potential and muscle glycogen.

Transport and lairage did not affect pH at 30 min postmortem. At 3 h postmortem, the slightly decreased muscle glycogen and glycolitic potential after short compared with long lairage ($P < 0.05$) were reflected in a higher pH. The pH values seemed to be more increased when short lairage was combined with long transport (transport x lairage interaction; $P < 0.05$). Ultimate pH, however, was not affected by transport conditions or lairage duration. Similar to cortisol concentrations, LM temperature at 40 min was increased ($P < 0.05$) for the short transport group only when followed by short lairage. In agreement with the increased rate of lactate production, high stress decreased ($P < 0.05$) muscle pH at 30 min and 3 h postmortem. Corresponding to the lower glycolitic potentials, ultimate pH was increased ($P < 0.05$) in the high stress group. However, ultimate pH was still within the normal range of 5.3 to 5.7 (Briskey, 1964). At 3 h postmortem, high stress resulted in an increased LM temperature, but this increase was larger after long lairage (lairage x stress interaction; $P < 0.05$). This finding is difficult to explain since a similar effect was not found at 40 min postmortem. However, it is possible that long lairage allowed the pigs to relax before stress shock occured, or toward the end of long lairage pigs began to fight (resulting in an increased body temperature) and combined with the high stress, fueled the increased in muscle temperature.

High preslaughter stress increased ($P < 0.05$) filter paper moisture uptake, electrical conductivity and drip loss throughout the entire 7 day storage period. This is in agreement with the elevated muscle temperature and lower pH values that are known to be related to inferior pork quality (Cassens et al., 1963; Bowker et al., 2000). Moreover, other experiments studying the effect of high preslaughter stress on pork quality confirm the detrimental effects of stress on pork quality (van der Wal et al., 1999; Hambrecht et al., 2004a). However, despite the influence of preslaughter stress on postmortem pH, lightness and redness were not affected ($P < 0.05$). Long lairage resulted in an increased ($P < 0.05$) paleness (i.e. high L* values) in loins.

Conclusions

Preslaughter stress exerted the largest influence on animal welfare and ultimate pork quality. Therefore, it is imperative that slaughterhouse employees are educated with regard to proper, low stress animal handling procedures. Furthermore, slaughter plant design should be considered as an important tool in improving pork quality and animal welfare.

MEAT TENDERIZATION BY ACIDIC LISOSOMAL PROTEINASES ASSOCIATED WITH GENOTYPE IN BEEF

Oliván, M.[1], Coto-Montes, A.[2], Caballero, B.[2], Sierra, V.[2], Aldai, N.[1], Rodríguez-Colunga, M.J.[2], Osoro, K.[1]

[2] Departamento de Morfología y Biología Celular, Universidad de Oviedo, 33006 Oviedo, Asturias, Spain

Background

Tenderness is one of the most important quality traits of beef for consumers. It is well known that meat tenderizes during storage, mainly due to the breakdown of key myofibrillar proteins, however the physicochemical and biochemical mechanisms involved in this process are still unclear. The calcium-dependent calpain system has been indicated as the major responsible for tenderness development in the early *post-mortem* periods (Koohmaraie, 1994). Nevertheless, lysosomal cathepsins may be involved in later tenderization processes, when pH conditions are favourable for acidic enzymes (Christensen et al., 2004). Ouali (1992) suggested that meat tenderization may result from the synergistic action of both calpains and cathepsins.

Objectives

The aim of the present study was to analyze the evolution of instrumental toughness and cathepsin B, B+L, D and H activities during later *post-mortem* storage of beef from different genotypes. Cytosolic and lysosomal enzymatic activities were separately considered, in order to obtain information of the differential contribution of both compartments to tenderization processes.

Materials and methods

Twenty yearling bulls of two local breeds from northern Spain, Asturiana de los Valles (AV) and Asturiana de la Montaña (AM) were studied. Animals of the AV breed were homozygous (*mh*/*mh*), heterozygous (*mh*/+) or normal (+/+) for muscular hypertrophy gene. Bulls were fattened by feeding concentrate meal and barley straw *ad libitum* and were slaughtered at a live weight around 500 kg.
At 24h *post-mortem* the ultimate pH (pH24) of the *Longissimus dorsi* muscle (LD) was measured at the 5th rib level. The muscle was sliced, vacuum packed, aged at 4º C and stored at -20ºC for further analysis. Samples for toughness and enzymatic analyses were aged 7, 14 and 21 days (except samples of double-muscled (*mh*/*mh*) AV bulls which were aged 3, 7 and 14 days). Water holding capacity was estimated with two different methods: drip loss at 48h *post-mortem* (Honikel, 1998) and expressible juice (EJ) at 7 days ageing (Sierra, 1973). Warner-Bratzler (WB) shear force (kg) was measured on cooked meat in an Instron 1011 equipment. Enzyme assays were performed on lysosomal and cytosolic extracts, obtained according to Béchet et al. (1986). The cysteine proteinases B (EC3.4.22.1), B+L (L; EC.3.4.22.15) and H (EC.3.4.22.16) were assayed fluorimetrically (Barret, 1980, modified by Schreus et al., 1995) using different specific substrates. The aspartate proteinase cathepsin D (EC3.4.23.5) was assayed spectrophotometrically (Takahashi & Tang, 1981) with modifications (Schreus et al., 1995). Protein concentration was determined as described by Bradford (1976). Enzyme activities were expressed as enzymatic units/mg of protein.
An ANOVA was used to analyze the effect of genotype on the physico-chemical and enzymatic variables. The effect of ageing period on each genotype was analyzed by ANOVA with ageing time and animal as fixed factors. Differences between means were test by LSD procedure. Principal component analysis was made to describe the relationships between physico-chemical and enzymatic variables at 7 and 14 days of ageing. All the statistical analyses were performed using the SPSS programme 11.5 (2002).

Results and discussion

The genotype affected to the ultimate pH ($p<0.05$), which was significantly lower in meat of AV bulls with muscular hypertrophy (*mh*/*mh* or *mh*/+) than in AM bulls. This could be result of the higher proportion of fast-twitch fibers and the higher glycolytic metabolism in the LD muscle of double-muscled animals (Oliván

et al., 2004). Genotype affected also significantly to the drip loss of meat at 48h *post-mortem* (p<0,001), with meat of *mh*/*mh* AV bulls showing higher juice losses than any other genotype.

Table 1. Effect of genotype on pH24 and water holding capacity of meat.

	GENOTYPE				
	AV (*mh*/*mh*)	**AV (*mh*/+)**	**AV (+/+)**	**AM(+/+)**	**Sign.**
N	5	5	5	5	
pH24	5.48 a	5.53 a	5.58 ab	5.67 b	*
Drip loss (%)	2.68 a	1.18 b	1.49 b	0.81 b	***
EJ (%)	21.72 a	20.75 ab	20.35 ab	19.15 b	NS

Means in the same row followed by different letters are significantly different (p<0.05).

Figure 1(a) shows the tenderization pattern of the different genotypes during the ageing process. Meat of AV bulls homozygous (*mh*/*mh*) or heterozygous (*mh*/+) for muscular hypertrophy showed a higher tenderization rate than AV (+/+) or AM (+/+) bulls. This produced significant differences among genotypes in the WB shear force after long storage (14 and 21 days, Table 2), when meat of AM breed showed the highest toughness. This higher tenderization rate of meat from double-muscled bulls may be related with the lower ultimate pH recorded at 24h *post-mortem* and its positive influence on the activity of acidic enzymes, like cathepsins.

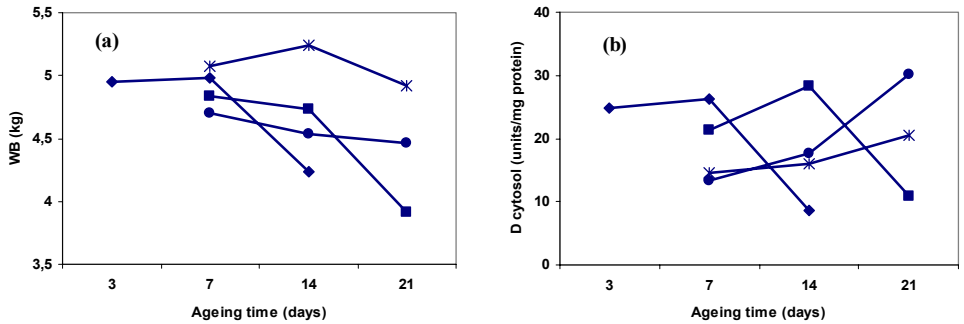

Figure 1. Time course changes in (a) WB shear force and (b) D cathepsin activity in cytosol extracts of the different genotypes (♦: *mh*/*mh* AV; ■: *mh*/+ AV, ●: +/+ AV; *: AM).

The evolution of the activity of cathepsins showed a similar pattern in lysosome and cytosolic domains, since they are complementary processes: the release of lysosomal proteases to cytosol and consistent breakdown of proteins by them produces an increase of endosomal vesicles, which interact to lysosomes giving them new substrates to act on (Alberts et al., 2002). In general enzyme activity levels were higher in cytosolic than in lysosomal extracts in all periods (Table 2), which could mean that the leakage of enzymes from lysosomes started in an early stage. The activity of cathepsins B, B+L, D and H at 7 days *post-mortem* was higher in meat of AV bulls with muscular hypertrophy (*mh*/*mh*, *mh*/+) than in other genotypes (AV(+/+), AM) in both extracts, but only reached significant differences in cytosolic space (for H cathepsin also in lysosomes). These data contribute to the hypothesis of faster tenderization rate of meat from double-muscled bulls, probably due to the lower pH conditions detected on the LD at early *post-mortem* periods, which activate processes of cellular membrane breakdown and enhance the release of the lysosomal proteases to the cytosol, as proposed by Berge et al. (2001). At later ageing the activity of most cathepsins (B, B+L and H) decreased both in lysosomal and cytosolic compartiments, probably due to the drop of availability of specific substrates, being this decrease more pronounced in double-muscled bulls than in other genotypes.

Cathepsin D showed the highest activity in both extracts and cathepsin H the lowest. That increase of cathepsin D along *post-mortem* ageing seems to be consequence of the absence of an endogenous inhibitor in muscular tissue specific for this enzyme. Rather, the role of cathepsin D as regulator of cystein-proteases could be responsible of the low activity of B, L and H cathepsins observed (Lenarcic et al., 1991), although it has been described that cystatin activity in the LD muscle is low (Koohmarie et al., 1988).

The activity of the D isoform in the cytosol showed different pattern in double-muscled (*mh*/*mh* and *mh*/+) and normal (AV(+/+) and AM) bulls (Fig. 1b). In animals with muscular hypertrophy the activity of cathepsin D was high at early and medium storage times (3-7 or 7-14 days, respectively) and showed a strong decrease after long storage (14 and 21 days respectively). However, in AV (+/+) and AM bulls there was a continuous increase of cathepsin D activity in the cytosol along the ageing period studied, which could

indicate an important implication of cathepsin D at the end of the tenderization process, that seems to be reached at longer ageing periods than those studied for these genotypes.
Figure 2 shows the relationship between the different parameters obtained through principal component (PC) analysis. Two groups of variables were clearly distinguished on the first PC. The first group included juice losses (drip loss and EJ) and high activity of all cathepsins (H, D, B and B+L) in the cytosol and in lysosomes at 7 days *post-mortem* This means that meat with high proteolytic activity at 7 days ageing exhibited higher juice losses, as a consequence of miofibrilar structure destabilization due to destruction of sarcomeres and fragmentation of actin-miosin complex. These variables were negatively correlated with the other group, composed by toughness (WB) at 14 days *post-mortem* and high enzyme activities in lysosomes (B, B+L H, D,) and cytosol (B, B+L, D) at 14 days.

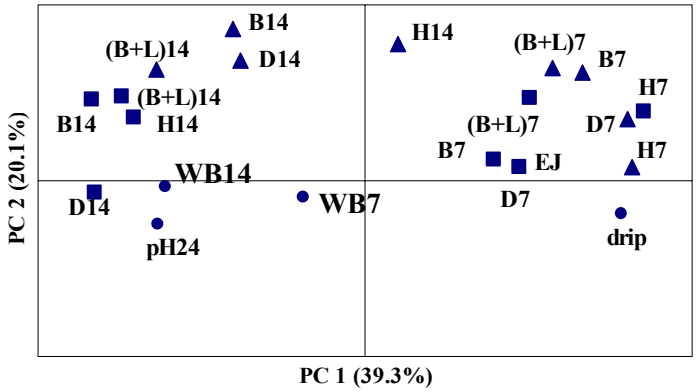

Figure 2. Principal component analysis of physico-chemical traits (●) and enzyme activities (■: in lysosome, ▲: in cytosol) at 7 and 14 days post-mortem for the whole set of samples.

Conclusions

The evolution of instrumental toughness and cathepsin activity in cytosolic and lysosomal extracts showed different pattern in the different genotypes studied. Homozygous or heterozygous animals for muscular hypertrophy presented higher enzymatic activity at early ageing periods and a higher tenderization rate than normal AV (+/+) or AM (+/+) bulls, for which the end of the tenderization process should be expected at longer ageing times. It seems that cathepsin D is the most implicated in later tenderization processes.

Means in the same row followed by different subscripts are significantly different ($p<0.05$).
For a given genotype, values in the same column with different capital letters are significantly different ($p<0.05$).

SDS-PAGE ANALYSIS OF TCA SOLUBLE BOVINE MUSCLE EXTRACTS OVER THE POSTMORTEM AGEING PERIOD

O' Reilly, K., Troy, D.J., Lennon, A. and Mullen, A.M.
National Food Centre, Teagasc, Ashtown, Dublin 15, Ireland.

Background

Muscle proteins fall into three divisions according to their structure, function and/or degree of solubility (Ito *et al.,* 2003) and consists of; myofibrillar (salt-soluble), stomal or connective tissue (acid-soluble) and sarcoplasmic (water-soluble). In most publications dealing with meat proteins and/or polypeptides, the investigated fraction is usually determined by the extraction and separation methods applied (Claeys *et al.,* 2004). Much work concerning the proteolysis of ageing beef has focused on the myofibrillar fraction and the emergence of a 30 kDa fragment from Troponin T (Huff-Lonergan *et al.,* 1995 and Wheeler and Koohmaraie, 1999). However as fragments which are cleaved from myofibrillar proteins may themselves be soluble, analysis of the myofibrillar fraction only may not provide the researcher with a comprehensive overview of the proteolytic profile during postmortem ageing. Recently proteolytic fragments of troponin T were observed in a tricholoracetic acid (TCA) extract of beef (Nakai *et al*., 1995 and Stoeva *et al.,* 2000). Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) analysis can provide a clear profile of postmortem proteolytic pattern muscle extracts and maybe useful to view changes in a broad range of proteins/peptides over the ageing process. Altering the concentration of TCA used to obtain these extracts may be useful to optimise this visualisation technique.

Objectives

The purpose of the study was to monitor the changes in protein patterns in TCA extracts of bovine *M. longissimus dorsi* (loin, LD), over a fourteen-day ageing period, using SDS-PAGE and varying concentrations of TCA.

Materials and Methods

Sample collection Bovine *M. longissimus dorsi* (loin, LD) samples were collected at 1h, 3h, 2d, 7d and 14d post mortem, snap frozen in liquid nitrogen and stored at –80°C.

Protein Extraction Soluble protein extracts were prepared from two LDs at 1h, 3h, 2d, 7d and 14d using increasing concentrations of TCA, (0.5, 1.0, 5.0, 10.0 and 20,0%, w/v) following a modification of the method of Stoeva *et al.,* (2000).

Protein Concentration was determined using the Biuret method (Gornall *et al.,* 1949).
SDS-PAGE extracts were prepared by incubation in SDS-reducing buffer for 15 minutes at 50°C then stored at –20°C. Electrophoresis was performed according to the method of Laemmli (1970). Samples were applied to 12 % acrylamide 2mm dual vertical slab gels (BioRad) for a total of 3,500V/h then stained with either Coomassie Blue G-250 or Silver. Gels were then scanned using a colour image scanner (Epson Perfection 3200) for the visualisation of bands.

Repeatability study In order to determine the validity of the extraction method and its ability to return consistently similar degradation patterns, a repeatability study was carried out. To this end a single 2d muscle sample was independently extracted five times and run on an SDS-PAGE gel to determine if a quantitatively similar profile was obtained in each lane.

Results and Discussion

Results obtained show that increasing TCA concentrations have a negative effect on the extent of protein retrieval. The lower (0.5 and 1.0% TCA concentrations) gels have a higher degree of protein extractability,

compared to that of 5.0% (Figure 1). Higher TCA concentrations examined (10.0%) resulted in remarkably less protein extraction, with an absence of protein at 20.0% (results not shown).

The lower percentages of TCA (0.5 and 1.0%) provided extracts which were easily visualised on SDS-PAGE gels. As shown in Figure 1., clear banding patterns were observed from below 20kDa up to 205kDa. The most obvious changes over the ageing process were the increased intensities of bands appearing in the 20kDa to 36kDa region and the higher molecular weight 116kDa to 205kDa region. In terms of actual protein recovery, differences are visible between the two animals. Animal 2 has an absence of lower (< 29kDa) molecular weight proteins at lower TCA concentrations, with sharper more pronounced bands in animal 1 for the same concentration. Further characterisation of the individual animals will rule out if this is due to other factors such as, phenotypic differences.

A repeatability study was conducted on a single 2d sample. In this way the efficiency of the assay procedure to consistently isolate proteins in a reproducible manner was assessed. The results for the gel that was silver stained for greater sensitivity, show that the extraction procedure is indeed reproducible qualitatively, as the banding pattern of all five profiles are similar.

Conclusions

- SDS-PAGE separation techniques are useful in tracking changes in bovine TCA soluble protein extracts, over the post mortem ageing period.
- TCA concentration is a major factor in the extent of protein retrieval.
- Further work will be necessary in order to quantitatively categorise the specific changes observed.

CHARACTERISTICS OF CARCASS COMPOSITION FOR HANWOO (COW, BULL, STEER) AND HOLSTAIN STEER

Park, B. Y[a]., Cho, S. H[a]., Kim, J. H[a]., Chae, J.M. [a], Kim, D.H. [a], Yoon, Y.T[b]., Lee, J.M. [a]
[a] National Livestock Research Institute, Rural Development Administration, Suwon, Korea
b Animal Products Greading Service, Seoul, Korea

Background

According the Korean animal products grading service, the frequency of carcass weight slaughtered from 1998 to 2002 decreased 2.9%, 14.7% and 12.2% for lighter than 200 ㎏, 200～250 ㎏ and 250～300 ㎏, respectively. On the other hand, that increased 8.1% and 14.8% for 300～350 ㎏ and 350～400 ㎏, respectively. Dairy cattle also showed the similar trend over the period. The tendency was understood as a consequence of improvement of feeding technique and long feeding period in response to consumer's demand of high quality beef. The rate of castration increased from 8.6% in 1998 to 38.2% in 2002. As a result, frequency of carcass heavier than 350kg increased from 16.3% in 1998 to 42.5% in 2002 which was the result of farmer's effort for producing high quality Hanwoo beef. According to the US National Beef Quality Audit in 2002, the most important task for beef producer included consistent product, yieldness, over-fattening. In the case of the US, carcass weight increased from 344kg in 1991, 339 kg in 339 to 357 kg. However, backfat thickness was 1.5cm in 1991, 1.2 ㎝ in 1995 and 1.24 ㎝ in 2000. In addition, average carcass weight for each quality grade was 370 kg for prime, 359 kg for choice and 355 kg for select grade.

Objectives

The current study was conducted to investigate characteristics of carcass quality and yieldness for Hanwoo cow, bull and steers within the range of market weight for each breed.

Materials and methods

The current analysis used industrial data collected from July 2003 to November 2003 across Korean best six slaughter houses. Seventy three carcasses of total 631 carcass were excluded for which a sum of deboned meat, bone and fat was higher than carcass weight, or which had higher than 15 kg of processing loss. Finally 558 carcasses were used for the analysis. Seven Hanwoo cows with carcass weight range of 350～400 ㎏, 77 Hanwoo bulls, 50 Hanwoo steers, 71 castrated daily cattle and thus total 212 cattle were used for analyzing carcass weight, cutability (10 primal cuts), body fat, bone weight. Carcass separation was performed according to the methods described by Ministry of Agriculture and Forest Act 1- 69. Subcutaneous fat was determined according to the beef regulation which requires remaining rate of 0 ㎜. Yieldness was calculated carcass weight against carcass weight without kidney and kidney fat. Back fat thickness and ribeye area were determined according to the method described by Animal products grading service.

Results and discussion

Table 1 shows characteristics of carcass traits. Average carcass weight of Hanwoo cow, bull and steer, and Holstein steer were 326.7 ㎏, 372.6, 378.6 and 396.7 ㎏, respectively. Holstein steer had the highest carcass weight, and that for bull and steer was similar. On the other hand, Hanwoo cow had a significantly lower carcass weight ($p<0.05$). Hanwoo cow had the most thinker back fat with 11.34 ㎜, followed by Hanwoo steer with 10.54 ㎜, Holstein steer with 7.69 ㎜, and Hanwoo bull with 6.16 ㎜ ($p<0.05$). Ribeye area was largest for Hanwoo bull with 85.7, followed by Hanwoo cow with 76.01 and Hanwoo steer with 74.20 ($p<0.05$). Yieldness was highest for Hanwoo bull with 67.8%, followed by Holstein steer with 64.0%, Hanwoo steer with 61.5%, and Hanwoo cow with 61.1% ($p<0.05$). Bone percentage was highest for Holstein steer with 15.0%, followed by Hanwoo bull 13.4%, Hanwoo steer with 12.0%, and Hanwoo cow with 11.8%. Difference in bone percentage between Hanwoo bull and Holstein steer was approximately 1.6%, while that between Hanwoo steer and Holstein steer was approximately 3.0% with higher percentage for Holstein steer. Body fat percentage was lowest for Hanwoo bull with 17.4%, followed by Holstein steer with 19.4%, Hanwoo steer with 24.6%, and Hanwoo cow with 25.0% ($p<0.05$).

With regard to carcass characteristics, Hamlin et al. (1995), Reiling et al. (1995) and Barber et al. (1981) reported that yieldness was linearly increased with carcass weight, but cutability against yieldness was decreased. Johnson et al. (1991) reported that high carcass quality with increased carcass weight resulted in reduction in cutability and increase in body fat percentage. In this regard, the current result of Holstein steer and Hanwoo steers supported the previous result. In addition, Abraham et al. (1980) and Talamantes et al. (1986) reported that body fat varied between breeds, sex, slaughter weight and between carcasses. Thus the percentage of body fat was a significant factor determining slaughter age for the best economic value of carcass.

Table 2 shows difference in carcass characteristics. Carcass weight did not differ with the selected range ($p>0.05$). However, retail cut percentage was highest for Hanwoo bull with 254.0 kg, followed by Holstein steer with 242.8 kg, Hanwoo steer with 229.6 kg, and Hanwoo cow with 221.2 kg($p<0.05$). Yieldness which reflects cutability was highest in Hanwoo bull with 67.8%, followed by Holstein steer with 64.5%, Hanwoo steer with 61.3%, and Hanwoo cow with 59.2% ($p<0.05$). Difference in cutability between Hanwoo and Holstein steers were 3.2% with higher percentage for Hanwoo steer. Bone percentage was highest for Holstein steer with 15.4%, while Hanwoo cow was lowest with 11.1% ($p<0.05$). Difference in Holstein steer and Hanwoo bull were 2.13%, and that between Holstein and Hanwoo steers were 3.45%. In body fat content, Hanwoo bull and Holstein steer had 17.6% and 18.5%, respectively. Hanwoo steer and Hanwoo cow were 24.8% and 27.1%, respectively ($p<0.05$).

Similar results with the current study were reported by Amer et al.(1994) and Jacobs et al.(1977) who reported in the study of comparing carcass characteristics between breeds and sex , steer had a higher back fat thickness and lower yieldness than those for bull at the same carcass weight. Hopkinson et al.(1985) buff had higher carcass weight, cutability, and dressing percentage than steer when these were slaughtered at the same live weight. On the other hand, body fat was higher for steer than bull. Miller et al.(1988) and Karima et al.(1986) studied the effect of sex on carcass traits for similar live weight and found that dressing percentage was higher for steer than bull and cow, while cutability was higher for bull than cow and steer.

Conclusions

Hanwoo bulls showed the highest yieldness with 67.8% between carcass weight 350~400 kg, followed by Holstein steer with 64.5%, Hanwoo steer with 61.3% and Hanwoo cow with 59.2% ($p<0.05$). In comparing yieldness between Hanwoo and Holstein steers, Hanwoo steer showed lower percentage by 3.2% then Holstein. In bone weight, Holstein showed the highest percentage with 15.4%, while Hanwoo cow was the lowest 11.1% ($p<0.05$). Difference in bone percentage between Holstein and Hanwoo bull were 2.13%, and that between Holstein and Hanwoo steers was 3.45%. Body fat was low in Hanwoo bull and Holstein with 17.6% and 18.5%, respectively, while that for Hanwoo steer and Hanwoo cow were 24.8% and 27.1%, respectively($p<0.05$).

A METHOD FOR DETERMINING THE MUSCLE FIBRE LENGTH

Puolanne, E. and Räsänen, P.
Department of Food Technology, P.O. Box 66, FI-00014 Helsinki, Finland

Background

Muscle fibres are the result of the fusions of thousands of myoblasts to form a long tube. The length of a mammalian muscle fibre is variable, and can be the length of the muscle. They are not, however, usually as long as the muscle, but still the length may even be 340 mm in long muscles (Lawrie, review 1998, p. 39). Fibres are arranged end-to-end series with their tapering ends overlapping adjacent fibres. About 50% of their length is of constant diameter, and taper at both ends by 25% of their length the angle of the taper being about 1º. (McCormick, review 1994, pp. 30-31). There is no data about porcine muscle fibre lengths easily available.

Objectives

The purpose of this study was to develop a method to estimate the fibre length of a muscle in order to count the total number of fibres in a muscle.

Materials and methods

M. longissimus dorsi muscle from three pigs of about 110 kg live weight were excised on the day following slaughter caudally to 5th *Thoracic vertebra*. Three 1 cm thick slices were cut, from both ends at 1/5 of the total length and from the middle, of each excised muscles (Figure 1A). From each slice five 1x1x1 cm cubes were usedfor fibre length measurements and five smaller pieces, of about 300 mg, for fibre diameter measurements were cut as shown in Figure 1B.

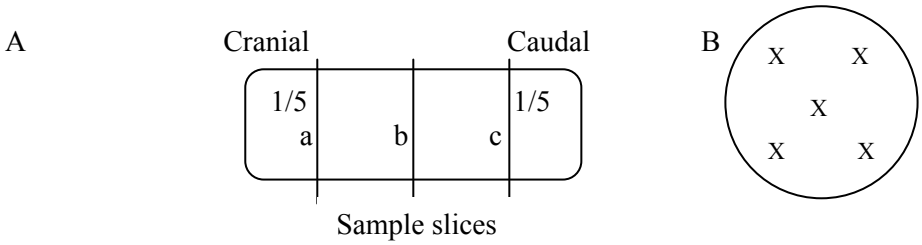

Figure 1. Sampling from *M. longissimus dorsi* muscle A: Slice locations; B: Fiber samples from a slice

Fibre length. Muscle fibres were separated by the Hooper method (1976; 1981). A sample cube was placed into a 50 ml beaker with 15 ml 4 N HNO_3. Beakers were covered with aluminium foil and kept overnight at room temperature. After the acid treatment the dimensions of the cubes were measured to determine the shrinkage (shortening) caused by the acid treatment. The cubes shrank longitudinally along the fibre axis 10%. Then each sample cube was inserted into a test tube with 5 ml Ringer-Locke solution. Test tubes were sealed and shaken vigorously by hand and by using test tube shaker, for one minute. Part of the suspension was poured on a slide and left to dry overnight.

The suspension was studied with a microscope (Olympus BH-2, Japan) at 40x magnification, with a commercial Zeiss AxioCam MRc digital camera (Zeiss GmbH, Germany) (Figure 1). Images were analysed with software package (Zeiss KS300 3.0, Germany). Individual fibre fractions were marked manually, on the images at their both ends, and the program then determined the length of the fibre. The results were stored cumulatively. Simultaneously, the number of fractions that visually seemed to be the very end of the tapered end of a fibre, was counted. From each slide sufficient fields were analysed so that the total number

of fibre fractions was at least 400. Totally over 20 000 fractions were measured (3 muscles x 3 slices x 5 cubes x more than 400 fractions).

The length of fibres was counted assuming that the tapered ends are equally distributed within the fractions (Equation 1).

$$L = \frac{\sum F}{(N/2)}$$

L= length of the fibres [mm]

F= total length of fractions [mm] (Eq. 1.)

N= number of the tapered ends.

Cross sectional area of slices. The slices were photographed, and the cross sectional area was determined using the image analysis program Zeiss KS300.

Number of fibres in a cross section. Due to an error in sample preparation, only two muscles were analysed for fibre numbers. The sample pieces were frozen in liquid nitrogen and kept then in -80 ºC. Cross sections (12 µm) were cut at -26 ºC in a cryostat (Reichert-Jung 2800 Frigocut E, Germany). The sections were not stained. From the sections, the counting area of the image and the number of fibres on the counting area were determined. The number of fibres per image was about 100. Two images per sample were analysed, totalling 10 images per slice (30 per muscle, 60 in grand total). The fibre number was counted by dividing the cross sectional area of the slice by the average cross sectional area of fibres.

Results and discussion

The fibres were well separated by the Hooper method. The fractions were clearly seen and marked for the automatic determination in the image. The tapered ends were also easy to identify, but the major obstacle was their small number. It was not possible to use a lower magnification or an automatic determination of the fractions directly from the image, because the first stage of the analysis had to be done manually. On one hand, the tapered ends of the fibres are very thin and difficult to see, but on the other hand, if this done always by the similar way, the fractions of certain size will always be counted similarly. An increase of the fields counted, however, would also much increase the work needed.

The aim of this study was develop a method for fibre length determination. Therefore, the conclusions below are only speculative, especially because the number of tapered ends was so small (varying between 4–14 within the total about 2000 fractions counted per slide). In such a small number, a change of one tapered end only has a marked effect on the results.

The fibres seem to be more than 100 mm long (Table 1). They seem to be longer in the middle of the muscle than at the end, which is in agreement with the statement of McCormick (review 1994). In this study we had actually only one end, the caudal (rear) end. The authors did not find any literature data about the length of porcine muscle fibre, and therefore no comparisons were made here. It seems, however, that the lengths obtained with this method are very long, and more analyses are needed for the validation of the method.

The fibre cross sectional areas were similar to that reported previously in Finland (Ruusunen and Puolanne, 2004) (Table 2). Because the fibres seem to be so long, theoretically there would be no need to have tapered ends at slice c, because it is closer (about 10 cm) to the caudal end of the muscle than the average length of the fibres. (On the contrary, the cranial end of the sample is not at the very end of the muscle, because a part of *M. longissimus dorsi* remained in the forepart of the carcass). Therefore, for reliable results, more slices taken at shorter spacings should be analysed, this would tremendously increase the amount of work needed.

The cross sectional area of fibres is larger in the middle of the muscle, which is a logical consequence of the observation (McCormick, review 1994) that the fibres are tapered at the end of the muscle. It must be noted, however, that the fibre axis in *M. longissimus dorsi* in not fully parallel with the muscle axis, and therefore the fibres have a slight pennate-type arrangement in the muscle. The number of fibres per muscle cross

section is about 1.1–1.3 million, on average 1.2 million. A very rough estimate of the total number of fibres in the whole muscle (length 60–70 cm, weight ca 4.0 kg) is about 4.2 million. Consequently, one fibre, 173 mm long and diameter Ø 40 µm, has a weight of about 1 mg.

Table 1. Muscle fibre lengths of porcine *M. longissimus dorsi* (n=3)

Slice (see Figure 1A on Page 1)	Muscle fibre length (mm)
a (cranial)	183 (156–298)
b (medial)	218 (186–346)
c (caudal)	137 (112–235)
Grand mean	173

Table 2. Muscle fibre cross sectional area and cross sectional fibre number in porcine *M. longissimus dorsi* (n=2)

Slice (see Figure 1A on Page 1)	Cross sectional area $x10^3$ µm^2	Number of fibres $x10^3$
a (cranial)	5.14	1147
b (medial)	5.17	1153
c (caudal)	4.67	1299
Grand mean	5.00	1198

Conclusions

A rough estimate of the muscle fibre length of porcine muscle length can be made by disintegrating muscular tissue and counting the tapering ends of muscle fibres in relation to the total length of the fibres counted. The method is, however, time consuming and hard to automatize. A fibre type staining could be included to increase the relevant data obtained from samples. The average cross sectional area of the fibres seems to vary within the muscle, being smaller at the ends of the muscle.

GLYCOGEN, LACTIC ACID AND PH IN MEAT (META ANALYSIS)

Puolanne, E.[1], Yli-Hemminki, M.[2] and Kylä-Puhju, M.[1]

[1]Department of Food Technology, P.O. Box 66, FI-00014 Helsinki, Finland
[2]Meat Industry Research Centre, P.O..Box 56, FI- 13101 Hämeenlinna, Finland

Background

Lactic acid has a pK_a-value of 3.86. This means that 90% is dissociated at pH 4.9, and 99% at pH 5.9, i.e. practically totally. Consequently, only ca. $3*10^{-5}$ M lactic acid solution would decrease the pH of distilled water to a value of 5.5. Analyses have shown that in meat the relationship between pH (a logarithmic measure) and the lactic acid content (a linear measure) is practically linear. On the assumption of a linear relationship, the buffering capacity of meat has been calculated from titration curves, to be 50–60 mmol H^+/(kg*pH) over the pH range of 7 to 5.5. Consequently, ca. 80 to 100 moles lactic acid per kilogram lean meat is needed to decrease the pH value from 7.2 of living muscle to 5.5.

In a simplified model glucose (glycogen) is broken down to lactic acid causing the pH to decrease. The protons formed are bound to buffering substances, such as proteins, organic and inorganic phosphates and dipeptides. The buffering capacity of all of these depend on pH. The buffering capacity of proteins is from about 20 mmol H^+/(kg*pH) (pH 7.0) to 35 mmol H^+/(kg*pH) (pH 5.5). The effect of the other substances ranges from ca. 30 mmol H^+/(kg*pH) (pH 6.8) to 15 mmol H^+/(kg*pH) (pH 5.5). At lower pH values, lactic acid becomes increasingly important, as its buffering capacity increases, while the capacity of other components decreases. Proteins, however, have another buffering capacity maximum at pH 4, due to the pK_a of the nonpeptidyl carboxyl group. Consequently, the buffering capacity is different at different pHs (Kivikari, review 1996).

In addition to the buffering capacity, there are difficulties obtaining unbiased determination of pH value of meat, as well as determining the glycogen, its derivates and lactic acid, especially in the small and inhomogenous samples generally used in meat research. The amount of water added during sample preparation and titration, added salt etc. have effects on the pH and also on the buffering capacity. This makes it understandable that the data given in the literature is somewhat variable.

Objectives

The purpose of this study was to analyse the relationships between glycogen and lactic acid contents and pH, based on the data presented in the literature (meta analysis).

Materials and methods

The data used in this meta analysis were collected from the literature relating to porcine *M. longissimus dorsi* (i) pH value, (ii) lactic acid content and (iii) glycogen content at (iv) different times post mortem. We used the value 7.2 (Kylä-Puhju, Ruusunen, Kivikari and Puolanne 2004) for the pH of zero lactate meat and buffering capacity of 52 mmol H^+/(kg*pH) (Kivikari 1996; Puolanne and Kivikari 2000). All data were converted into same units and calculated as follows (the underlinings refer to Table 1.):

The Measured pH value was the pH value that was given in the reference at the given time
The Calculated pH value was obtained as follows: pH calc. = 7.2 – lactic acid (mmol/kg)/52 mmol/(pH*kg)
Difference pH = pH measured – pH calculated
Measured Δ lactic acid LA (mmol/kg) = lactic acid time 2 – lactic acid time 1
Calculated Δ lactic acid LA (mmol/kg) = (glycogen time 1 – glycogen time 2)*2
Difference lactic acid LA (mmol/kg) = measured Δ lactic acid – calculated Δ lactic acid

Results and discussion

The differences between the measured and calculated lactic acid values did not show any consistent pattern, varying between -0.14 and +0.66 (Table 1.). The calculated pH values, however, tended to be lower than the measured.

The data in Table 1 are only a sample of the data available in the literature, and the following discussion is based on a more general analysis of the literature data. It was clearly seen in this study that the determination of pH values as well as lactic acid content and glycogen content are subject to large variation which may sometimes have lead to even biased results. This does not necessarily mean that the analyses have not been carefully done. The measurement of pH value is particularly difficult just after slaughter. Therefore it is recommended to utilise iodoacetate method to stop the glycolytic reactions which would also allow the measurement to be carried out at the room temperature. The sample sizes are sometimes small, from 10 mg (2 mg freeze dried) to several grams. Sometimes blood, fat and visible connective tissue had been carefully removed, but not always.

The intermediates of the glycolytic pathway which are not determined by the normal methods for detemining glycolytic potential may represent less than 10 mmol/kg as lactic acid (Kastenschmidt et al., 1968; Hamm and Fischer, 1980). These do not seem to be the major cause of the variability in the results. It was found that the value for buffering capacity is also very variable. Kivikari (1996) and Puolanne and Kivikari (2000) gave a buffering capacity of 52 mmol H^+/(pH*kg), but in her review Kivikari (1996) had found values from 42 to 64 mmol H^+/(pH*kg). In a previous study the value was 49 mmol H^+/(pH*kg) (Kylä-Puhju, Ruusunen and Puolanne, 2004), and in the current study the best fit was obtained with a value of 62 mmol H^+/(pH*kg). This was done by solving the value of the regression equation y = -0.1927x + 1.3843 at pH 5.5 (Figure 1). When the measured pH value x was 5.50, y was 0.32, meaning that the calculated pH value was 5.18 (5.50 – 0.32 = 5.18). From this it was possible to calculate that if the buffering capacity value was 62 mmol H^+/(pH*kg), the measured pH value and calculated pH value would be the same. The 62 mmol H^+/(pH*kg) gives ΔpH values between measured and calculated values that are on average zero independently of the pH value of the meat at the time of the determinations (Figure 2.). The buffering capacity values, however, should not be directly compared because they are from different sources. This still shows the uncertainty of the methodology involved.

Conclusions

It was concluded that much effort should be put on the analyses of pH values, glycogen contents and lactic acid contents. If they all are determined at the same times, it might be worthwhile to do the simple calculations in order to see, how well the figures fit together as glycolytic potential. It must, however, be pointed out, that during the post mortem reactions the calculations discussed above may be a over-simplification, and also other factors and components may have a marked role. In addition, it is recommended always to use the same control sample within the study to check the variation between the different sets of analyses. The buffering capacity of *M. longissimus dorsi* seems to depend on the method of determination, the values varying between 49-62 mmol H^+/(pH*kg).

ARE CATHEPSINS B AND D INVOLVED IN POST-MORTEM MYOFIBRILLAR DEGRADATION?

Reville, W.J.[1], Motherway, M.M.[1], Griffin, C.[1], Zeece, M.G.[2]

[1]Biochemistry Department, University College Cork, Ireland.
[2]Department of Food Science and Technology, University of Nebraska, U.S.A.

Background

There is considerable evidence that the increase in tenderness that occurs during the post-mortem storage of muscle at 4°C is caused by limited proteolysis of the myofibril, although the detailed mechanism remains to be elucidated (Zeece et al. 1992, Jiang, 1998).
The principal proteinase systems in the muscle fibre are (a) the calpains, (b) the lysosomal cathepsins, and (c) the proteasome-ubiquitin system. Calpain seems to account for much of the post-mortem proteolysis in the myofibrils (Geesink and Koohmaraie, 1999), but the role of the cathepsins is unclear (Goll et al. 1983). The post-mortem activity of the proteasome has not been extensively investigated.
If cathepsins are to act post-mortem on the myofibril they must be released into the cytosol from the lysosome. Some studies, (e.g. Dutson, 1983) report post-mortem release of lysosomal enzymes, others (e.g. Lacourt et al. 1986) report no release. However, careful biochemical studies by Chambers et al. (1994) found limited release of lysosomal enzymes during the post-mortem storage of bovine muscle at 4°C and this finding was confirmed by Mobarak et al. (1999) using enzyme histochemistry and by Mobarak et al. (2000) using immuno electron microscopy.
Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) can detect the subtle proteolysis that occurs post-mortem in myofibrils. The release of easily releasable myofilaments (ERM) from myofibrils is another sensitive test of post-mortem myofibrillar degradation. ERM are a sub-population of myofilaments on the myofibril surface that are easily shed from the myofibril under 'relaxing' conditions, i.e. 0.1M KCl, 3mM Mg-ATP, 3mM EGTA, 1mM DTT, 2-mM Tris-Maleate, pH 7.1. Reville et al. (1994) showed that the yield of ERM in beef muscle rises steadily over the conventional 14 day post-mortem ageing period of 14 days at 4°C.

Objectives

Assuming that lysosomal cathepsins are released into the cytosol post-mortem the present study investigated whether catheptic activity against myofibrils *in-vitro* mimics myofibrillar changes known to occur during post-mortem ageing of beef. The effect of pre-treatment of bovine myofibrils with cathepsin B or cathepsin D on ERM release from these myofibrils was examined. The proteolysis of the myofibrils by cathepsin B and cathepsin D was monitored by SDS-PAGE.

Materials and methods

Myofibrils were prepared from bovine sternomandibularis muscle (18 month old Friesian heifers) by the method of Etlinger et al. (1976) and stored in Low Salt Buffer (LSB) – 0.1MKCl, 3mM $MGCl_2$, 3mM EGTA, 1mM DTT, 20mM Tris-Maleate, pH 7.0 containing 50% glycerol at –20°C until required.
Cathepsin B treatment of myofibrils at pH 5.5: Bovine spleen cathepsin B and its inhibitor leupeptin were purchased from Sigma. The enzyme was reconstituted in 2mM phosphate buffer, pH 7.0 at a concentration of 1mg/ml. Myofibrils were resuspended in 0.1M KCl, 1mM EDTA, 50mM Imidazole, pH 5.5 at a protein concentration of 3mg/ml and digestion was started by adding cathepsin B at a ratio of 1 part enzyme to 100 parts myofibril (w/w). Two controls were employed – myofibrils incubated for 60 mins in the KCl, EDTA, Imidazole buffer, and myofibrils plus enzyme plus leupeptin incubated for 60 mins at 37°C. The active treatment conditions were myofibrils plus enzyme for 5 minutes or for 60 mins at 37°C. Treatment was terminated by the addition of leupeptin at a concentration of 20µg/ml.
Cathepsin D treatment of myofibrils at pH 5.5: Bovine spleen cathepsin D and its inhibitor pepstatin were purchased from Sigma. Cathepsin D, was reconstituted in distilled water, but otherwise the treatment of myofibrils with cathepsin D was effected as described for cathepsin B, except that 0.1M NaCl substituted for

0.1M KCl and digestion of myofibrils with cathepsin D was terminated by addition of pepstatin to a concentration of 20mM.

Assay of Mg-ATP Stimulated Release of Protein from Cathepsin Treated Myofibrils: Control and enzyme-treated myofibrils were resuspended in LSB and assayed for Mg-ATP stimulated release of protein in the ERM assay as described by Reville et al (1994). Released protein is expressed as a percentage of the total myofibrillar protein. Release of protein in the presence of LSB alone (i.e. no ATP) was also measured.

Electrophoresis by SDS-PAGE: SDS-PAGE was carried out on control myofibrils and on myofibrils treated with cathepsin D or cathepsin B. Myofibrils were solubilised in 4M urea, 1M thiourea, 0.025M Tris-Acetate pH 6.8, 37mM DTT, 1.5% SDS, 0.025% Bromophenol blue. Samples were heated at 55°C for 15 mins. and subsequently stored at –20°C until SDS-PAGE was performed.

SDS-PAGE followed the method of Laemmli (1970), using a 5% stacking gel and a 7%-18% linear acrylamide gradient separating get. 30µg of protein was loaded per lane. The gels were stained with coomassie-blue.

Results and discussion

Figure 1 shows that pre-treatment of myofibrils with cathepsin B or D enhanced Mg-ATP stimulated release of protein from myofibrils, even after 5 minutes pre-digestion of the myofibrils. In the case of cathepsin D pre-treatment, Mg-ATP stimulated release of protein rose from a mean of 1.3% total myofibrillar protein in controls, through a mean of 1.89% after 5 mins., to a mean of 5.0% after 1 hour's pre-digestion of the myofibrils. The corresponding figures for cathepsin B were a rise from 1.05% for controls, through a mean of 1.8% after 5 mins, to a mean of 3.1% after 1 hour's pre-digestion. Neither cathepsin D nor cathepsin B treatment of myofibrils had any significant effect on release of protein in the absence of Mg-ATP.

Figure 2 shows the protein subunit composition of control myofibrils and myofibrils after digestion for 5 mins. and 60 mins. with cathepsin B or cathepsin D at pH 5.5 as assessed by SDS-PAGE. Five minutes treatment with cathepsin B had little effect on the myofibril. Treatment of myofibrils for 1 hour with cathepsin B had pronounced effects, of which the most notable are:- most of the high molecular weight material above myosin is removed; myosin and actin bands are notably diminished compared with controls; many new bands, presumably degradation products, are evident, e.g. a ladder of bands in the range 120 kDa to 150 kDa relative molecular mass.

The effects of treatment of myofibrils with cathepsin D are similar to the results described for cathepsin B, although there are differences in the pattern of degradative products produced (Figure 2). Five minutes treatment at pH 5.5 shows but a minor effect on protein subunit pattern, most notably on the very high molecular weight sub-units. Sixty minutes treatment with cathepsin D shows a marked effect – a big diminution in very high molecular weight material, a marked decrease in myosin band intensity, and some degradation of α-actinin (not seen after cathepsin B digestion).

Increased ERM yields from cathepsin D or cathepsin B 60 minute pre-treated myofibrils compare favourably with the natural increase in ERM yield in post-mortem bovine muscle from 1.4% at-death to 5.5% after 14 days storage at 4°C. However, proteolysis of the myofibril during conventional ageing of meat is very minor and there is no degradation of actin or myosin, whereas 60 mins. digestion of myofibrils with cathepsin B or cathepsin D produces marked degradation of myofibrillar proteins, including actin and myosin. Therefore the effects of primary interest in the present study are the effects of limited (5 mins.) digestion of myofibrils by cathepsins.

Five minutes digestion of myofibrils by cathepsin B or D had only minor effects on the protein subunit composition of the myofibrils. This amount of pre-digestion of the myofibrils allowed an increase of about 75% in the amount of protein released from myofibrils in the presence of Mg-ATP compared to controls in the case of cathepsin B and 46% in the case of cathepsin D. If both enzymes were acting together, and if the effects were additive, this would produce about a 120% increase in the yield of releasable protein. If cathepsins are released from the lysosome post-mortem, other cathepsins, in addition to B and D, could also contribute to the degradation of the myofibril, e.g. cathepsin L.

Conclusions

Concerted but limited action of cathepsins on myofibrils post-mortem could account for much of the increase in Mg-ATP stimulated release of protein from myofibrils that is seen during the conventional post-mortem storage of beef at 4°C.

MODELING CHANGES WITH AGEING IN THE MECHANICAL PROPERTIES OF BEEF CONNECTIVE TISSUE

*Sandrin Aurélie, *Beakou A., [X]Favier R., [X]Lepetit J.

INRA 63122 Saint Genès Champanelle, France
*IFMA, Campus de Clermont-Ferrand / Les Cézeaux, 631750 Aubière, France

Background

Perimysium connective tissue is known to play an important role in the variations in meat toughness. It is a network of collagen fibers organized in ply and embedded in a ground substance made of various proteoglycans (Eggen, Malmstrom, Sorensen and Host 1997) which constitute the matrix of the tissue. During ageing, there is a weakening of the perimysium which separate into collagen fibers and fibrils. Whereas collagen remains unchanged at the molecular level, however, during ageing, there is a degradation of proteoglycans. This degradation as been put forward to explain the weakening of the perimysium connective tissue during storage. Nevertheless there are no data on the mechanical properties of this matrix and of these changes with treatments.

Objectives

The aim of this study was to quantify the mechanical changes occurring in the matrix of proteoglycans of perimysium connective tissue during storage.

Materials and methods

Muscles: *Semimembranosus* muscles were taken from a Charolais - Frisonne cow (3 ½ years old). The muscles were removed from the carcass at 24h *post-mortem*. They were divided into several parts which were vacuum packed and stored at 4°C for 2 or 14 days and then frozen.

Measurements :
All the samples were thawed in water at 10°C. Sheets of perimysium (approximately 10 mm long x 4 mm wide) were dissected and tested with a micro-tensile device developed in this laboratory, for the determination of breaking stress, breaking strain, Young's modulus, breaking energy and total energy. The width of the samples were determined using a microscope and the thickness determined with a Mitutuyo micrometer under a force of 0.2N applied on the whole surface of the sheets. During the tensile test the samples were immersed in meat drip. The procedure for handling samples is similar to that described by Lewis and Purslow (1989). After dissection, strips of perimysium were glued on aluminum foil frames with cyanoacrylate glue. The samples on the aluminum frames were then fixed on the micro-tensile device so that the direction of tensile strain corresponded to the direction of muscle fibers.
The extension rate was 130 µm/s. The software applied a slack toe correction to the force – displacement curves to remove the part of the displacement where collagen fibres are just unfolded. The Young's modulus was calculated as the slope in the straight region of the stress – strain curves.

Statistical analysis :
For all mechanical variables means were obtained from 80 to 120 measurements. Data were analysed using the general linear model procedure of SAS Software (SAS/Stat Cary, NC: SAS Institute Inc., 2000).

Mechanical model

The purpose of this model was to quantify the changes in Young's modulus and Poisson ratio of the matrix during ageing. The model proposed in this paper combines laminated membrane theory and reciprocal identification method to estimate the Young's modulus and Poisson ratio of the matrix. Evolutive anisotropy of the tissue due to the reorientation of collagen fibres with the perimysal strip elongation is taken into

account from measurements of the variation with strain of the angle between collagen fibres and the direction of strain. As a first approximation, the model does not account for the crimping effect along the collagen fibres.

Model description:

Four engineering constants are needed to describe the mechanical behaviour of a ply; the longitudinal Young's modulus E_L, the transversal Young's modulus E_T, the longitudinal Poisson ratio ν_{LT} and the longitudinal shear modulus G_{LT}. They are expressed in terms of engineering constants of the constituents and fiber volume fraction using a parallel system for E_L, ν_{LT} and a series system for E_T and G_{LT}. Then the on-axis stiffness matrix [Q] of each ply can be computed and the off-axis stiffness matrix [Q(θ)], expressed in terms of [Q] and a transformation matrix [T(θ)]. Next, laminated membrane theory is used to derive the mechanical behavior of the perimysal strip made of two plies lying at +θ and - θ to the muscle fiber direction (Christensen, 1991). As expected in the case of tensile test, the shear stress in a ply is balanced by the oppositely directed shear stress in the second ply, such that the net shear force over the tissue is cancelled out. The equations of in-plane behavior of the tissue are not linear as usual because of the dependency of fibers orientation on the strip elongation; so iterative methods must be used to compute the stress-strain curves. As the model does not account for the fibers crimping, the initial non-linear region of the tensile curve can not be described.

Reciprocal identification method:

It has been assumed according to Liu, Nishimura and Takahashi (1994) that the collagen of intramuscular connective tissue remains unchanged at the molecular level during *post-mortem* ageing of meat. The model is also based on the assumption that the matrix is mechanically isotropic, which is a simplification as proteoglycan matrix is not amorphous. The following data were used for the simulations: collagen fiber Young's modulus E_f= 1000 MPa, collagen fiber Poisson ratio ν_f = 0.5, fiber volume fraction V_f=8%. For given values of matrix Young's modulus E_m and Poisson ratio ν_m, a numerical stress-strain curve of the perimysal strip was computed and the gap between numerical and experimental curves was evaluated. Discrepancies were reduced by adjusting E_m and ν_m. The fitting were done on part of the stress-strain curves limited by strain = 0 and breaking strain.

Results and discussion

The data in Table 1 show the overall changes in mechanical properties of perimysium sheets due to storage. Significant reductions were observed in breaking stress and Young's modulus.

Duration of storage (Days)	Breaking Stress (MPa)	Breaking strain	Modulus (MPa)	Beaking energy (mJ)	Total energy (mJ)
2	0.76 *a*	0.77 *a*	1.34 *a*	2.9 *a*	5.2 *a*
14	0.51 *b*	0.70 *a*	1.05 *b*	2.6 *a*	4.1 *a*

Table 1: Mechanical properties of perimysium sheets
In each column the values followed by different letters are significantly different at a 5% level.

The results of the modeling are given in Table 2. It appeared (data not shown) that when both Poisson ratio and modulus of the matrix were adjusted freely by the software to give the best fit of the stress – strain curves then the final value of the Poisson ratio was systematically negative which means that during the tensile test there is an expansion of the matrix volume. It is not a classical behavior of materials although already mentioned by Vincent (1990). So, the Poisson ratio of the matrix was fixed in the range $0 < \nu_m < 0.5$.

Storage (days)	N	Modulus (MPa)
2	80	0.47 *a*
14	119	0.38 *b*

Table 2 : Matrix modulus obtained from modeling.
In each column the values followed by different letters are significantly different at a 5% level

There was a reduction of about 20% of the matrix modulus between 2 and 14 days of storage. The Poisson ratio being zero at 2 and 14 days.

Conclusions

The results obtained in this study agreed with those from Nishimura, Hattori and Takahashi (1995, 1996) in beef, which showed that there is a progressive weakening of perimysium connective tissue during storage explained by a degradation of proteoglycans. This study shows that after 14 days of storage there is a a 30% reduction in breaking stress and a 20% reduction in Young modulus measured in tension. A similar decrease in breaking stress has been found by Lewis, Purslow and Rice (1991). A mechanical model based on the composite theory has been developed in order to quantify the mechanical changes occurring in the proteoglycans matrix during storage. It appears that a decrease of the modulus of the matrix by 20 % associated with a null Poisson ratio can explain the changes observed at the level of the perimysium network between 2 and 14 days of ageing.
An improvement of the model is needed as it does not take into account the unfolding of collagen fibers and assumed that the matrix was isotropic.

PROTEOMIC APPROACH TO CHARACTERIZE PALE AND DARK TURKEY BREAST MEAT SORTED BY IMAGE VIDEO

[1]Santé-Lhoutellier Véronique, [2]Le Pottier Gilles; [1]Sayd Thierry & [1]Monin Gabriel

[1]Biochimie et Physiologie du Muscle, Station de Recherches sur la Viande, INRA, 63122 Saint Genès Champanelle, France. [2]CIDEF 35310 Mordelles, France

Background

In the past decade, the turkey meat industry has developed new products based on cured and cooked meat. Meat processors need to adapt the raw material to further processing. The technological quality of the processed meat depends on its major component: the proteins. The state of the proteins will mostly determine the water holding capacity of fresh meat and colour, themselves correlated with pH value. A previous study has shown that early pH determines partly the colour of the fresh meat (Santé *et al*., 1996). Studying proteins requires the use of separating techniques such as 1-D electrophoresis. Utilisation of 2-D electrophoresis is developing since it allows separation of several hundreds of proteins. Further steps includes identification of spots of interest using mass spectrometry. Then, characterisation of meat could be performed through its protein mapping. Besides, Lametsch *et al*. (2003) showed that proteome was correlated to textural trait in pig meat.

Objectives

Predicting the process ability of meat is challenge for meat processors. Even if the turkey BUT9 represents 95% of slaughtered turkey in France and the environmental conditions (slaughter, chilling, etc..) are well defined, the variability still exist in terms of meat quality, i.e. WHC and colour. These traits are influenced by (denaturation of) sarcoplasmic proteins (Sosnicki *et al*., 1998; Wilson & Van Laack ,1999). The aim of the study is firstly to use video image colour on line to sort turkey breast meat according to their potential yield to prevent excess of purge and secondly characterize this meat according to its 1-D and 2-D electrophoretic protein patterns.

Materials and methods

Animals and samples

A total of one hundred and twenty turkey breast muscles were collected in a slaughter plant on the cutting line. The breast meat was obtained from 15-week old male turkeys (line BUT 9) after conventional chilling over a minimum of 8 hours. Firstly selected visually to obtain the largest range of colour, from lightest to darkest, the breast meat colour was measured using a tri-CCD DXC 990 P SONY camera and analysed according to the method developed by CEMAGREF (Marty-Mahé *et al*., 2002). The ultimate pH value (pHu) was determined 24 h post mortem using a portable pH meter equipped with a glass electrode directly inserted into the muscle. The results were expressed as L*, a*, b*, C* and h* coordinates for lightness, redness, yellowness, chroma ($C= (a^{*2}+b^{*2})^{1/2}$) and hue angle (h=arc tang (b*/a*)), respectively. Part of breast meat was cut into scallops, weighted Day1, wrapped and weighted again after 48 h.

The breast meat was subsequently vacuum packaged, immediately frozen and stored at –20°C for further analysis. After thawing, the cooking yield was measured on a muscle sample of standard size (15 x 5 x 2,5 cm; 337 ± 14 g, n=170) after injection of brine (136 g of nitrite salt x l^{-1}) at the rate of 15 %, vacuum packaging and cooking in a water bath until a 68°C internal temperature was reached.

Protein breast samples were frozen in liquid nitrogen and stored at –80°C until analysis.

Protein extraction/fractionation

The extraction buffer consisted of KCl 50mM, Tris 20mM, $MgCl_2$ 4mM, EDTA 2mM, pefabloc 5mM, DTT 2% (w/v) 1% pH 7. 150 mg of muscle were added to 1 ml of extraction buffer in an Eppendorf containing a glass bead. Homogenisation was performed using a Retsch MM2 agitator (Retsch, Haan, Germany) for 1 h at 4°C. Homogenates were centrifuged at 10,000g for 15 min at 10°C. Supernatant was collected, pellet was

washed 3 times using a washing buffer (KCl 75mM, $KH2PO_4$ 10mM, $MgCl_2$ 2 mM, EGTA 2mM, pH 7). Protein content was measured using a Bio-Rad Bradford protein assay kit.

1D eletrophoresis

SDS PAGE was performed on both pellet and supernatant using a Hoefer 250 cell (Amersham) on 11% polyacrylamide gels at 40 volts for 1h then 110 volts for 2 h. Gels were stained with blue coomassie. Gels images were acquired using a GS-800 densitometer and analysed using Sigmagel software (SPSS, Chicago, USA).

2D electrophoresis

2D electrophoresis was performed on 3 samples per group (C1 vs C4). Immobilised pH gradient (IPG) isoelectric focusing (IEF) was carried out in a Protean IEF cell (Biorad), using Bio-Rad ready strip , 17 cm, pH 3-10 non linear. 90µg of sarcoplasmic proteins were loaded onto the strips for analytical gels. Proteins loading on strips, IEF and SDS-PAGE were performed according to Morzel *et al*. (2004). Gels were silver stained following the protocol of Yan *et al*. (2000). Gels were produced in triplicate. Gels images were acquired using a GS-800 densitometer and analysed using the PDQuest software (Bio-Rad).

The meat quality data were subjected to analysis of variance using the general linear model procedure of SAS, and the means were separated using the Scheffe's test. 1D and 2 D electrophoresis data were analysed using student test.

Results and discussion

Meat quality

The muscle samples were distributed in 4 groups according to their L* value obtained by image analysis: 45-48 (C 1, n=18), 49-52 (C 2, n=66), 53-56 (C 3, n=58), and 57- 60 (C 4, n=30). Significant differences between C1, C2, C3 and C4 were found for the ultimate pH. Drip loss was higher in lighter meat (C4) but this difference remained not significant. Curing and cooking yield decreased as the lightness increased (Table 1). The Characterisation of turkey breast meat using image video was efficient to sort the meat according to its processing yield.

1D electrophoretic protein pattern

Sarcoplasmic proteins

The gels analysis showed that the density of some proteins increased in C4 group meanwhile others decreased (Table 2, Figure 1). Glycogen phosphorylase density tended to be lower for C4 group (4.7 vs 3.7), as well as creatine kinase (15.2 vs 14.3). In the C1 group, aldolase and enolase had lower density on gels. Glycogen phosphorylase and creatine kinase lower contents in C4 group could be explained by more protein denaturation or / and protein degradation. In unstructured ham, partly characterized by it very pale colour , it was reported that creatine kinase was proteolysed (Sayd *et al*., 2003). In fact, group C4 showed similar traits: pale colour, higher drip loss and lower curing and cooking yield.

Myofibrillar proteins

Small differences on the proteins pattern were found between the two groups C1 and C4 at 24 h. However, in C4 group, we observed the absence of a band at 35-40 kDa approximatly (Figure 2). Again for this group, a 30kDa band was present at a higher density. This band has been well described as a marker of proteolysis in muscle. For turkey, one day ageing was enough to get a 30kDa fragment, which has been well described as a product of troponin-T proteolysis (Ho *et al*., 1996; Negishi *et al*., 1996). 1D electrophoresis did not allow to show more differences as expected in such a group of meat quality.

2D electrophoretic protein pattern

Up to 600 spots were detected per gel. After removal of saturated or poorly reproducible zones, 334 spots were successfully matched across the whole set of the 2 goup (C1 and C4) images. The relative quantities of spots from each group were analysed. Differences were noted when the ratio of the relative quantity was above 2: 158 spots did not differ among the two groups, 26 spots had a higher quantity in the C1 group (darker meat) and 150 spots had a higher quantity in C4 group. 18 spots were only present in the C4 group gels. Among them, one spot is suspected to be a creatine kinase fragement by comparison to results of Sayd *et al*. (2003). With our data, we are not able to evaluate protein denaturation neither its level. However, Van

laack (2000) reported that other factors than protein denaturation are responsible for the low water-holding capacity of pale, soft, exudative chicken breast muscle. So, our results showed higher protein solubilisation, which could indicate either less denaturation or more proteolysis in the paler meat. In further work we will identify spots of interest (either proteins or fragments) by Maldi-tof spectrometry.

Conclusions

The characterisation of turkey breast meat using image video was efficient to sort the meat according to its processing yield : as the lightness increased, curing and cooking yield decreased. In 1 DE gels, proteins pattern differed in a small extent between the paler and darker meat (C4 group *vs* C1 group). Using 2DE gels allows the separation of 10 to 20 more protein bands. The meat with the lower processing yield differed by a higher level of protein solubilisation, indicating either less denaturation or more proteolysis in the paler meat.

Background

Consumers have considered from long time tenderness as the principal quality attribute of meat. Related to this, Jeremiah (1982) concluded that the most common cause of unacceptability in beef, pork and lamb meat purchases was toughness. This problem is strongly related with the inconsistency and unpredictable variability of meat texture, which avoids the standardization of meat quality and satisfaction of consumer demands, being one of the main problems that Meat Industry actually has to solve. The main origin of this variability is the large biological diversity of skeletal muscle [Pette and Staron, 1990]. Therefore it is not surprising to observe, in standardized processing conditions, a large animal variability in the rate and extent of postmortem meat texture development.

Endogenous muscle proteolytic enzymes are assumed to play a key role in this question, because they are responsible of myofibrilar disruption during ageing, a phenomenon directly related with the development of meat tenderisation [Sentandreu et al., 2002; Ouali, 1992]. So, the possibility to accurately quantify levels of some of these proteolytic enzymes has been proposed as a way to explain and predict meat texture variability. Cathepsin L is one of these target enzymes. Methods actually in use for quantification are based in the determination of its endopeptidase activity. However, quantification of cathepsin L activity in muscle crude extracts is imprecise due to absence of a specific substrate, being the interfering action of other peptidases, such as cathepsin B, always present. Immunochemical methods such as Enzyme Linked Immunosorbent Assay (ELISA) can be an interesting alternative for a more specific, sensitive and faster quantification of cathepsin L directly in crude extracts allowing a correct analysis of large number of samples per day. However, attention must be paid because ELISA can display important sources of error when not working in the appropriate conditions. Normally, the development of an ELISA test includes a first coating step consisting in the adsorption of antigens or antibodies to a plastic surface by non-specific binding (NSB). However, NSB of other undesired protein components during subsequent steps of the assay can give an overestimation of the signal not corresponding with the desired antigen-antibody reaction, which is detrimental for its sensitivity and specificity. Traditionally, undesirable NSB may be minimized by saturating the remaining binding sites of the plastic surface with different protein additives that must not interfere with the immunoassay. Not all blocking proteins that are commonly used for that purpose are adequate for each particular ELISA test, being necessary to determine the suitable one by empirical testing.

Objectives

In a previous work, a specific polyclonal antibody against highly purified bovine cathepsin L has been raised in rabbits [Sentandreu et al., 2004] with the aim to develop an immunoassay able to overcome the actual difficulties existing for cathepsin L quantification. The present work had as main objective the study of various blocking agents in their ability to prevent NSB of the reactants, other that capture IgG in the coating step, that will be utilized for the quantification of cathepsin L from both bovine and porcine muscle crude extracts by sandwich ELISA.

Materials and methods

Preparation of muscle crude extracts: 500 grams of either bovine or porcine muscle were used as the starting material to prepare a lysosomal-rich extract as initially described by Lardeaux (1983). The extract was then fractionated with ammonium sulphate, collecting the precipitated protein between 30-70 % saturation. The pellet was redissolved in a minimum volume of 20 mM Bis-Tris buffer, pH 6.0, containing 200 mM NaCl and 1 mM EDTA. The redissolved extract was aliquoted in volumes of 200 µl and immediately frozen and stored at –20 ºC until used.

Development of specific IgG against bovine cathepsin L: A polyclonal antibody against purified bovine cathepsin L was raised in rabbits as described in a previous work [Sentandreu et al., 2004]. The IgG fraction was obtained by chromatography on Q-Sepharose Fast Flow, being a part of this IgG fraction biotinylated.
ELISA protocol for the present study: Microlon microtiter plates, each one containing 96 flat-bottom wells of high binding capacity (600 ng/cm^2) were routinely used for the assays. Effectiveness of each blocking agent in preventing NSB was assayed over a range of eight different concentrations of crude extracts ranging from 0 to 4,600 and 0 to 8,600 µg/ml of bovine and porcine muscle crude extract concentrations, respectively. 1) In a first step columns of eight wells, corresponding to the different muscle crude extract concentrations, were incubated with either solutions of goat serum, skimmed milk, bovine serum albumin (BSA), fish gelatine (surcoating step, 5 % in PBS) or with PBS only (no surcoating step), for 1 h at 37 ºC. At the end of each incubation step wells were routinely washed five times with PBS containing 0.1 % Tween 20 (washing buffer); 2) After washing, wells were incubated with the eight different concentrations of bovine or porcine muscle crude extracts during 1 h at room temperature, using the washing buffer containing the corresponding blocking agent (1%) as diluent (assay buffers). Additionally, two columns per plate were not exposed neither to a surcoating step nor addition of any blocking agent to the assay buffer, thus serving as reference for determining total NSB on the plastic surface at each muscle crude extract concentration; 3) Wells were incubated with the biotinylated IgG fraction of the developed polyclonal antibody against cathepsin L in a 1/2000 dilution with each one of the assay buffers for 1 h at room temperature. After washing, wells were incubated with Extravidin®-horseradish peroxidase conjugate (Sigma, St. Louis, MO; 1/1000 dilution in assay buffers) for 1 hour at room temperature. Peroxidase activity was determined by incubation of wells with 3,3' 5,5'- tetramethyl-benzidine liquid substrate (TMB), 20 min for bovine samples and 10 min for the porcine ones. Reaction was stopped with a commercial stop reagent (Sigma), reading the O. D. values at 650 nm in an automated plate reader.

Results and discussion

The ELISA protocol developed in the present work aimed at the evaluation of different types of blocking agents in their capacity for avoiding unwanted NSB. So, the experimental protocol design presented here is basically the sandwich ELISA that will be used for cathepsin L quantification but avoiding the initial coating step of binding the capture antibody. In these conditions, the effectiveness of blocking agents will be proved by their ability to avoid any kind of binding to the plastic surface, which will be reflected in the absence of O. D. at 650 nm due to peroxidase activity.
The developed polyclonal antibody was raised against bovine cathepsin L, but previous studies have shown that this antibody cross-react with porcine cathepsin L so that quantification of this latter would be also feasible. In figure 1.A we can see results obtained for the ELISA carried out with different concentrations of bovine muscle extract, whereas figure 1.B shows the same ELISA but performed with a porcine muscle crude extract as antigen. In both assays the positive control, serving as reference for total NSB, was given by the curve developed in absence on any blocking protein.
In the case of bovine (figure 1.A), we can observe that skimmed milk was the most effective blocking agent, avoiding NSB for all of the assayed crude extract concentrations, obtaining fully comparable results with or without the surcoating step. Only for the highest concentration (4,600 µg/ml extract) we can observe a little increase in the O. D. value but negligible compared to the reference curve. This would indicate that using skimmed milk as blocking agent the surcoating step could be suppressed, always that it was contained in the reaction buffer. Similar results were obtained for porcine species except for the highest crude extract concentration (8,600 µg/ml extract), in which the blocking capacity of skimmed milk is lost (see figure 1.B). As reported in the literature, this can be due to electrostatic interactions between antigen, antibody and/or maybe other sample compounds because of the high concentration of the reactants. Like bovine, the surcoating step wouldn't be necessary, as previously pointed out [Vogt et al., 1987]. Other authors working with completely different samples also observed the effectiveness of skimmed milk in preventing NSB [Kaur et al., 2002; Zimmermann and Regenmortel, 1989].
Even if they yielded slightly higher O. D. values, both BSA and goat serum proved to be also effective blocking agents for bovine samples. However, and contrary to skimmed milk, results clearly indicated that the surcoating step is necessary to achieve an effective blocking effect (see figure 1.A, differences of BSA and goat serum with and without surcoating). This is in opposition to results obtained by Pruslin et al. (1991), where BSA exerted an optimal blocking effect with and without the previous blocking step. The similar behaviour between serum and BSA can be explained by the fact that albumin is one of the major

components of the serum [Kaur et al., 2002]. Opposite to bovine, neither BSA nor goat serum exerted an effective blocking of NSB for pork crude extracts. With the previous surcoating step, only a partial blocking effect was achieved, whereas in its absence similar O. D. values to the reference curve were obtained (figure 1.B), in accord to results obtained by Zimmermann and Regenmortel (1989).

The worst blocking results were obtained with fish skin gelatine. Even if it is commonly used and it has been recommended as a model blocking agent between gelatine preparations [Vogt et al., 1987], we realized that fish skin gelatine was only able to partially prevent NSB of bovine crude extract when the surcoating step is done (figure 1.A), whereas in the case of pork we did not observe any blocking effect, being the O. D. values obtained for all the concentrations in both cases (with and without the surcoating step) similar to that of the reference curve (figure 1.B).

Comparing the O. D. values obtained for all curves in the absence of muscle crude extract (zero values of the X-axis) we can observe that even if there are some differences, these are minimal. This indicated that in the absence of crude extract, biotinlylated anti-cathepsin L IgG and/or Extravidin®-peroxidase conjugate did not inespecifically bind to the plastic surface, being also true for the reference curve.

Conclusions

In the development of a sandwich ELISA test for bovine or porcine cathepsin L coming from muscle crude extracts, the choice of and adequate protein agent is essential to prevent non-specific binding (NSB) of components itegrating the immunoassay with the solid support. As previously suggested [Engvall and Perlmann, 1972; Mohammad and Esen, 1989], NSB of the anti-cathepsin L polyclonal antibody and/or Extravidin®-peroxidase conjugate can be minimized just with the inclusion of Tween 20 in the reaction buffer. However, and contrary to them, for reduction of background due to NSB of muscle crude extracts (antigen) to the matrix, it is necessary the use of a suitable blocking agent in addition to Tween 20. Binding of some components of the crude extract to the plastic surface is detrimental for sensitivity and reproducibility of the assay because we do not know if the obtained O. D. values were exclusively due to the detection of bound cathepsin L or to the union of the antibody to other absorbed components from the extract.

Skimmed milk revealed to be the most efficient of the assayed blockers, as also observed by other authors. In the case of pork, this would be the only suitable blocking agent but avoiding the highest assayed concentration. All the same attention must be paid, since some authors pointed out the possibility that skimmed milk may interfere the antigen-antibody reaction under certain conditions [Mohammad and Esen, 1989; Vogt et al., 1987]. For the ELISA quantification of cathepsin L from bovine species, goat serum and BSA, together with skimmed milk, could be used as effective blockers always that a surcoating steps be included in the assay in addition to be present in the assay buffer.

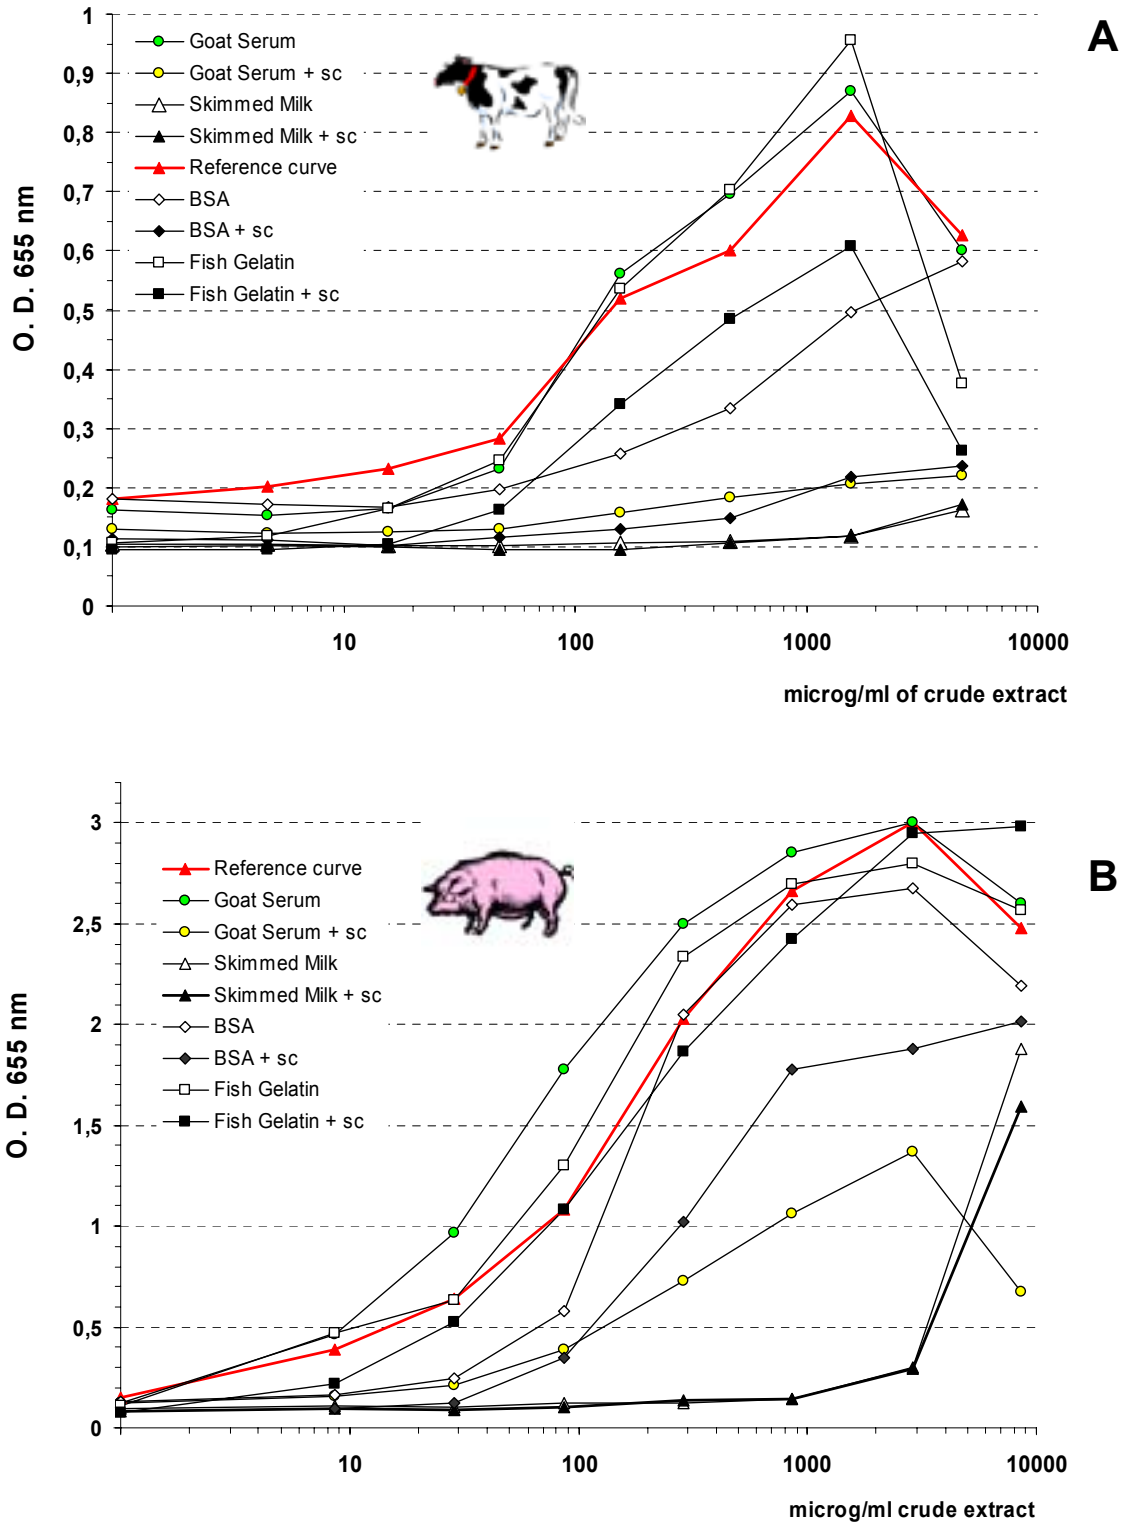

Figure 1: Effectiveness of blocking agents for preventing non-specific binding in indirect ELISA for cathepsin L using increasing concentrations of A) bovine or B) porcine muscle crude extracts. Legends showing "+ sc" indicate the curves in which a surcoating step has been carried out with the corresponding blocker. Those not showing "+ sc" belong to curves for which the surcoating step was not carried out, the corresponding blocking agent being only contained in the reaction buffer. Experimental points placed on the Y-axis correspond to 0 microg/ml of crude extract.

THE INDUCIBLE FORM OF HSP70 IN PORCINE SMALL INTESTINE, COLON AND SERUM

K. Sepponen and A.R. Pösö

Department of Basic Veterinary Sciences, PO Box 66, FIN-00014 University of Helsinki, Finland

Background & Objectives

Modern swine production includes practicalities that may be stressful to pigs. At cellular level, stress response includes synthesis of special stress proteins, heat shock proteins (HSP), which have several roles in helping to maintain the protein homeostasis. HSPs form a protein family, classified according to their molecular weights. One of the best-known is the 70 kDa family (HSP70), which contains both inducible (HSP72) and constitutive (HSP73) forms. Many environmental and pathological factors are known to activate HSP72 expression, also including psychological stress (Fukudo et al. 1997). Altough HSPs are intracellular proteins, small amounts of HSP72 can be found in serum, also in unstressed individuals (Pockley et al. 1998), but the source of serum HSP is still unclear. Among the organs that respond to stress, intestines belong to those that are most stress-sensitive (Söderholm & Perdue 2001). The main question asked in this study was whether HSP72 in the intestines varies with growth rate, and whether serum HSP72 correlates with known indicators of stress.

Material & Methods

40 experimental pigs (EP) used in this study were raised individually in 1.0 x 2.5 m pens and slaughtered two together at an experimental slaughterhouse. Additional samples were taken from 10 ordinary slaughterhouse pigs (SP). Five of the SP were physically injured (muscle and tail) and five showed no signs of injury. The animals were slaughtered in a commercial slaughterhouse and stunned with CO_2. The samples from small intestine, colon and blood were taken in the connection of slaughter. The inducible HSP70 was analysed immunologically, blood lactate concentration with a lactate analyser and serum cortisol by radioimmunoassay. Differences in the amounts between the two groups were calculated by paired t-test using GraphPad Prism software (GraphPad Software, USA). Differences were regarded as significant at $P=0.05$. Linear regression analysis was used to calculate the coefficients of correlation.

Result & Discussion

The carcass weight of the 40 EP was 81.0 ± 7.5 kg and that of SP significantly ($P<0.05$) lower, 74.7 ± 10.9 kg. HSP72 was detected in the small intestine, colon and serum. Amounts of HSP from all tissues studied were significantly higher in SP than EP ($P<0.001$), but also among SP the injured pigs had higher colon HSP72 than the apparently healthy pigs ($P<0.05$). There were positive correlations between the amounts of HSP72 in colon and small intestine ($r=0.54$; $P<0.001$; $n=50$), colon and serum ($r=0.66$; $P<0.001$; $n=50$), and small intestine and serum ($r=0.41$; $P<0.01$; $n=50$). A negative correlation was found between carcass weight and HSP72 content in colon ($r=-0.54$; $P<0.001$; $n=50$) or serum ($r=-0.45$; $P<0.01$; $n=50$). HSP72 in colon correlated with carcass weight also in both groups separately (SP, $r=-0.70$, $P<0.05$, $n=10$; EP, $r=-0.35$, $P<0.05$, $n=40$). Lactate and cortisol concentrations did not correlate with HSP72 in any tissue.

The negative correlation between HSP72 in colon and carcass weight suggests that pigs with high concentration of HSP72 were stressed and did not grow as well as less stressed animals with lower HSP72 concentration. This speculation is supported by a finding, which shows that chronic stress reduces the growth of the animal (Santos et al. 2000). We detected HSP72 also in serum and there was a positive correlation between HSP72 in serum and colon. A closer analysis of the data shows that the levels of serum HSP72 start to rise when colon HSP72 reaches approximately 3.9 μg/g tissue. If serum HSP72 comes from the colon, this may represent the point when colonal epithelium starts to loose its integrity.

Conclusions

The correlation between HSP72 in serum and colon suggests that at least part of the serum HSP72 comes from the colon, but a larger number of pigs is needed to show whether serum HSP72 is a useful stress indicator.

EFFECT OF LAIRAGE TIME ON INCIDENCE OF DIFFERENT QUALITY OF *M. SEMIMEMBRANOSUS* FROM HALVES OF MULTI-RACE HYBRIDS

Tomović, V.[1], Petrović Lj.[1], Džinić, N.[1], Manojlović, D.[1], Timanović, S.[2], Vidarić D.[2]
[1]Faculty of Technology, Bul. Cara Lazara 1, 21000 Novi Sad, University of Novi Sad, Serbia and Montenegro
[2]MI "Neoplanta", Primorska 90, 21000 Novi Sad, Serbia and Montenegro

Background

Pigs are prepared for slaughter in the lairage, and the aim of resting is to bring back the animals to »normal« state, as they were at the breeding place, e.g. the resynthesis of glycogen in the muscles and removal of metabolyte products. The resting time should be proportional to the fatigue due to transport, elsewhere, longer time may have a contrary effect. While in lairage, unnecessary stress and disturbances should be avoided (Rede and Ljiljana Petrović, 1997; Lawrie, 1998). According to a number of authors, resting after transport of pigs affects positively the quality of meat. Fortin (1988) found decrease of PSE incidence by 27% in pigs slaughtered 3 hours after the transport at the slaughterhouse, compared with pigs slaughtered next to the arrival. Grandin (1989) found 1,3% of PSE meat incidence in pigs slaughtered 2,5 h after the arrival to the slaughterhouse, and in pigs slaughtered 15 min after the arrival the PSE meat incidence was significantly higher, up to 18%. The slaughter immediately or a short time after the arrival can increase the incidence of PSE meat (Eikelenboom et al., 1991). Malligan et al., 1998; van der Wal et al., 1997; Wariss et al. (1998) cite that the most favorable resting time is 2-3 hours. Bendal and Swatland (1988) and Wittmann et al. (1989) found that very long resting can induce the apearance of DFD meat.

Objective

The objective of this study was to investigate the quality of the halves of three-race pigs obtained in a mutual crossbreeding program at a farm in Serbia and Montenegro, and the influence of lairage time on meat quality. Further, to determine the incidence of different quality (RFN, RSE, PSE, DFD) on the basis of technological parameters pH_i, pH_u, WHC and L*, measured on *M. semimembranosus* as well as of our quality criteria (Tomović, 2002; Natalija Džinić et al., 2003, 2004).

Materials and methods

Two groups of pigs, multi-race hybrids, in all 33, were investigated. The pigs from the first group were slaughtered immediately after the transport (n=15) and the other group after resting of 48 hours in the lairage (n=18). The pigs were fed conventional feed during fattening, and heads of approximately same age and uniform mass were transported in autumn (october–november) to the slaughter-house, about 10 km from the farm. The pigs were stunned, debleeded and processed on the slaughterline applying standard technological procedure.

The quality of halves was determined on right halves at the end of the slaughterline, using the FOM-device (SFK-Technology, Denmark).

The temperature was determined in *M. semimembranosus* (MSM) of right halves 45 min post mortem (T_i) using the portable thermometer, HI 8757 (Hanna Instruments, Italy).

The pH_i was measured in right halves 45 min p.m., and pH_u 24 hours p.m. in the caudo-medial part (MSM) with pH-meter ULTRA X, UX-390 (Gronert, Germany) with INGOLD combined penetrating electrode.

Meat yield (%) was determined by partial dissection method (Walstra and Merkus, 1996) of cooled left halves.

Samples (200 – 300 g), taken at the caudo-cranial part (MSM) were used 24 hours p.m. for color and water holding capacity (WHC) determination. Colour was determined using the MOM Color 100 device (CIE L*a*b*) (Robertson, 1977). WHC was determined using the compression method and expressed as % of bound water (Grau and Hamm, 1957).

The incidence of different MSM quality depending on resting time in the lairage was determined on the basis of parameters and quality criteria for MSM quality (PSE: pH_i<5,8, pH_u<5,4, WHC<50%, L*>55; RSE: pH_i=5,8-6,0, pH_u=5,85-6,2; WHC=50-60, L*=50-55; RFN: pH_i>6,0, pH_u =5,4-5,85, WHC=60-70, L*=45-50; DFD: pH_u>6,2, WHC>70, L*<45).

Results and discussion

The average meat yield in halves of cross-breed pigs determined with FOM device was 52,60% and 52,15%, and the difference between two groups is not significant (P>0,05). The average meat yield determined by partial dissection is by 2% higher in both investigated groups of crossbreeds (54,21%, 54,48%) and the differences are not significant (P>0,05), compared with the average meat yield determined with FOM device.

Table 1. Quality of halves, of multi-race pigs rested for different time in lairage, determined with FOM device and by partial dissection

Lairage time	% lean meat (FOM)	% lean meat (partial dissection)
0 hour	52,60 ± 5,03	54,21 ± 4,78
48 hours	52,15 ± 3,87	54,48 ± 3,78

^{NS}P>0,05 *P≤0,05 ** P≤0,01

The results of investigation of technological parameters are presented in Table 2. It was found that the average pH_i of pigs slaughtered immediately after the arrival e.g. after 48 hours of rest in the lairage was 6,22 and 6,23, respectively, and these values respond to muscles of potentially normal quality (pH_i>6,0) (Tomović, 2002). Higher average pH_u (5,91) was found in MSM of multirace hybrids which were resting for 48 hours, and responds to muscles of RSE quality. The average pH_u (5,81) found in MSM of pigs slaughtered after arrival points to muscles of normal quality (pH_u=5,4-5,85). The average T_i of MSM from halves of pigs slaughtered without resting (42,2°C) was significantly higher compared to pigs rested for 48 hours (41,4°C). The average temperatures determined in MSM of multi-race hybrids are higher than the allowed temperature for meat with certificate (T_i=40°C) (Honikel, 1999, 2000). This finding indicates that the pigs were under great stress when slaughtered without resting, and that the stress was somewhat lower after 48 hours of resting. The stress induced fast glycolysis, which caused the increase of T_i, and this should reflect on the measured pH_i values, e.g. further decrease rate of pH_i values. Somewhat higher WHC (56,74%) was measured in MSM of pigs rested for 48 hours, however, not significantly higher than the WHC (56,25%) of MSM of pigs slaughtered without resting. On the basis of criterion for WHC, the investigated MSM were on the average of RSE quality (WHC=50-60%).
Regarding colour lightness L* of investigated MSM, it can be noticed that MSM of pigs slaughtered without resting are significantly lighter (L*=52,05) (P≤0,01) compared to lightness of pigs rested for 48 hours (L*=51,85). According to our criterion for colour lightness L*, the investigated MSM of pigs of both groups are of RSE quality on the average.

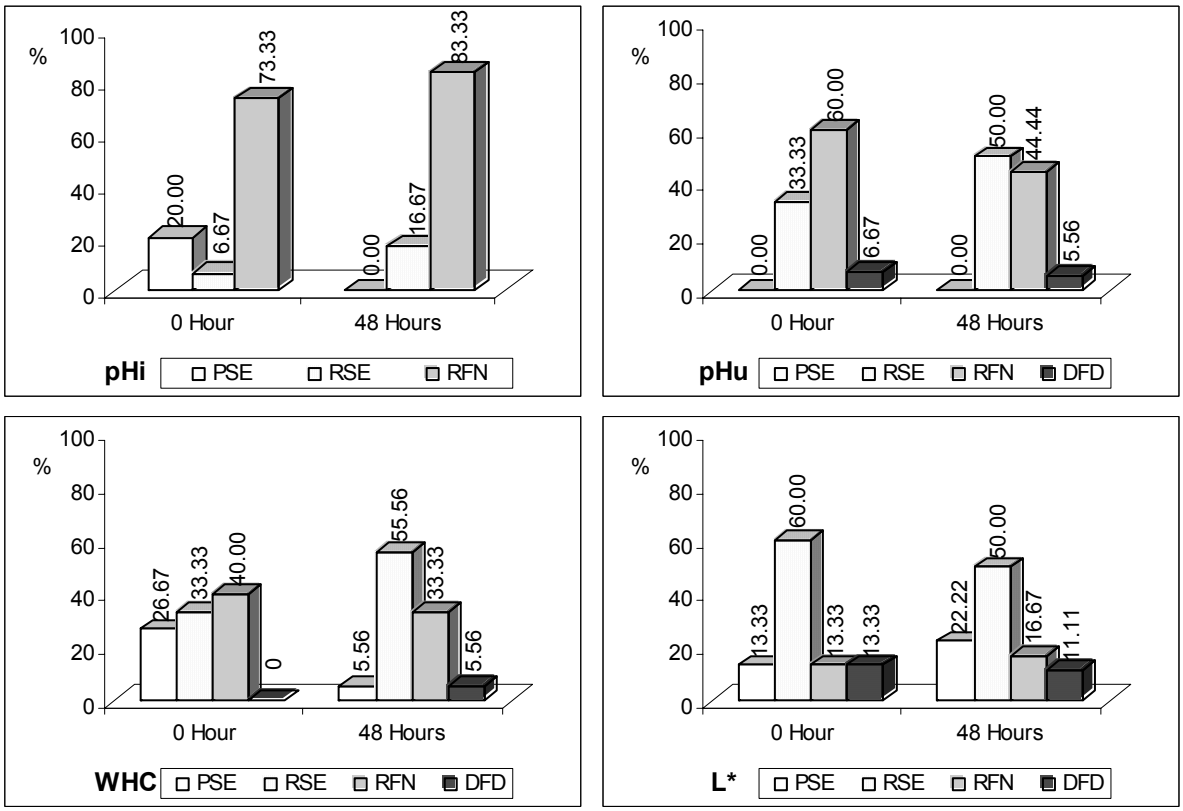
Table 2. Influence of lairage time of pigs on technological quality of *M. semimembranosus*

Lairage time	pH_i	pH_u	T_i	WHC	L*
0 hour	6,22 ± 0,30	5,81 ± 0,33	42,2 ± 0,74**	56,25 ± 7,91	52,05 ± 5,96**
48 hours	6,23 ± 0,23	5,91 ± 0,18	41,4 ± 0,58	56,74 ± 5,69	51,85 ± 4,94

^{NS}P>0,05 *P≤0,05 ** P≤0,01

The incidence of PSE, RSE, RFN and DFD quality of MSM of pigs rested for different time in the lairage is presented in Graph 1, on the basis of criteria for pH_i, pH_u, WHC (%) and L*.
According to the criterion for pH_i it was found that the potential incidence of MSM of RFN quality is higher (83,33%) in pigs which rested for 48 hours before slaughter, compared to pigs slaughtered without resting (73,33%). The obtained results show further that 60% of MSM of pigs slaughtered without resting and 44% of pigs slaughtered 48 hours after transport are of N quality, on the basis of criterion for pH_u. On the basis of criterion for colour lightness L*, it was found that the highest incidence of MSM (60%) is RSE quality in pigs slaughtered without resting and 13,33% of PSE quality, and in pigs slaughtered 48 hours after transport the incidence of PSE and RSE quality is 22,22% and 50%, respectively. Further, according to criterion for WHC, 40% e.g. 33,33% of MSM of pigs slaughtered without resting e.g. after 48 hours of lairage time are of RFN quality. A number of multi-race hybrids (three-race) was slaughtered after 24 hours of resting and the investigations showed that the incidence of MSM of RFN quality was 78,6% for the same season (autumn) (pH_i) (Natalija Džinić et al., 2004), 92,8% of RFN quality (pH_u), 7,1% of RFN quality (WHC) and 7,1% MSM of RFN quality (lightness – L*). It can be concluded on the basis of the presented results that MSM

quality of pigs was even lower (WHC and L*) when the resting time before the slaughter was 24 hours and regarding the results obtained in our investigations it is the most favorable to slaughter the pigs next to the arrival to the slaughter-house, e.g. that it is possible to decrease the incidence of lower quality meat prolonging the resting time to several hours (Malligan et al., 1998).



Graph 1. Incidence of different quality meat on the basis of criteria

Conclusion

The average meat yield in halves of cross-breed pigs after resting for different time in the lairage (0 and 48 hours) determined by FOM device was 52,60%, e.g. 52,15% (P>0,05). The average meat yield in halves determined by partial dissection was 54,21% and 54,48 (P>0,05). The investigated MSM of crossbreed pigs slaughtered immediately after the arrival were of RFN quality, on the basis of criterion for pH_u, and of pigs resting 48 hours in the lairage, according to the same criterion of RSE quality, on the average. The investigated MSM of both groups of crossbreeds was on the average of RSE quality, regarding the criteria for WHC and colour lightness – L*. The incidence of RFN quality of MSM, on the basis of criterion for pH_u is generally the highest 60% (without resting) and 44,44% (48 hours of resting). The incidence of RFN quality MSM is 40% e.g. 13,33% (without resting) e.g. 33,33% and 16,67% (48 hours of resting) according to criteria for WHC (%) and colour lightness – L*.

ZINC PROTOPORPHYRIN IX CONTRIBUTES TO THE BRIGHT RED COLOR IN PARMA HAM

Wakamatsu J., Nishimura T., & Hattori A.

Division of Biosource & Product Science, Graduate School of Agriculture,
Hokkaido University, Sapporo, Hokkaido 060-8589, Japan

Background

Myoglobin in meat products to which nitrate and/or nitrite have been added is converted into stable red nitrosylmyoglobin coordinated to nitric oxide, and nitrosylmyoglobin changes into pink-reddish nitrosylhemochromogen after the meat has been heated. The north Italian traditional dry-cured ham "Prosciutto di Parma (Parma ham)" is made from only the leg of a fattened pig by salting with sea salt, drying, and maturing over a period of one year. Despite the fact that nitrite or nitrate has not been added, the color is an extremely stable bright red and is hardly changed by exposure of the ham to light. Morita et al. (1996) reported that the red heme pigment was easily extracted with 75% acetone and that it was a new myoglobin derivative unknown in meat and meat products. It has recently been reported that the amount of this lipophylic stable red pigment in Parma ham increases with aging (Parolari et al., 2003).

Objectives

The objective of this study was to identify the stable red pigment in Parma ham in order to obtain information for producing bright red meat products without nitrite and/or nitrate.

Materials and methods

Preparation of the red pigment from Parma ham: Minced Parma ham (5 g) was homogenized in 20 ml distilled water, and the homogenate was centrifuged (3,000 rpm, 5 min, 4 °C) and then filtered through a filter paper (No. 5C Toyo Roshi Co., Ltd., Tokyo, Japan). Three volumes of ice-cooled acetone were added to the filtrate, and the mixture was placed in ice for 15 minutes. The mixture was centrifuged at 3,000 rpm for 5 min at 4 °C. An equal amount of distilled water was added to the supernatant, and the mixture was applied to a disposable C18 column, Sep-Pak® Vac C18 Cartridge (12 cc/ 2g; Waters Co., MA U.S.A.) prewashed with 15 ml of methanol and 15 ml of distilled water. The column was washed with 25 ml 37.5% acetone, and then the red pigment preparation was eluted with 10 ml of 75% acetone. All of the operations were carried out under shading as much as possible.

Absorption and fluorescent analysis: The absorbance spectrum of the red pigment preparation was measured from 350 to 700 nm using a Model U-3210 spectrophotometer (Hitachi Ltd., Tokyo, Japan). The fluorescent and excitation spectra of the prepared red pigment were measured from 500 to 700 nm at 420 nm for excitation and from 300 to 500 nm at 590 nm for emission using a Model 650-60 fluorescence spectrophotometer (Hitachi Ltd., Tokyo, Japan), respectively.

Elemental analysis: Elemental analysis of the red pigment preparation was performed by scanning electron microscopy/energy dispersive X-ray microanalysis (SEM-EDX). The red pigment preparation from Parma ham was dried up using a centrifugal evaporator and was fixed on a metal stub using carbon tape. The sample was coated with carbon and was analyzed with a scanning electron microscope (S-800, Hitachi Ltd., Tokyo, Japan) equipped with an energy dispersive X-ray micro-analyzer (EMAX-2000, Horiba Ltd., Kyoto, Japan) with an accelerating voltage of 20 KeV and a spectral resolution of 10 KeV per channel.

Mass spectrometry analysis: Electrospray ionization high resolution mass spectrometry (ESI-HR-MS) analysis of the red pigment preparation from Parma ham was carried out using a JMS-SX120A (JEOL Ltd., Tokyo, Japan) equipped with an ESI ion source (JEOL MS-ESI 10, JEOL Ltd., Tokyo, Japan). The sample diluted in a chloroform/methanol/acetone (1:1:8 v/v) solvent mixture was infused into the ESI ion source at a flow rate of 1 µl/min. The needle voltage and capillary voltage were 2681 V and -1230 V, respectively. The chamber temperature was set to 105 □. A mixture of PEGs was used as an internal standard.

Results and discussion

The red pigment preparation from Parma ham was purplish-red, and the absorbance spectrum is shown in Fig. 1. A peak at 416 nm in the Soret band and peaks at 544 and 583 nm in the beta band were observed. Since this spectrum pattern was consistent with those previously reported (Morita et al., 1996; Parolari et al., 2003), the unidentified pigment in Parma ham could be prepared. Although metal-free porphyrins generally have four peaks in the beta band, the number of peaks in the beta band of metalloporphyrins decreases to two because of improvement in symmetry of the molecular structure. Therefore, the elemental analysis was carried by using a scanning electron microscope equipped with an energy dispersive X-ray micro-analyzer. As shown in Fig. 2, several peaks originating in zinc were observed, but no peak originating in iron was observed. This may indicate that the red pigment in Parma ham is not an iron-porphyrin complex but a zinc-porphyrin complex. A zinc-porphyrin complex emits fluorescence unlike many metalloporphyrins. Hence, the fluorescent and excitation spectra of the prepared red pigment were measured (Fig. 3). An excitation peak at 423 nm and emission peaks at 589 and 630 nm were observed. Since the fluorescent spectrum was similar to that of Zn protoporphyrin IX, we attempted to identify the red pigment prepared from Parma ham by ESI-HR-MS analysis. As shown in Fig. 4, the highest molecular ion peak was detected at m/z 624. Six main peaks were found when the peak region was expanded (Fig. 4, inset). This peak pattern agrees well with that of Zn protoporphyrin IX ($C_{34}H_{32}N_4O_4Zn$) (Fig. 4, inset), because Zn has five isotopes (m/z = 64, 66, 67, 68 and 70) and the isotopic ratio is characteristic. Iron has four isotopes (m/z =54, 56, 57 and 58) and its isotopic ratio is different from that of Zn. The exact mass of the principal molecular ion computed from the internal standard was 624.1711 and differed by only 0.4 milli- mass units from the monoisotopic mass (624.1715) of Zn protoporphyrin IX. On the other hand, peaks originating in Fe protoporphyrin IX (MW 616.49), Mg protoporphyrin IX (MW 584.95) or Cd protoporphyrin IX (MW 673.05) were not observed.

These results indicate that the unidentified red pigment in Parma ham is not an Fe-porphyrin complex but a Zn-porphyrin complex, i.e., Zn protoporphyrin IX. It was speculated that the Zn protoporphyrin IX in Parma ham was formed by substitution of Fe in heme to Zn. In a study on surface autofluorescent changes of Parma ham during processing, it was found that the amount of a fluorescent component that is likely to correspond to Zn protoporphyrin IX increased from raw to salted meat (3 months) and then hardly increased during the maturing process (Møller et al., 2003). Thus, Zn protoporphyrin IX might be formed during the early period of the manufacturing process, not during the maturing period. Further studies are needed to elucidate the mechanism of Fe-Zn substitution that occurs in Parma ham during the manufacturing process.

Conclusions

The red pigment extracted from Parma ham by water and then 75% acetone was crudely purified by solid phase extraction. The red pigment was purplish red and fluorescent metalloporphyrin. Element analysis using an SEM-EDX revealed that the red pigment preparation contained not iron but zinc. By mass analysis, the red pigment was identified to be Zn protoporphyrin IX. Zn protoporphyrin IX in Parma ham might be formed with heme and zinc contained in pork during the early period of the manufacturing process.

MANIPULATION OF PRE-RIGOR GLYCOLYTIC BEHAVIOURS TO PRODUCE CONSISTENT BEEF TENDERNESS

White A., O'Sullivan A. O,Neill E.E., Troy D.J.

[1]Teagasc, The National Food Centre, Ashtown, Castleknock, Dublin 15, Ireland.
[2]University Collage Cork, Cork, Ireland.

Background

One of the most important challenges met by the meat industry today is to provide a product of consistent eating quality in which tenderness is a strong attribute. Beef is generally variable in eating quality, which stems mainly from how the muscles are treated up to the time of rigor. (Koomaraie, 1996). Variance in temperature, pH and their relationship with time *post-mortem* is important in pre-rigor beef. Fluctuations within a carcass in the temperature/pH profile, post slaughter, is a root cause in the inconsistency beef tenderness. Hot boning is defined as the removal of muscles or muscle systems from the carcass prior to chilling (West, 1983) and is beneficial for both industrial and experimental reasons as each muscle can be treated individually according to its own glycolytic behaviours. Hot boning allows for the manipulation of muscles during the critical pre-rigor period, therefore, optimum conditions in terms of pH/temperature profiles can be determined for the production of consistently tender beef.

Objectives

The objective of this study was to alter rigor development via post mortem manipulation for the optimisation of consistently tender beef.

Materials and methods

Hereford cross Friesian heifers (n=8) were captive bolt stunned and exanguinated conventionally at the Meat Industrial Development Unit, National Food Centre, Dublin 15. From each animal both *longissimus dorsi* muscles were hot-boned within 90 minutes post slaughter. Each muscle was divided in 3 so that there was 6 samples per replicate. Each sample was randomly selected and submerged in water baths pre-set at the following temperatures; 0, 5, 10, 15, 20 and 25^{0}C. After eight hours the muscles were placed in a 2^{0}C chill and aged for 14 days post- slaughter. pH profiles were observed by inserting a glass electrode approximately 2 inches in to the muscle Sarcomere length, was determined by diffraction of a laser beam according to the method determined by Cross *et al.* (1980) 2 days *post-mortem*. Steaks were cut (2.5cm thick) at day 2, 7 and 14 *post-mortem* and stored at –20^{0}C for Warner Bratzler Shear Force (WBSF) analysis, which was carried out according to the method described by Shackelford *et al* (1991). Samples were taken at days 2, 7 and 14 to measure proteolytic activity.

Results and discussion

Pre-rigor incubation temperature had an effect on the rate of pH decline (Fig. 1), with higher temperatures giving a faster rate of pH decline. The 0^{0}C samples had the shortest sarcomere length followed by the 5^{0}C samples, whereas 10-25^{0}C samples did not cold shorten (Table 1). These results are reflected in the WBSF results (Fig. 2), where cold shortened muscle (0 and 5ºC) was found to be toughest. Fig. 3 shows the interaction of pH taken at 3 hours post-mortem (pH_3), WBSF at day 14 and temperature. The most tender and least variable beef was found at pH_3 between 5.9 and 6.2. However, this is not the case for cold shortened samples as cold shortened muscles were more variable in tenderness and pH. The absolute rate of tenderisation between day 2 and day 14 (ΔWBSF) was greatest for cold shortened muscles, particularly muscles incubated at 5ºC. Muscles with the highest ΔWBSF were also found to be most variable in tenderness at day 14. Therefore variability may be due to tenderisation of cold shortened muscles. Analysis of protein profiles showed that the appearance of the 30-kDa band was related to the rate of tenderisation, therefore proteolysis might be a root cause of variation in tenderness of cold shortened muscle.

The rate of pH fall is a good indicator of the rate of glycolysis (Bendall 1978) as pH fall is generally due to an increase in lactic acid, a product of anaerobic glycolysis. Therefore the incubation temperature influenced the rate of glycolysis. Cold shortening is a toughening of meat that occurs due to chilling meat below 10^0C before the onset of rigor, when pH reaches 6.2. This explains the results obtained following sarcomere length analysis. Each muscle aged over a 14-day period, irrespective of cold shortening, hence measuring the sarcomere length at day 2 *post-mortem* is a useful tool for predicting tenderness but not toughness as muscles with short sacomeres tenderise over time.

Conclusions

A pH_3 range of 5.9 to 6.2 produces consistently tender beef where the sarcomere lengths are long (above 1.5µm). Cold shortened muscle tenderises, the absolute rate of tenderisation between day 2 and day 14 was greatest at 5ºC where most variability in tenderisation exists. Proteolysis of cold shortened muscles may induce variability.

Background

Consumers surveys have revealed consistent eating quality, in which tenderness is a strong characteristic, is one of the most important attributes of beef. There are 3 phases *post-mortem* which have an influence on tenderness; the pre-rigor phase, rigor or the phase of maximum toughness and the tenderisation or post-rigor phase. The biochemical dynmaics of the pre-rigor phase influence the maximum contraction at rigor. Tenderisation may be defined as a decrease in toughness post-rigor (Hopkins and Thompson 2002) and mostly attributed to changes in the myofibrillar proteins. The extent of contraction at rigor may be monitored by measuring the length of the sarcomere and its influences on the rate of tenderisation (Herring et al 1967). The glycolytic behaviours pre-rigor are dependent on temperature and therefore can be altered through the chilling regime. Reducing the rate of the glcolytic pathway would enable the examination of the pre-rigor period and its effect on rigor.

Objective

Examination of the early post mortem period using different rates of glycolysis to monitor the effect of proteolysis and sarcomere length on the tenderness of beef.

Materials and methods

Hereford cross Friesian heifers were slaughtered at the research abattoir in The National Food Centre, Dublin. Hot-boned *longissimus dorsi* muscles (LD) (n=8) were split in half, one half was immersed in a water bath pre-set at 5ºC and the other half was immersed in 15ºC for the first 8 hours *post–mortem* before being transferred to a chill. Temperatures were selected on the basis of results presented by the authors in these proceedings. pH and temperature profiles were recorded. Samples were taken for sarcomere length at day 2, 7, 14 and 21 *post-mortem*. Steaks were cut on alternating days up to day 21and stored at –20º C for Warner Bratzler Shear Force (WBSF) analysis. Samples were taken at 1.5,4,8, 24, 48 hours *post-mortem* for analysis of myofibrillar protein profiles.

Results and Discussion

Temperature had an effect on the rate of pH decline; LD incubated at 15ºC had an accelerated rate of pH decline when compared to those incubated at 5ºC. WBSF carried out over a 21-day period illustrated that the muscles incubated at 15ºC were more tender then those incubated at 5ºC, suggesting the occurrence of cold shortening (Fig 1). The greatest degree of tenderisation in muscles tempered at both 5ºC and 15ºC occurred before day 3 *post-mortem*. Analysis of a gradient 3-15% SDS-PAGE (Fig 2) illustrated that the differences in the rate of myofibrillar proteolysis, between muscles held at 5 and 15ºC, are minor. Therefore it is unlikely that the difference in tenderness is due to degradation of the myofibrillar proteins (Fig 2). The emergence of the 30kDa appeared similar over a 21-day period for both 5 and 15ºC (not shown). Temperature was found to have an impact on sarcomere lengths. Cold shortening of muscles tempered at 5ºC caused a greater maximum contraction at rigor than those tempered at 15ºC. Cold shortened sarcomeres (5ºC) did not lengthen significantly over time (table 1).

Conclusions

The majority of tenderisation for both cold shortened and non cold shortened muscles occurred before day 3 post-mortem. Despite the fact that cold shortened muscle ages, it still remains tougher and than its non-shortened counterparts. A reduction in maximum toughness appears to be more favourable than an increase in tenderisation.

DIETARY CREATINE AFFECTS MEAT QUALITY OF PURE BREEDS OF DUROC AND LANDRACE DIFFERENTLY

Young, J.F., Bertram, H.C. and Oksbjerg, N.

Danish Institute of Agricultural Sciences, Department of Food Science, Research Centre Foulum, Denmark

Background

Dietary creatine has been shown to increase total muscle creatine (Balsom, Söderlund, Sjödin & Ekblom, 1995), of which approximately two-thirds is creatine phosphate (Balsom, Söderlund & Ekblom, 1994; Casey, Constantin-Teodosiu, Howell, Hultman & Greenhaff, 1996). Increased availability of creatine phosphate is believed to contribute to the increased maximum and total work capacity (Casey & Greenhaff, 2000) and reduce the recovery period (Balsom et al., 1995) of humans supplemented with creatine. In relation to meat quality, it has been suggested that the increased creatine phosphate may delay the lactate formation in the muscle and consequently postpone the pH decline post mortem. On the basis of postponed pH decline, and possible increased water retention due to increased intracellular osmotic draw caused by the creatine phosphate, Berg and Alle (2001) proposed a hypothesis of increased WHC in meat from pigs supplemented with creatine. Alteration in the water mobility has been indicated in several studies by tendencies to greater myofiber hydration (Berg & Allee, 2001), reduced cooking loss (Maddock, Bidner, Carr, McKeith, Berg & Savell, 2002) and increased WHC (James et al., 2001).

Objectives

The objectives was to study interactions among breeds, creatine supplementation, and cooling profile in relation to WHC in pork.

Materials and methods

A total of 80 pigs, 40 Duroc and 40 Landrace pigs were allocated to 4 groups and supplemented with 0, 12.5, 25 or 50 g creatine monohydrate (CMH)/d for 5 days prior to slaughter. Pigs were fed 2 x 1375 g feed mixed with CMH for 5 days prior to slaughter. The body weight was registered in the morning 5 days before slaughter and before transport to the slaughter plant. The development in water mobility and distribution was measured in LD muscles of control and pigs supplemented with 25 g CMH/d by NMR T_2 relaxation (Bertram, Karlsson & Andersen, 2003) from 20 min to 210 min post mortem. The temperature was logged every min from 20 min until 24 h *post mortem*, and duplicate pH measurements were made in *longissimus dorsi* (LD) at 1, 15, 30, 45, 60, 120 and 1440 min (24 h) *post mortem*. After 1 h one half of the carcass was placed in a chilling room at 4°C (temperature profiles in Figure 1) and the other half in the freezer for 1 h at approximately –28°C, and then transferred to a separate chilling room at 4°C. Water holding capacity (WHC) was also determined as drip loss in LD in approximately 100 g samples using the plastic bag method (Honikel, 1998). The data was statistically analysed using the mixed procedure in SAS (SAS V8).

Results and discussion

Body weight gain of the pigs after 5 days of supplementation increased linearly with dietary inclusion of CMH and at a dose of 50 g/d the gain was increased by approximately 2 and 3 kg in Duroc and Landrace respectively (Table 1). When disregarding the breed, all groups of CMH supplemented pigs had a significantly increased weight gain compared to control animals. Weather this increased gain is as lean body mass (Balsom et al., 1995) or as increased water retention (Juhn, 1999) will be investigated further in this study.

In Duroc pigs pH was higher compared to Landrace at all time points, but in control animals and those supplemented with 12.5 g CMH/d this difference was only significant 24 h *post mortem* (Table 2). Contrary, in groups of pigs supplemented with 25 and 50 g CMH/d the Duroc breed had significantly higher pH at all time points, except after 15 and 30 min for pigs supplemented with 50 g CMH/d. Among Duroc animals pH was higher in pigs supplemented with 50 g CMH/d at 30, 45, 60 and 120 min *post mortem* compared to

control Duroc animals, whereas there was no systematic differences between supplementation groups within the Landrace. In general the difference in cooling profile (Figure 1) only affected pH of the meat after 2 and 24 h *post mortem*. As a whole, carcasses frozen for 1 h had a higher pH at 2 h *post mortem* ($P = 0.005$) and specifically Duroc supplemented with 50 f CMH/d and Landrace supplemented with 25 g CMH/d had increased pH upon freezing. After 24 h the effect of cooling profile was more pronounced; generally pH was higher in frozen samples ($P < 0.0001$) and specifically Duroc supplemented with 12.5 g CMH/d and all groups of Landrace had increased pH upon freezing.

Delaying the pH decline initially during the conversion of muscle to meat reduces protein denaturation and may consequently reduce the drip loss. In this context the drip loss is assumed to be reduced in meat from Duroc pigs compared to Landrace, and in Duroc pigs supplemented with 50 g CMH/d compared to control Duroc animals. Furthermore, different cooling profiles may affect the drip loss despite the pH of the frozen meat was only significantly higher 2-24 h *post mortem*.

In general terms this theory was confirmed, since drip loss, as determined by the bag drip method, was reduced up to 30% in Duroc but slightly increased in Landrace upon CMH supplementation (Table 1). The difference in cooling profile did not affect drip loss.

NMR T_2 relaxation data were analysed using distributed exponential fitting, which revealed the presence of three water populations in the muscles. The slowest T_2 population, T_{22}, expresses the amount of extra myofibrillar water and has been shown to be positively correlated to the drip loss (Bertram, Donstrup, Karlsson & Andersen, 2002). The difference in drip loss between breeds determined by the bag drip method was not directly reflected in the NMR T_2 population measured initially *post mortem* (Figure 2). This may be due to a difference in the contribution from intra muscular fat to the T_{22} population between the two breeds, since Duroc is known to have more intra muscular fat than Landrace. However the tendencies towards reduced drip loss in Duroc and increased drip loss in Landrace upon CMH supplementation was confirmed by the *post mortem* development in the NMR T_{22} population, which revealed a smaller and larger increase in the T_{22} population in muscles of Duroc and Landrace, respectively, upon CMH supplementation, although none of the NMR data was significantly different because of the variation in the material. A large increase in the T_{22} population *post mortem* is known to result in a high drip loss (Bertram et al., 2003).

Conclusions

In general, a breed by dietary CMH interaction was observed for *post mortem* pH and drip loss. Thus, in Duroc dietary CMH addition increased pH, and reduced driploss, while no significant effects of dietary CMH addition were observed in meat from Landrace pigs.

Table 1. LSMeans of weight gain (g) of the live animals and WHC of the meat expressed as drip loss (%) (n = 10). Weight gain expressed as difference before and after 5 days of creatine monohydrate (CMH) supplementation.

Abstract

The amount, spatial distribution and composition of the connective tissue within muscle vary with muscle position and the carcase and with animal age. This has long been recognised to influence the tenderness of cooked meat. This paper builds upon some historical perspectives with a review of some recent clarifications of the biological function of intramuscular connective tissue IMCT and of its contribution to meat texture, which is clearly multifactorial. The perimysial component of (IMCT) varies most in amount between muscles, and is also the IMCT structure most involved in defining the mechanical integrity of cooked meat. The distribution of perimysium defines muscle fascicle size (muscle "grain" size), which is also still regarded as an indicator of tenderness. Postmortem conditioning of meat has consistently been shown to reduce the strength of intramuscular connective tissue in the raw state, but equally consistently, this has been shown not to affect the toughness of cooked meat. Cooking increases IMCT strength in the range 20-50°C and decreases its contribution at higher temperatures and longer cooking times. Crosslinking of collagen in older animals is generally considered to result in tougher meat, although definitive links between mature crosslink content and cooked meat toughness have been difficult to prove. In the last quarter-century IMCT has been increasingly viewed as a "background" contributor to meat texture, which is difficult to change. However, the large variation in perimysial content of muscles in one animal represents an incredible range of expression. This appears to be firmly fixed to the functional properties of different muscles. In particular, it is hypothesised that definition of muscle fascicle size and shape by the bounding perimysium is related to the need for sub-sections of the whole muscle to slip past each other in the normal contractile function of the tissue. However, the amounts and composition of IMCT can be manipulated by animal nutrition and exercise, and factors affecting the turnover of IMCT may especially be a future target for manipulation of meat texture.

(**Note!** Figures are on Pages 15–19**)**

Introduction

The morphology, composition and amount of intramuscular connective tissue (IMCT[1]) vary tremendously between muscles, species, breeds and with animal age. We intrinsically acknowledge the large influence of IMCT on meat toughness in age-old preferences in choosing cuts of meat to purchase. The large price differential at retail between fillet steak (loin steak) and shin beef reflect our expectations of eating quality, based principally on their different IMCT content, and the preference for meat from younger, less mature, animals reflects the fact that the IMCT contribution to cooked meat toughness is higher in older animals, due to its increased mechanical and thermal stability. Although only a small component (in terms of mass fraction), the disproportionately large influence of IMCT on meat toughness ha resulted in studies trying to relate its amount, or various aspects of its composition and distribution in muscle tissue to variations in meat texture for more than three-quarters of a century (Lehmann, 1907; Hammond, 1932; Carpenter, Kauffman, Bray, Briskey, Weckel, 1963; Marsh, 1977; Light and Bailey 1989; Brooks and Savell, 2004). Modern production practices for pork, lamb and especially beef clearly aim to minimise the variations in texture due to animal maturity, so that young animals of a narrow age range at slaughter of the same breed show variation in the texture of a meat from a given muscle that is only minimally related to characteristics such as collagen content and solubility. In recent years, work to reduce unwanted meat toughness has largely been focussed on postmortem proteolysis of the cytoskeletal and myofibrillar proteins within muscle fibres, as this process can be influenced by post-mortem handling to a great extent. (This focus has led to the view that, whilst the IMCT contribution to meat texture is certainly important, it is also rather immutable and forms a "background toughness" that we can do little about in practical terms (Ouali, Demeyer, Raichon, 1992; Sentandreu, Coulis, Ouali, 2002). However, the amount, composition and distribution of IMCT is possibly the
most variable phenotypic difference between muscles within an animal, and represents a tremendous variation in protein expression and turnover. Given the large influence of IMCT on meat texture, even small manipulations of its expression and turnover may have considerable potential for reducing unwanted variations in meat tenderness.

Structure and composition of intramuscular connective tissue

The basic structure and composition of IMCT has been comprehensively reviewed by several previous authors (Borg & Caulfield, 1980; Mayne & Sanderson, 1985; Sanes, 1986; Bailey & Light, 1989; Purslow & Duance, 1990; McCormick, 1994; Greaser, 1997; Purslow, 2002; Kjær, 2004) and only a brief description will be given here as background. IMCT is principally comprised of fibres of the proteins collagen and elastin, surrounded by a proteoglycan (PG) matrix. The total collagen content in beef muscles can vary from 1-15% of dry weight; elastin is a smaller component varying from 0.6% to 3.7% (Bendall, 1967). Collagen types I, III, IV, V, VI, XII and XIV have been identified in IMCT (Listrat et al., 1999,2000). Types I and III are the major fibre-forming types in endomysium, perimysium and epimysium, and type IV collagen is the principal non-fibre-forming component of the basement membrane linking the fibrous (reticular) layer of the endomysium to the muscle cell membrane (sarcolemma). In mammalian species type V is a minor component of IMCT, although it is much more abundant in the major IMCT structure of fish muscle, the myocommata (Sato et al., 1998). As reviewed in detail elsewhere (Purslow, 2002), the relative concentration of different types of collagen varies through embryonic development in bovine (Listrat, Picard, Geay, 1999; Listrat et al., 2000) and chicken (Lawson & Purslow, 2001) muscle. There have been a number of PG components identified in IMCT, principally decorin (Eggen, Malmstrom, Kolset, 1994; Nakano, Li, Sunwoo, Sim, 1977). Heparan suphate-containing PGs are associated with the basement membrane and higher concentrations of chrondroitin sulphate and dermatan sulphate are found in the perimysium (Carrino and Caplian, 1984; Andersen, Klier, Tanguay, 1984; Nishimura, Hattori, Takahashi, 1996a). Vellman and

[1] The abbreviation IMCT has been used in the past, e.g. by Mohr and Bendall (1969) and others subsequently. In more modern biological parlance connective tissues are referred to as extracellular matrix (ECM). Although "ECM within muscle" has been used in some papers, the historical and shorter "IMCT" will be used here. Needless to say, these terms are synonymous.

coworkers (Vellman, Liu, Eggen, Nestor, 1999) reported the high levels of chondroitin sulphate-containing PGs in early developmental stages of turkey pectoralis muscles to be replaced by heparan sulphate-containing PG's later in embryonic development.

There are three main structural components of IMCT. (1) The *endomysium* is the thin connective tissue layer separating individual muscle fibres. The vast majority of its thickness is made up of a near-random feltwork of fine, wavy collagen fibres, as shown in Fig. 1. This collagen feltwork can easily reorientate with changing muscle length (Purslow & Trotter, 1994; Trotter, Richmond, Purslow, 1995). (2) The *perimysium* is the connective tissue layer that separates each muscle into muscle fibre bundles, or fascicles. There are large (primary) fascicles and smaller (secondary) fascicles, and therefore primary and secondary perimysial layers separating them. Collagen fibres in the perimysium are arranged in a crossed-ply arrangement of two sets of wavy collagen fibres (Rowe, 1981), with the fibres in each ply parallel to each other but at an angle to the muscle fibre axis (typically $\pm$54° in resting muscle, but this angle changes with changing muscle length; Purslow, 1989). Again, reorientation of this collagen network allows the perimysium to easily follow elongation or shortening of the muscle fascicles. (3). The *epimysium* is the connective tissue sheath delineating and separating individual muscles. In many muscles (e.g. bovine sternomandibularis; Fig. 2) collagen fibres in the epimysium take on the same crossed-2-ply arrangement in the perimysium. In pennate muscles, however (e.g. gastrocnemius), or in muscles where the epimysium clearly participates in transferring load to adjacent structures (e.g. bovine semitendinosus), the collagen fibres are more close-packed and longitudinally arranged, like a tendon.

The role of perimysial IMCT in meat texture

Whilst cooked meat toughness and the total collagen content of a muscle often rank similarly, precise correlations between textural measures such as Warner-Bratzler shear force (WBSF) and collagen content are poor. Dransfield (1977) showed some of the best correlations between Volodkevitch bite force on cooked meat and collagen content (measured by hydroxyproline concentration), but even so the correlation explained less than half the total variation in texture. Previous structural and mechanical studies of cooked beef (Carroll, Rorer, Jones, Cavanaugh, 1978; Purslow, 1985) have clearly demonstrated that separation of the perimysium from the endomysium of fibres on the surface of the fascicle is relatively easy in cooked meat, but that the individual perimysial layers are strong and so dominate the fracture behaviour of meat and therefore is the major contributor to toughness. The high strength of the perimysium relative to the weaker endomysial-perimysial interface in cooked beef was quantified by Lewis and Purslow (1990). Fig. 3 shows a steak of bovine semitendinosus muscle cooked to 80°C being pulled apart. In the early stages of separation (Fig. 3 top), fascicles separate from each other, by endomysial-perimysial separation, leaving intact perimysium clearly visible in the gaps between them. At later stages of rupture (Fig. 3 bottom), the perimysial layers have to be broken down to separate the whole sample into pieces. This process clearly mimics the breakdown of cooked meat in the mouth during mastication, which also involves separation of intact fascicles in the first few chew cycles (Lillford, 1991, 2000).

The collagen content in the perimysium varies much more between muscles than endomysial content (Light, Champion, Voyle, Bailey, 1985; Purslow 1999; Nakamura, Iwamoto, Ono, Shiba, Nishimura, Tabata, 2003). In a study of six bovine muscles, Light et al. (1985) show a range of 1.4% to 7.0% in perimysial mass as percentage of muscle dry weight but only a range of 0.1% to 0.5% in endomysial mass between six beef muscles. A more extensive study of fourteen beef muscles reported by Purslow (1999) showed perimysial collagen as % of muscle dry weight ranging from 0.45% to 4.76%, whereas endomysial collagen % varied from 0.47% to 1.20%. Thus endomysial content varied by a factor of 2.5, whereas perimysial content varied by more than an order of magnitude. Although techniques of separating endomysial IMCT from perimysial IMCT are far from perfect, these studies indicate that it is the amount of perimysium that varies most between functionally different muscles. Brooks and Savell (2004) report that perimysial thickness in bovine semitendinosus muscle is on average 2.4 times thicker than in psoas major from the same animals. There are indications from the work of Swatland and coworkers. (Swatland, Gullett, Hore, Buttenham, 1985), Carpenter et al. (1963) and Cooper and coworkers (Cooper, Breidenstein, Cassens, Evans, Bray, 1968) that thicker perimysium is associated with reduced tenderness, although in some of these studies animal age is a

confounding variable. Unpublished results from the study on 14 beef muscles reported by Purslow (1999) showed the maximum thickness of primary perimysium to be 2.53 times greater than the thinnest, with variations in secondary perimysial thickness being slightly smaller (1.9). However, correlations between shear force values of muscles cooked to 80°C and perimysial thickness were low. Light et al. (1985) were able to show similarities in ranking between toughness and perimysial content of their six muscles, but correlations between WBSF and perimysial content or perimysial thickness (Brooks and Savell, 2004) remain low. Light et al (1985) demonstrated that variations in ratio of type I:III collagen, the diameter of collagen fibrils and the amount of divalent (immature) crosslinks are also seen in the perimysium of the six muscles they studied, suggesting that there are multifactorial contributions to the IMCT component of meat texture.

Muscle "grain" and meat texture

The division of muscles into fascicles by the perimysium can easily be discerned by eye, or by the ball of the thumb moving over a cut surface, as the "grain" of a muscle. The USDA grading scheme for beef has for many decades contained a reference to grain size; fine grain is a requirement for the top grades. (Large grain size is primarily mentioned in the current scheme as an indication of meat from older animals.) Grain size ("graininess") is included in the sensory parameters of note in a review of the history of sensory evaluation of meat by Szczesniak (1986). Much of the work cited in the literature on muscle grain and meat texture is 40-70 years old, and so does not appear in modern databases. For the sake of completeness, it is reviewed in some detail here. In these early works the term "texture" was specifically used to describe the visual perception of graininess of muscle cut across the fibre direction, i.e. how smooth or divided the cut surface appeared, and the size/nature of the divisions. It is assumed in the majority of the literature that grain size is synonymous with muscle fibre bundle (fascicle) diameter. Figure 4 compares fascicular architecture in cross-sections of three muscles from the same (bovine) animal: pectoralis profundus, sternocephalicus and rhomboideus cervicus. Large differences in primary fascicle size, the thickness of the perimysium, and the degree of adipose tissue associated with the perimysium can be seen in theses sections.

Hammond (1932) reviews the experimental work of his group from 1913 to 1922, together with contemporary work of others in this area in his large monograph on sheep meat quality. He notes a general belief at that time that cooked meat from fine-grained muscle is more palatable than from coarse-grained muscle, which is often described as "stringy". Thigh muscles with the highest rates of post-natal growth were felt to have the largest grain (e.g. semimembranosus, vastus externus, biceps femoris).
Hammond (1932) examined the effect of sex, age and breed differences on grain size. His comparison between 23 different leg and thigh muscles (Table CXXV, p 512) shows consistent patterns of variations in grain size between muscles between individual animals. Due to the ranking system used, the absolute variation in grain size from the biggest to the smallest cannot be quantified. However, from the examples of histological sections presented, fascicle size can easily be seen to vary by a factor of two or more. Hammond also compared the grain size of 7 muscles in rams at birth, 5 months and "adult" age, and 8 muscles in wethers at 5, 11 and 22 months. He concludes that muscle fibre bundle size increases with animal age. Rams, on average, have coarser grain sizes in the same muscles at comparable ages than wethers, and these in turn are larger than in ewes. Hammond also investigated differences in grain size between sheep breeds by ranking each of 7 muscles from 6 animals from 5 breeds. On average across the 7 muscles, grain size ranked with breed as follows:

Suffolk > Merino > Shetland > Soay > Hampshire.

Although the individual animals were all at different ages (Shetland 5yrs; Soay 2yrs; Merino 5yrs; Suffolk 4 yrs; Hampshire 11 months), the general inference drawn by Hammond is that muscle grain size is related to animal size.

In quantitative terms, this work by Hammond (1932) contains only a small amount of non-parametric data on the effect of breed on grain size. There is no correlation attempted between grain size and tenderness, but he infers that coarse grain size leads to less palatable, "stringy" meat. Hammond's conclusions (that coarse

texture is found in male animals and large-framed animals, and that this frame size effect also holds between breeds and species) are reiterated by Lawrie in his standard text on meat science (Lawrie, 1985).

Brady (1937) reports results from experiment using 6 yearling Hereford x Shorthorn steers and 7 mature Holstein cows. Measurements of the number of fibres per fascicle and fibre diameter were made on histological sections of 4 muscles (Triceps brachii, Longissimus, Adductor and Semitendinosus) in the raw and cooked state. Warner-Bratzler shear force measurements and taste panel scores for texture and tenderness were also taken. To confuse the issue, non-intuitive definitions of texture were used in the taste panel; large muscle fibre bundle size (coarse graining) was described and rated as the most desirable ("finer") texture. Brady concludes that these correlations are significant and that the data warrant the interpretation that the larger the bundle (which Brady confusingly defines as the finer the texture), the more tender the meat. Note that this conclusion is apparently in contrast to Hammond, who asserted that small grain size is associated with tenderness.

There is therefore an important difference in the use of the term "fine" to describe texture or grain size between Brady (1937) and Hammond (1932). Hammond uses "fine" to describe small grain (small bundle or fascicle size). Brady uses the term "fine" to indicate most desirable texture; in this case the "finest " texture is actually the largest grain size, i.e. the largest bundle diameter. So, although it is true that both Hammond and Brady relate "fine texture" with tenderness, they mean completely opposite things by the word "fine".
Ramsbottom, Standine and Koonz (1945) studied variations in tenderness between the muscles within the carcasses of 3 heifers of unspecified breed. They define texture as being determined by the size of the muscle fibre bundles (fascicles), but also the amount or thickness of the perimysial connective tissue separating them. They associate these rankings in grain size and definition with the same order of ranking in muscle toughness, i.e. the larger the grain size, the tougher the meat.

Cooper et al. (1968) found that the muscle bundle size increased greatly with maturity in bovine longissimus muscle. In their study, bundle size was significantly associated with visual scores of texture ($r = 0.37$, $P<0.01$), positively related to shear force ($r = 0.39$, $P<0.01$) and negatively correlated to taste panel tenderness ($r = -0.41$, $P<0.01$). They also found a significant negative correlation between the overall opinion of acceptability and bundle size ($r = -0.30$, $P<0.05$). .

Carpenter et al. (1963) studied muscle fibre bundle size and the coarseness (thickness) of perimysial connective tissue strands in 78 loins from pigs aged 4-42 months. Bundle size and CT coarseness were rated subjectively on a 5-point scale, and related to tenderometer and taste panel scores of tenderness. They give correlations of -0.39 ($P<0.01$) between muscle bundle size and tenderness, and -0.38 ($P<0.01$) between connective tissue thickness and tenderness. The trend of these relationships agrees with that found by Cooper et al. (1968) and inferred by Ramsbottom et al. (1945) and Hammond (1932), and so disagrees with Brady (1937).

Lepetit and Culioli (1994) review much of the French work on connective tissue morphology in meat. From work by Dumont (1985), they point out that if the force required to shear raw muscle is divided by the overall collagen content of the muscle, then 30-40% of the variance in shear force value remains, which they feel may be related to IMCT morphology. They cite Dumont (1983) as showing a high correlation between raw muscle shear force and the linear density of the perimysial network (i.e. the number of tracts encountered per unit length of transect). However, as discussed below, shear force measurements on raw meat are poor predictors of cooked meat texture, and so these results should be viewed with caution.

Taken together, these studies point to some consistent pattern that tenderness is partly correlated with small diameters of muscle fascicles, but as is so common in meat science, this single variable is of extremely limited value in predicting the toughness of cooked meat, due to the highly multifactorial nature of texture.

Variations in the Amount of Intramuscular Connective Tissue Relate to Muscle Function

From the forgoing two sections it is clear that IMCT varies in amount and, especially at the perimysial level, in spatial distribution between muscles. It is generally accepted that this must reflect differences in

physiological (mainly biomechanical) function between muscles, but until recently it has not been clear what the functional role of IMCT is. However, in the last decade there has been a great advance of our understanding of role of IMCT in coordinating force transmission in muscle. Evidence for load sharing via the endomysium between muscle fibres within a fascicle and via the perimysium between fascicles within a muscle is comprehensively reviewed by Trotter et al. (1985), Huijing (1999a,b) and Monti, Roy, Hodgson & Edgerton. (1999). Endomysial connective tissue facilitates load sharing within a fascicle by linking adjacent muscle cells by shear (Trotter & Purslow, 1992; Purslow & Trotter, 1994; Trotter et al, 1995). It has been shown that the easily-deformable tensile properties of the endomysial network allow it to follow necessary shape changes in contracting muscle fibres without restraining this process, but the shear properties though the thickness of the endomysium are suitable for efficient load transfer over a wide range of physiological muscle fibre lengths (Purslow, 2002). These endomysial linkages can be thought of as coordinating the deformations within a fascicle, especially in the usual physiological circumstances where not all motor units are contracting.

In terms of the very variable spatial distribution of perimysium, and via the perimysium, (Purslow, 1999) proposed that division of a muscle into fascicles by the perimysium reflects the need to accommodate shape changes as the muscle contracts, and that this is achieved by allowing fascicles to slide past each other. Ultrasonic imaging data of Fukunaga and colleagues on changes in muscle geometry during human locomotory function (e.g. Fukunaga, Ichinose, Ito, Kawakami, Fukashiro, 1997) clearly demonstrates that that these shape changes do occur in living muscle. Purslow (2002) calculated the shear strains that occur between fascicles within various muscles over their physiological range of contraction based on the data from a series of papers by Fukunaga and colleagues and showed them to be substantial, and variable between muscles. Functionally different muscles have very different requirements to accommodate the shear strains that necessarily occur as the muscle contracts and changes shape, and this begins to explain why the amounts and distribution of perimysial connective tissue varies so much between functionally different muscles. Variations in IMCT between functionally different muscles represents a great variation in expression from a given genome, and whilst genomics and proteomics approaches to describing such variation in expression may assist our understanding of this in relation to meat quality (Eggen & Hocquette, 2003), in terms of meat science a prime question is what possibilities exist to manipulate variability in IMCT expression so as to improve meat texture? Although there is clearly some possibilities, as evidenced by differences between breeds and in some hypertropic genetic conditions, these considerations of the physiological function of IMCT imply that the variations in expression of perimysial IMCT between muscles is tightly related to muscle activity, and so may not easily be manipulated without compromising muscle function in the live animal.

Postmortem effects on IMCT

Although little in the way of new concepts has come up in work on both the effects of cooking temperature and time, and on effects of postmortem storage (conditioning or ageing) of meat on IMCT since previous reviews (Purslow, 1999, 2002), it is perhaps worthwhile to highlight some salient points where there still seems to be contrary interpretations of previously established views in the last 5 years.

Cooking influences on IMCT contributions to toughness.

The toughness of meat increases with temperature of cooking. A sharp increase in toughness occurs between 40ºC and 50ºC, followed either a dip between 50º and 60ºC or a plateau in toughness depending on measurement technique, and then a second phase of increasing toughness above 65ºC. Several studies have intuitively correlated these changes with the thermal denaturation of myosin in the range 42-65ºC and collagen above 65ºC (Davey & Gilbert, 1974; Davey & Winger, 1979; Martens, Stabussvik, Martens, 1982). Although this interpretation has been proved incorrect, it still is used by some to infer that collagen and shrinkage above 65ºC is primarily related to toughness development at higher temperatures (e.g. McCormick, 1999, 2001).

The evidence for IMCT actually contributing to the first phase of toughening, at 40-60°C, goes back to Bouton, Harris & Ratcliff (1981), who inferred from their Warner Bratzler PF-IY measurements that the connective tissue contribution to toughness is high at low cooking temperatures and decreases above 60ºC. Lewis and Purslow (1989) showed by direct measurements on perimysium isolated from cooked beef meat that perimysial connective tissue strength increases in meat cooked up to 50ºC and decreases above this temperature. Mutungi, Purslow & Warkup (1996) showed that the strength of porcine muscle fibres continually increases up to 90ºC. Christensen, Purslow & Larsen (2000) confirmed these two previous findings by examining the strength of both perimysium and individual muscle fibres from the same muscle samples cooked to various temperatures. These studies all add confirmation to the interpretation of Bouton et al. (1981); cooking increases the IMCT contribution to toughness in the range 20ºC-50ºC, with myofibrillar contributions being more prominent above 60ºC. Because isolated IMCT forcefully shrinks above 65ºC when rapidly heated (Kopp and Bonnet, 1987), there is still a feeling that high-temperature shrinkage of collagen could cause the shrinkage of meat seen at 65º-80ºC, and that this shrinkage cause volume reduction in the muscle fibres, so increasing their toughness (Lepetit, Grajales, Favier, 2000). Powell and coworkers (Powell, Hunt, Dikeman; 2000; Powell, Dikeman, Hunt, 2000) have provided some interesting new findings in this area by relating the pronase-extractable fraction of collagen to its thermal denaturation above 55ºC. They report strong correlations between this fraction and peak shear force in experiments; salt-soluble collagen is not nearly as well correlated to toughness. Their explanation is that this insoluble but enyzmically extractable fraction is more related to changes in the structural integrity of the fibrous IMCT network on cooking. However, it has been pointed out previously (Purslow, 1999) that the ratio of transverse to longitudinal shrinkage in meat on cooking, and especially how these vary with sarcomere length, is not simply explainable on the basis of collagen network shrinkage. It is possible that other events, such as cytoskeletal protein denaturation, cause the shrinkage to toughen myofibrillar components at higher temperatures. Obuz, Dikeman, Grobbel, Stephens and Loughin (2004) conclude that variations in cooking losses between different sample sizes and different cooking methods alter the WBSF values seen and also complicate the relative contributions of IMCT softening and myofibrillar hardening.

Post-mortem proteolysis has no effect on the integrity of IMCT after cooking

During post mortem storage (conditioning) of meat there is significant proteolysis of both collagenous and PG components of IMCT, which increases the amount of collagen that can be solubilised from meat (Stanton and Light, 1987) and significantly reduced the strength of perimysium in raw meat after conditioning (Lewis, Purslow, Rice, 1991), as shown in Fig 5.

Over the last ten years there has been a large amount of work to reaffirm that conditioning increases the amount of collagen that is easily extracted from muscle, decreases their structural integrity as viewed by SEM, degrades PG components of IMCT and reduces the strength of IMCT networks, as demonstrated for example by shear measurements on raw muscle or on uncooked IMCT structures embedded in acrylamide gels or by Warner-Bratzler measures on raw meat (Nishimura, Hattori, Takahashi, 1994; Nishimura, Hattori, Takahashi, 1995;Nishimura, Hattori, Takahashi, 1996a,b; Nishimura, Liu, Hattori, Takahashi, 1998; Liu, Nishimura, Takahashi, 1994, 1995; Nakano, et al., 1997; Eggen, Ekholdt, Host, Kolset, 1998; Fang, Nishimura, Takahashi, 1999; Palka, 2003). Similarly, Torrescano and coworkers (Torrescano, Sánchez-Escalante, Giménez, Roncalés, Beltrán, 2003) recently found strong correlations between the total collagen content and insoluble collagen content of 14 beef muscles and raw Warner-Bratzler peak shear force values.

We must remember, however that the overwhelming majority of meat is cooked before it is eaten; textural measurements on raw meat miss out the interactions of proteolysis with effects of cooking, and it is this which leads to measurements on raw muscle being a poor predictor of cooked meat texture. Previous work by Bouton and Harris (1972) showed that measures of the connective tissue component of toughness were unaffected by extensive conditioning when followed by cooking. Lewis et al. (1991) demonstrated this clearly by measuring the strength of perimysium in conditioned meat both before and after cooking.; while there is a reduction in strength of IMCT with conditioning in raw meat, these effects are negated after cooking to temperatures of 60ºC and above, where both aged and unaged perimysial IMCT has the same strength. It is work reiterating this result, shown in Fig. 5, to caution against the recent trend to interpret properties of IMCT in raw meat and degradations during conditioning as if these will inevitably translate into

cooked meat toughness. They do not, as has been known from the work of Harris and colleagues for more than 30 years. Palka (2003) recently was compelled to revisit previous conclusions that the texture of raw meat is poorly related to cooked meat toughness.

Animal maturity, crosslinking and turnover of IMCT

Animal maturity is associated with increased thermal and mechanical stability of IMCT (Bailey and Light, 1989). Meat tenderness generally decreases with animal age, and collagen-rich muscles show this effect more than those with a low IMCT content (Shorthose & Harris, 1990). Increasing collagen fibre diameter and especially the development of mature crosslinks from immature divalent forms accompany this. Although an in-depth investigation of the relationships between a large number of types of collagen crosslinks and cooked meat toughness showed no conclusive correlations in pigs of similar maturity (Avery, Sims, Warkup, Bailey, 1996), or in beef animals in the age range 400-800 days (Avery, Sims, Warkup, Bailey, 1998), it is generally accepted that the development of mature crosslinks with age in IMCT cause it to have increased contributions to cooked meat toughness (Bailey& Light, 1989; McCormick, 1994, 1999). The mechanisms of crosslinking on maturation and ageing of collagen are extensively reviewed by Bailey and coworkers (Bailey, Paul, Knott, 1998). The formation of the immature, divalent crosslinks is controlled by post-translational modifications and can be assumed to be positively directed to provide the mechanical stability required for collagen to fulfil its functional roles.

Collagen in muscle is relatively slow to turnover. Rucklidge, Milne, McGaw, Milne & Robins (1992) report a half-life of 45 days, and although Laurent (1987) inferred a faster turnover, there are good reasons to suppose that the long residence time reported by Robins is more realistic. Relatively slow turnover of IMCT components gives time for slow modifications, including the conversion of divalent to trivalent crosslinks between collagen molecules, slowly increasing the thermal and mechanical stability of IMCT with age. This consequence of slow turnover may not be a functional adaptation, but simply an ageing process. Thus, if the turnover of collagen in muscle could be increased, there is a possibility that less mature, less thermally stable IMCT could result in more tender meat.

Woessner (1968) long ago pointed out that for growth to occur there must be degradation of collagenous networks; during animal growth the hypertrophy of a fixed number of muscle fibres s responsible for muscle weight gain and to accommodated bigger muscle fibres and fascicles, endomysial and perimysial networks must necessarily be remodelled, otherwise they will limit growth.

Turnover of connective tissue is principally under the control of matrix metalloproteinases (MMPs) and their specific inhibitors, TIMPs. Fifteen out of sixteen known MMPs and 3 out of 4 TIMPs have been found in either bovine skeletal muscle, or IMCT, fibroblasts and myoblasts isolated from it (Balacerzak, Querengesser, Dixon, Baracos, 2001). Both muscle cells and fibroblasts within muscle are known to secrete MMPs and TIMPs. MMPs are secreted in inactive forms and activated in a cascade involving plasmin, tissue kallikrein and other factors (Parsons, Watson, Brown, Collins, Steele, 1997). Injury of (cardiac) muscle stimulates MMP expression by fibroblasts in response to the cytokines IL-β and TNF-α (Siwik, Chang, Colucci, 2000). Both TNF-α and other growth factors such as bFGF stimulate increased MMP activity in skeletal myoblasts (Allen, Teitelbaum, Kurachi, 2002). Mechanical stimulus (e.g. exercise) has long been known to be a factor controlling muscle growth and turnover (Goldspink, 1999, 2003). Turnover of IMCT is especially evident in repair of injury or hypertrophic response to exercise (Koskinen et al., 2001) and down regulated during immobilization (Ahtikoski, 2003). It is not known whether turnover of IMCT structures is solely mediated by the fibroblasts that sparsely populate the IMCT, or whether MMPs are expressed by muscle cells in response to mechanical signals. Interactions between muscle cells and extracellular matrix structures involved in muscle development and in cell signalling have been reviewed recently (Purslow, 2002). Muscle strain or injury leads to a rapid production (fibrosis) of endomysial and perimysial connective tissue (Stauber, Knack, Miller, Grimmet, 1996). The remodelling of muscle tissue during rapid the hypertrophy involved in compensatory growth following feed restriction necessarily involves remodelling of the IMCT structures which link and coordinate the various level of structure within the tissue. It has previously been recognised that animals slaughtered after a period of rapid growth will have less contribution to toughness from IMCT (Aberle, Reeves, Judge, Hunsley, Perry, 1981; Miller, Tatum,

Cross, Bowling, Clayton, 1983). Allingham, Harper & Hunter (1998) showed that rapid compensatory growth after weight loss can reduce the strength of IMCT in bovine semitendinosus. Sylvestre, Balcerzak, Feidt, Baracos and Bellut (2002) have demonstrated that dietary manipulation of growth rate in lambs does alter the amounts, activation and activity of MMPs.

Conclusion

The expression of connective tissue within muscle is amazingly variable, depending on developmental stage, muscle position/function, animal breed, nutrition, exercise and injury. Much of the work on IMCT in relation to meat texture in the last century has bee devoted to documenting and understanding the variations between muscle and breed and brought on by animal age. Investigations of post-mortem treatment of meat to reduce the IMCT contribution to meat toughness has met with extremely limited success outside the sphere of long, slow cooking to dissolve extracellular matrix components in tough muscles, and has led to the view that the IMCT contribution to texture is a "background" feature that little can be done about. In the post-genomic era it is possible to return attention on how expression of IMCT components may be manipulated, so as to improve tenderness. The amounts and distribution of connective tissue in muscles seem to vary for very good reasons of muscle development, growth, and especially function. This may limit the scope for manipulation of its expression. Manipulation of the state of IMCT maturity may, however, be a possible means of reducing unwanted variability in meat tenderness.

Abstract

Biochemical processes and structural changes that occur in muscle during the first 24 hours postmortem play a great role in the ultimate quality and palatability of meat and are influenced by the chilling processes that carcasses are subjected to after the slaughter process. For beef and lamb, employing chilling parameters that minimize cold shortening is of the greatest importance and can be best addressed by ensuring that muscle temperatures are not below 10°C before pH reaches 6.2. For pork, because of the impact of high muscle temperatures and low pH on the development of pale, soft, and exudative (PSE) pork, a more rapid chilling process is needed to reduce PSE with the recommended internal muscle temperature 10°C at 12 h and 2 to 4°C at 24 h. Spray chilling, a system whereby chilled water is applied to carcasses during the early part of postmortem cooling, is used to control carcass shrinkage and to improve chilling rates through evaporative cooling. Delayed chilling can be used to reduce or prevent the negative effects of cold shortening; however, production constraints in high-volume facilities and food safety concerns make this method less useful in commercial settings. Electrical stimulation and alternative carcass suspension programs offer processors the opportunity to negate most or all of the effects of cold shortening while still using traditional chilling systems. Rapid or blast chilling can be an effective method to reduce the incidence of PSE in pork but extreme chilling systems may cause quality problems because of the differential between the cold temperatures on the outside of the carcass compared to the warm muscle temperatures within the carcass (i.e., muscles that are darker in color externally and lighter in color internally).

Introduction

Most postmortem chilling processes of livestock carcasses are primarily employed to ensure food safety, maximize shelf-life, and reduce shrinkage with less emphasis on maintaining tenderness and color factors of the finished product. Whether chilling conditions are being met for regulatory requirements, as part of a critical control point of a HACCP system, or as best practices, other factors may be more important than those affecting direct consumer satisfaction of the product.

Heat dissipation initially was accomplished through natural means such that animals would have been slaughtered in cooler seasons and product would have been stored in caves as a way to prolong keeping quality. Throughout the centuries, more sophisticated means were developed to reduce the heat from freshly slaughtered animals. Today, advanced refrigeration systems are used throughout most parts of the world to accomplish the task of chilling carcasses during the critical time period after slaughter and through the development of rigor mortis. The efficiency of heat removal became so great that a half century ago, it was discovered that the process of chilling could negatively affect the eating quality of beef and lamb (Lawrie, 1998). Conversely, with increases in pork carcass weights and mass over the years, the challenge oftentimes for this species is to get the product chilled more rapidly to reduce problems associated with temperature/pH relationships. These two examples reflect the importance of developing and implementing chilling systems that are neither too severe nor too mild for the particular species involved.

This is a review of past and current research on the effects of chilling systems on meat quality. Special attention is given to the impact of chilling systems on tenderness, color, and shrinkage.

The first 24 h postmortem

There are many biochemical and structural events that take place in the first 24 h period after the animal is slaughtered and the muscle is converted to meat. This period greatly impacts meat tenderness and muscle color and is species-specific in how the initial cooling process results in positive or negative consequences in meat quality.

Rigor mortis

After exsanguination, glycolysis proceeds without oxygen and produces lactic acid as a result of anaerobic glycolysis. This creates a lactic acid build-up and therefore a decrease in pH. In a normal setting, muscles begin the process of rigor mortis where permanent cross-bridges, called actomyosin, are formed between the actin and myosin filaments. Rigor begins in normal meat at pH values of 5.7 to 5.8 (Hannula and Puolanne, 2004). During the first phase of rigor, the delay phase, the muscle is still extensible because there is still ATP available to bind with Mg2+, which helps disconnect the actin/myosin cross-bridges and in turn allows the muscles to relax. Creatine phosphate is depleted during this phase, which inhibits the phosphorylation of ADP into ATP. This causes a sharp decrease in ATP production, which is the signal of the start of the onset phase of rigor. Because there is little ATP available to break down the actin and myosin bonds, muscles cannot relax and therefore become inextensible (Aberle et al*.,* 2001).

pH decline

Normally, the pH in the muscle decreases from 7.0 upon slaughter to approximately 5.3 to 5.8 (Smulders, Toldra, Flores, & Prieto, 1992). In extreme cases, this decline can take only 1 h. The typical decline for pork is in the range of 6 to 12 h, and beef usually completes its pH decline in 18 to 40 h (Smulders et al., 1992). Howard and Lawrie (1956) suggested that the rate of pH decline has an inverse relationship to tenderness. As the pH drops, it nears the iso-electric point. At this point, all of the negatively and positively charged amino acid side chains equal, which causes the maximal attraction between the two. This attraction holds the filaments closely together and does not allow any water to get in, greatly reducing the water-holding capacity (Smulders et al., 1992).

Because pork experiences a quicker pH decline than other species, it is more likely to experience elevated temperatures during the onset phase of rigor, which can be detrimental to the myoglobin pigment. This

causes the myoglobin structure to be "open" and scatter light, creating a pale colored product (Lawrie, 1998). When pork is not able to hold water, it loses color and firmness. This condition is described as pale, soft, and exudative (PSE). Quickly lowering the temperature postmortem will decrease the velocity of these chemical and biochemical reactions, therefore decreasing the rate of pH decline (Lawrie, 1998). Blast chilling will help with the reduction of this type of reaction (Meisinger, 1999). Offer (1991) reported that the effect of chilling on PSE conditions is strongly dependent on the rate of pH decline. Meisinger (1999) suggested chilling pork to muscle temperatures of less than 10°C in 12 h, and 2 to 4°C in 24 h to reduce the occurrence of PSE.

Tenderness

Koohmaraie et al. (1987) suggested that at slaughter all animals with the same pre-slaughter treatments have the same tenderness level, and that differences in tenderness are created in the first 24 h post mortem. It has been shown that there is a decrease in tenderness of muscles before the aging process begins (Koohmaraie, 1996). Koohmaraie (1995) showed that there is a large amount of variation in tenderness (shear force) after one day of postmortem storage, and that maximum toughness has been observed in the range of 9 to 24 h (Koohmaraie, 1996). After 24 h, an increase in tenderness is observed as a result of enzymatic degradation of muscle tissue. Temperature of storage can affect this enzymatic degradation, as well as other factors including: pH, muscle fiber type, amount and degree of cross-linking of connective tissue, and animal species (Smulders et al., 1992). Enzymatic degradation is caused by proteolytic enzymes such as calpains and lysomal proteases (Smulders et al., 1992). The aging process typically takes 1 to 2 d in chicken, 3 to 6 in pork, and 10 to 20 d in beef (Smulders et al., 1992).

The cause of toughening during the first 24 h has been debated, and there are numerous studies that suggest various reasons for this increase. Goll, Geesink, Taylor, and Thompson (1995) proposed that toughening was caused by the change in strength of the binding state of the actin/myosin interaction and the possibility of this change causing severe shortening in the first 24 h postmortem. Another theory is myofibril fragmentation index (MFI), which has been shown to be useful in characterizing tenderness groups (Culler, Parrish, Smith, & Cross, 1978; Parrish, Vandell, & Culler, 1979). Culler et al. (1978) found that MFI accounted for more than 50% of the variation in loin steaks, and that the MFI was a more important effecter of tenderness than collagen solubility or sarcomere length. In addition, many studies have shown that sarcomere length does not affect tenderness (Culler et al., 1978; Smith, Kastner, Hunt, Kropf, & Allen, 1979; Seideman & Koohmaraie, 1987; and Shackelford, Koohmaraie, & Savell, 1994). However, the majority of the research suggests that sarcomere shortening is the causative factor of the decrease in tenderness of muscles from the time of slaughter to 24 h postmortem. Bouton, Harris, Shorthose, and Baxter (1973) found significantly shorter sarcomere lengths in the *M. semimembranosus, M. gluteus medius*, *M. biceps femoris*, and *M. longissimus dorsi* muscles, as well as significantly tougher *M. adductor* and *M. vastus lateralis* muscles conditioned at 0 to 1ºC compared to those conditioned at 15 to 16ºC. They also found strong relationships between Warner-Bratzler shear force values and sarcomere lengths when sarcomeres were shorter than 2.0 µm. Overall, Bouton et al. (1973) found that shear force values decreased exponentially as sarcomere lengths increased. When comparing "less tender" and "more tender" steaks, Davis, Smith, Carpenter, Dutson, and Cross (1979) found that "more tender" steaks had longer sarcomeres (based on mean values) than "less tender" steaks did. Davey, Kuttel, and Gilbert (1967) found that myofibrillar contraction state affected the level of tenderness that could be achieved by aging, and specifically at 40% contraction, there was almost no effect from aging. Marsh and Leet (1966) found that decreases up to 20% of the initial excised muscle do not have a significant effect on tenderness, but toughness increases rapidly with further shortening, peaking at 40%. However, after 40%, the meat becomes progressively more tender. In addition, it was found that meat with 55 to 60% shortening had Warner-Bratzler shear force values similar to those that shortened less than 20%. Marsh and Leet (1966) concluded that the degree of rigor onset at time of cold application is inversely related to the degree of cold shortening.

Cold shortening

Cold shortening has been studied since the 1960's (Locker, 1985). Locker and Hagyard (1963) defined cold shortening as a rapid decline in muscle temperature to less than 14 to 19ºC before the onset phase of rigor mortis. When carcasses are cooled quickly, they have the potential to be affected by cold-induced shortening and/or toughening. Temperature and pH relationships at the moment of onset of rigor can be considered the decisive factor of degree of cold shortening (Hannula & Puolanne, 2004). When the muscle temperature is

reduced to 0 to 15ºC before the onset phase of rigor, the sarcoplasmic reticulin cannot function properly and is unable to bind calcium, which leaves an abundance of calcium in the sarcoplasm. Because there is still ATP left in the muscle, the muscle contracts at a maximum level, causing the filaments to slide over one another basically eliminating the I-band of the sarcomere. At internal temperatures of 1 to 2ºC, the sarcoplasmic reticulin is the least functional (Aberle et al., 2001).

The relationship of cold shortening and sarcomere length to toughness was first demonstrated clearly by Herring, Cassens, and Briskey (1965) who showed the direct relationship of sarcomere length to fiber diameter and toughness. Their theory is that the more contracted the sarcomere, the larger the fiber diameter becomes due to sliding of the filaments over one another. After cooking, meat with larger fibers is tougher.

Muscle types vary in their potential to cold shorten, with red being more susceptible than white (Bendall, 1973). Because white muscle fibers tend to have higher amounts of glycogen, they experience a more severe drop in pH earlier in the rigor process. This is especially relevant with pork. Because pork is comprised primarily of white muscle fibers, they are not as affected by cold shortening to the extent as beef and lamb. Pork takes approximately 6 h to complete the rigor mortis process, and only 15 min to 1 h to begin the onset phase of rigor. The combination of time, temperature, and pH differs between and within muscle, and also between species (Hannula & Puolanne, 2004). This indicates that all muscles are not affected by cold shortening to the same degree (Hannula & Puolanne, 2004).

Additional sarcomere shortening conditions are thaw and heat rigor. These conditions are caused when carcasses are exposed to extreme cold or hot temperatures pre-rigor. Thaw rigor is a form of rigor mortis that develops when muscle that was frozen prerigor is thawed (Aberle et al., 2001). Aberle et al. (2001) stated that when this muscle is thawed, contraction is produced by the sudden release of Ca^{2+} into the sarcoplasm resulting in a physical shortening of 60 to 80 percent of the original muscle length and a release of large quantities of meat juices and severe toughening. Heat rigor occurs when muscles are maintained at elevated temperatures up to 50°C resulting in a rapid depletion of ATP, which creates severe shortening and the early onset of rigor (Aberle et al., 2001). The severity of these two extreme conditions show the importance of designing chilling conditions that do not negatively impact meat quality.

Prevention of cold shortening

Although there is no way to prevent rigor and the shortening of sarcomeres completely, there are ways to reduce the extent and toughening effects of this process before, throughout, and after slaughter. Fat thickness can play a significant role in the reduction of cold shortening during the chilling processes of beef (Dolezal, Smith, Savell, & Carpenter, 1982) and lamb (Smith, Dutson, Hostetler, & Carpenter, 1976). Increased thicknesses of subcutaneous fat were found to improve tenderness by allowing the carcass to chill more slowly and to increase enzyme activity (Smith et al., 1976). The authors postulated that increased fatness either decreased chilling rate because of a greater amount of insulation or because of increased total mass.

Dolezal et al. (1982) found that carcasses possessing 2.54 mm of external fat received the lowest ($P < 0.05$) sensory panel ratings for myofibrillar tenderness, and had the highest ($P < 0.05$) shear force values. In addition, as fat thickness increased up to 7.61 mm, palatability also increased. Smith and Carpenter (1973) reported that a fat covering of 2.5 mm for lamb carcasses would prevent excessive postmortem shrinkage during chilling and transit. A subcutaneous fat depth of 0.62 cm at the 12th rib is suggested as the minimum level to prevent cold shortening in cattle.

Carcass weight and composition have both been deemed important factors of chilling rate (Kastner, 1981). In a study by Hippe et al. (1991), sides from thinner cows had a higher percentage of cooler shrink than sides from steers after 24 h. This is substantiated by research from Johnson, Hunt, Allen, Kastner, Danler, and Shrock (1988) that lean tissue retained less water than adipose after 20 h postmortem. More moisture loss occurs from lean than from fat tissue (Johnson et al., 1988). The major variables associated with reducing shrinkage are decreased surface area and/or increased subcutaneous fat covering (Smith & Carpenter, 1973). Increased fatness may decrease shrinkage by serving as a barrier against moisture loss (preventing evaporation from the lean), or it may act to minimize the total moisture content in the carcass (Smith & Carpenter, 1973).

Smith et al. (1976) determined that lamb carcasses with increased quantities of fat chilled more slowly, had less sarcomere shortening with less perceptible connective tissue, and were more tender. Increased levels of subcutaneous or intramuscular fat can increase lamb tenderness by altering the postmortem chilling rate, especially with little external fat (Smith et al., 1976).

Electrical stimulation helps prevent cold shortening by using up energy (ATP) before the onset stage of rigor. An electrical current is passed through the carcass during the slaughter process causing the muscles to violently contract and accelerating anaerobic glycolysis, which increases the rate of pH decline and reduces the overall time of rigor mortis. This in turn reduces the muscle's susceptibility to cold-induced shortening. Electrical stimulation of beef produces significant positive effects on lean maturity, overall maturity, and Warner-Bratzler shear force tenderness (Savell, Smith, & Carpenter, 1978; Calkins, Savell, Smith, & Murphey, 1980). Lean color also was found to be positively impacted, and heat ring (the distorted appearance of the outside edge of muscle, caused by rapid chilling and little external fat) was reduced. Also, Warner-Bratzler shear force values were significantly decreased for 21 d aged, electrically stimulated carcasses vs. control carcasses, and more interestingly, this was also true for 7 d electrically stimulated carcasses vs. 21 d controls (Savell et al., 1978). Shorthose, Powell, and Harris (1986) found this to be the case with lamb as well. Electrical stimulation had minimal (Johnson, Savell, Weatherspoon, & Smith, 1982) and even adverse (Swasdee, Terrell, Dutson, Crenwelge, & Smith, 1983) effects on quality, palatability, and weight loss in pork.

During chilling, the extent of shortening in a carcass depends on the physical restriction imposed by the attachment of the muscle to the skeleton (Hostetler, Landmann, Link, & Fitzhugh, 1970). Another method used to reduce sarcomere shortening is to alter the method of carcass suspension. Hostetler, Link, Landmann, and Fitzhugh (1972) looked at several methods including: vertical hanging (conventional hanging using suspension by the Achilles tendon), horizontal (side placed on table, with limbs tied perpendicular to the vertebra), neck-tide (side suspended from the cervical vertebra, with pelvic limb tide to thoracic limb), hip-free (side suspended from the obturator foramen and pelvic limbs free), and hip-tied (side suspended from the obturator foramen with the thoracic limb tide to the pelvic limb). The hip-free method was determined to be the most beneficial in improving sarcomere lengths and the ultimate tenderness of the muscles, especially in the loin and round. Hostetler, Carpenter, Smith, and Dutson (1975) found that carcasses suspended by the obturator foramen had muscles with 17% longer sarcomeres than those from carcasses suspended normally, and that this created less overlap of thick and thin filaments.

Times that the carcasses are placed into the cooler and temperatures at which they are held could be the most plausible way to affect cold shortening after slaughter. Bendall (1972) reported that muscles with temperatures less than 10ºC are susceptible to cold shortening until a muscle pH of less than 6.2 is reached, and at 16ºC cold shortening is less severe. Hannula and Puolanne (2004) found that the effects of aging should be more effective if the carcasses are maintained above 7 to 10ºC until the onset of rigor (pH 5.7). Olsson, Herzman, and Tornberg (1994) have set 7ºC internal muscle temperature as the upper limit for cold shortening, and Bendall (1973) recommends against cooling beef carcasses below 12ºC internally in less than 15 h, or before completion of rigor mortis. There are many different opinions on the exact temperature necessary to eliminate or reduce cold shortening. Conventional chilling allows for control of these factors that can promote or inhibit cold shortening. At the same time, there are additional techniques that can be applied during the chilling process that can alter the level of cold induced shortening.

Delay Chilling

Delay chilling has been defined by Smulders et al. (1992) as the process of keeping intact carcasses out of the chill room for some period of time. This is not to be confused with high temperature conditioning, which is subjecting primals or cuts to elevated temperatures after boning (Smulders et al., 1992). Marsh, Lochner, Takahashi, and Kragness (1980-81) indicated that beef sides delay chilled at 37°C for 3 h postmortem were more tender than conventionally chilled sides. Delayed chilling has been reported by some to have a positive influence on postmortem tenderness. In a study by Fields, Carpenter, and Smith (1976), steaks from steer and cow sides held at ambient temperatures of 14 to 19°C for 20 h were more tender than those from

normally chilled sides. Also noted was the fact that elevated temperature conditioned steaks stored for 7 d received higher panel ratings for tenderness than control steaks. In this study, pre-rigor storage at elevated temperatures improved the appearance of steaks from steer and cow carcasses (Fields et al., 1976). The authors reported that 115 out of 120 steaks from sides held at 14 to 19°C received higher ratings than control steaks for muscle color, consumer acceptability, and discoloration during 5 d of retail storage. Martin, Murray, Jeremiah, and Dutson (1983) also reported decreased toughness when carcasses were held at elevated ambient temperatures in the range to 10 to 42°C, but were unable to clearly define the mechanism responsible. Delay chilling in pork was studied by Møller and Vestergaard (1987), and *M. longissimus dorsi* with a high initial pH above 6.1 was determined to be tough, while *M. longissimus dorsi* with a low initial pH below 6.1 was not affected.

On the other hand, Will and Henrickson (1976) determined that shear force and penetration values between chill (1.1°C for 48 h) and delay chill (held 3, 5, or 7 h postmortem at 16°C) treatments were small (1.65 kg and 0.18 cm, respectively), and led them to the conclusion that there were no significant tenderness differences observed between the two regimes. Phoya and Will (1986) reported that a taste panel was able to detect differences between delay chilled steaks (16°C for 4 h, then some muscle excision and 1°C storage for another 44 h) and conventionally chilled steaks (1°C for 48 h before fabrication). Warner-Bratzler shear force values and preference and hedonic scale scores showed that delay chilling for 4 h with hot-boning did not increase beef tenderness when carcasses were suspended through the obturator foramen (Phoya & Will, 1986). In a similar study performed by Jeremiah, Martin, and Murray (1985), researchers determined that delay chilling (12.5°C for 2 h) along with electrical stimulation did not produce consistent changes in physical, cooking, or palatability traits in the *M. semimembranosus*, *M. longissimus dorsi*, or *M. triceps brachii* muscles of beef.

As noted by Smulders et al. (1992), the potential benefits of high temperature conditioning, which include prevention of cold shortening and increased proteolysis, must be weighed against the possibility of heat shortening. Also, Smulders et al. (1992) stated that the effect of increased tenderness of delay chilled muscle can disappear during storage, and could result from an increased rate of aging or accelerated start to aging because of increased temperatures. There are multiple mechanisms such as heat shortening or cold shortening prevention that can dictate the effect of delay chilling on tenderness.

4. Spray Chilling

Shrinkage represents a serious economic concern for the beef packing industry today (Hamby, Savell, Acuff, Vanderzant, & Cross, 1987). Conditions that must be kept in order to minimize shrinkage include maintaining low temperature conditions, minimal air circulation, and a high relative humidity (Smith & Carpenter, 1973). The principal purpose of spray chilling is to reduce carcass weight loss during chilling, especially during the first 24 hours postmortem (Allen, Hunt, Luchiari Filho, Danler, & Goll, 1987). Spray chilling systems are currently in use in North America, Europe, and elsewhere in the world for beef, lamb, poultry (Brown, Chourouzidis, & Gigiel, 1993), and pork (Brown & James, 1992). The process of spray chilling involves the intermittent spraying of cold water onto carcasses during the first three to eight hours post-slaughter (Hippe, Field, Ray, & Russell, 1991) to replace moisture lost by evaporation (Gigiel, Butler, & Hudson, 1989). With spray chilling, the surface remains wet allowing for maximum mass transfer and evaporative cooling without increasing carcass weight loss (Gigiel et al., 1989).

Postmortem shrinkage is the result of evaporation and drip loss of carcass wash water and loss of moisture by the carcass components (Smith & Carpenter, 1973). Evaporative weight losses of up to 2% of the hot carcass weight have been reported during the initial 24 h of conventional air chilling of beef, pork, and lamb (Greer & Jones, 1997). In a study conducted on 1,000 lamb carcasses, during the first 36 hours, 92% of the 72 h weight loss had already occurred (Smith & Carpenter, 1973). This study determined that shrinkage continues to increase with increased time in the cooler, but at a decreased rate (Smith & Carpenter, 1973). The majority of the initial carcass weight loss that was experienced in this study was due to evaporative losses of water added during washing. The approximately 39% of the weight loss remaining occurred in the next 60 h due to evaporative losses of moisture from carcass components (Smith & Carpenter, 1973). Lamb

can be considered fairly susceptible to cold shortening because of exposed musculature and high surface-to-volume ratio that leads to excessive evaporative weight loss (Brown et al., 1993).
In commercial practice, there is considerable variation in the duration of spray chilling, and the amount of water deposited on carcasses in a specified period of time is usually not known (Greer & Jones, 1997). It appears that spraying carcasses in the initial 3 to 12 h of carcass chilling is relatively common within the commercial setting (Greer & Jones, 1997).

Shrinkage
Shrouded beef carcasses chilled overnight in conventional systems typically shrink from 0.75 to 2% (Kastner, 1981). There have been numerous studies conducted on spray chilling systems that significantly reduce this inherent level of shrink. Heitter (1975) described the Chlor-Chil system used by Swift and Company as an innovative method to reduce carcass shrink while reducing the amount of spoilage bacteria normally present on carcasses in the cooler. This system involved the intermittent spraying of a mild solution of chlorine and water to achieve reductions of carcass shrink that varied from 0.5 to 1.25% (Heitter, 1975). Heitter (1975) went on to say that this shrink reduction that was realized in the chilling operation was carried through to the trimmed cuts. In one of multiple studies that compared spray chilled sides to conventionally chilled sides, Allen et al. (1987) found that after 24 h, spray-chilled beef sides shrank 1.14% less than conventionally chilled sides. In a similar study conducted by Jones, Murray, & Robertson (1988), beef sides spray chilled for 12 h and unshrouded beef sides spray chilled for 8 h had significantly lower carcass weight shrinkages to 6 d than control sides. Jones and Robertson (1988) found that shrinkage was reduced by 0.48 to 0.89 as the spray-chilling period was increased from 4 to 12 h. Hippe, Field, Ray, and Russell (1991) determined that the percentage of cooler shrink for beef sides at 2, 4, 6, and 24 h was lower for spray chilled versus conventionally chilled at all times postmortem.

Lee, Hawrysh, Jeremiah, and Hardin (1990) found that when comparing spray chilled and conventionally chilled beef sides that were both shrouded and unshrouded, unshrouded, spray chilled sides displayed the lowest percent carcass shrinkage after 24 h. They found that spray chilling unshrouded sides would result in a 1.3% savings in side weight. In a similar study by Strydom and Buys (1995), spray chilled beef sides resulted in a 1.1% savings in side weight versus conventionally chilled sides, regardless of duration of spray chilling. On a contrary note, Greer and Jones (1997) discovered a linear relationship between spray chill duration and carcass weight loss, and determined that carcass shrinkage was only reduced by 0.08 g/100 g for every hour of spray chilling.

Shrinkage of conventionally chilled pork can average from 1.85 to 100 g (Jones, Jeremiah, & Robertson, 1993). Conventional pig chilling systems work to reduce pork temperature to 4°C (Brown & James, 1992). James, Murray, and Robertson (1988) determined that a spray-chilling regime could have a significant effect on pork carcass shrinkage while increasing cooling rate of the muscles in the loin and ham. This study revealed that an average 79 kg pork carcass could receive an approximately 1.61 kg advantage in cooler shrink if spray chilling were utilized.

Quality characteristics
An additional benefit of spray chilling discovered by several researchers is an improvement in carcass quality. Allen et al. (1987) observed skeletal maturity to be significantly younger in beef sides that were spray chilled due to visual differences in skeletal ossification. This group determined that it would be advantageous to use spray chilling to improve quality grade when chilling carcasses with maturity that lies near the line drawn between younger and older classed grades. Jones and Robertson (1988) found that beef muscle color was not influenced by the spray chilling process, but fat from spray chilled sides where the spray period was 8 h or more had significantly higher Y^* values than control sides. Greer and Jones (1997) expressed similar results with no real effect of spray chilling on beef lean color, but fat L^* values that were consistently higher on spray chilled carcasses at most locations after 4, 8, 12, and 16 h of spray chill. They recovered generally lower a^* and b^* values after 12 and 16 h of spray chill, and fat developed a washed out, grey appearance after 16 h of spray chilling. It also has been reported that shear values, and therefore tenderness, are not affected by spray chilling (Hippe et al., 1991; Greer & Jones, 1997; Jones & Robertson, 1988; & Lee et al., 1990).

Purge loss

There is some evidence that the initial advantage noted in spray chilled beef sides is lost as purge during the first 15 days of vacuum storage (Allen et al., 1987). Greer and Jones (1997) demonstrated that spray chilling did not affect weight losses from the *M. longissimus thoracis* muscle in comparison to air chilled controls, after spray durations of 4, 8, 12, or 16 h, or storage temperatures of 1, 4, 8, and 12°C for up to 44 days of vacuum storage. Hippe et al. (1991) also reported that purge losses from vacuum packaged top rounds stored 5 or 10 weeks were not significantly different between spray chilled and conventionally chilled sides. Jones and Robertson (1988) determined that drip or purge losses over 6 days in vacuum packaged ribs and inside rounds were similar between spray chilled and conventionally chilled sides. Brown et al. (1993) also reported no increased drip-loss or cooking-loss from samples taken from spray chilled lamb sides. Strydom and Buys (1995) reported that 17 h of spray chilling had no effect on purge loss of vacuum packaged wholesale (7d) or retail display (3d) beef cuts. With this experiment, none of the moisture conserved during chilling was lost during vacuum packaging, retail display, or cooking. However, Allen et al. (1987) reported small (0.26%) increases in purge from inside rounds of spray chilled carcasses.

Shelf-life/microbial quality

There is some concern that the economic advantage of decreased shrinkage may be affected by a slight decrease in microbiological quality (Hippe et al., 1991). However, there is evidence that spray chilling does not affect bacterial counts (Hamby et al., 1987; Strydom & Buys, 1995; Brown et al., 1993), or may slightly reduce bacterial counts (Greer and Dilts, 1988). Greer and Jones (1997) showed that spray chilling had no effect on bacterial growth on the *M. longissimus thoracis* muscle (44 d) or retail cuts as compared to commonly chilled sides even after they were subjected to extremes in spray duration of up to 16 h and vacuum storage temperatures of up to 12°C. Dickson (1990) reported that spray chilling did not affect survival or growth of *Listeria monocytogenes* for up to 42 d of vacuum storage of beef. In a study performed by Jeremiah and Jones (1989), retail case life of chops from spray-chilled pork sides was typically shorter than those from conventionally chilled sides.

Rate of temperature decline

There are many variables influencing chilling rate including: size, shape, and fatness of the carcass, temperature, relative humidity, and flow pattern of the air (Smulders et al., 1992). It has been hypothesized by James (1996) that higher rates of heat transfer, and the heat extracted to evaporate the added water used during spray chilling, should substantially reduce carcass chilling time. Jones and Robertson (1988) indicate that spray chilling significantly affected rate of cooling in the *M. semimembranosus* (SM) and *M. longissimus dorsi* (LD) of beef. This group saw 1 to 2°C increases in the temperature declines of these muscles when sides were both shrouded and unshrouded with spray chilling duration of 8 and 12 h. This effect was most pronounced in the SM because of its position in the carcass and the fact that muscles in the round are closest to the source of water used in the spray chilling process. This effect is also enhanced by a relatively thin fat cover (Jones & Robertson, 1988).

In another study performed by Lee et al. (1990), after 8 h, LD and SM muscles from spray chilled sides had lower muscle temperatures than those that were conventionally chilled with both shrouded and unshrouded carcasses. Brown et al. (1993) also noticed small differences in chilling rate between lamb legs and loins of multiple spray chilled carcasses and those that were conventionally or double spray chilled. On a contrary note, Hippe et al. (1991) reported no differences in postmortem temperatures of *M. semitendinosus*, *M. longissimus*, or *M. serratus ventralis* muscles between sides that were spray chilled and those chilled normally.

Rapid/Blast Chilling

Systems to rapidly reduce carcass temperatures have been investigated for a variety of reasons and with a variety of results. Terms used to describe this category of chilling include but are not limited to “rapid,” “ultra-rapid,” “blast,” “very fast,” and “extreme,” with no consistent definition used by authors in defining

these systems. In this review, our focus was to maintain the terminology used by the authors rather than standardize it.

Some rapid systems are used for regulatory reasons. According to Bowater (2001), in the EU, beef and lamb carcasses must reach internal temperatures of 7°C after 24 h or before moving the carcass to the boning room (pork must reach 4°C after 24 h or before moving the carcass). In the U.S., there are no regulatory requirements for specific temperature endpoints for chilling livestock carcasses; however, the U.S. poultry industry routinely uses rapid chilling because of the United States Department of Agriculture, Food Safety and Inspection Service regulatory requirement that poultry be chilled below 4.4°C before 4 h postmortem.

All frozen poultry begins the chilling process by being immersed in chilled or ice water (Brown and James, 1992). Ultra-rapid chilling consists of two stages, the first of which is a pre-chiller, such as an air-blast tunnel (Brown and James, 1992). This pre-chiller works to quickly reduce surface temperature in order to decrease the amount of evaporative weight loss. It also helps to absorb the initial heat load of the chiller (Brown and James, 1992).

When used in beef, rapid chilling has been shown to produce considerable toughening and severe consumer reaction, and tenderness has been identified as the consumer's number one concern (Joseph, 1996). However, Bowling, Dutson, Smith, and Savell (1987) have shown that it may be possible to chill beef carcasses at extremely rapid rates with less carcass shrinkage and with no detrimental effects on quality grade or cooked beef palatability. According to McGeehin, Sheridan, and Butler (2002), rapid chilling in the lamb industry could eliminate the need for overnight chilling, allowing lambs to be shipped on the day of slaughter in order to combat the relatively short shelf life of fresh lamb.

In the study mentioned above conducted by Bowling et al. (1987), rapidly chilled sides produced beef that was more tender than conventionally chilled sides, and loin steaks from rapidly chilled sides were more juicy and desirable in overall palatability. Rapidly chilled sides experienced 0.9% less shrinkage during the first 24 h postmortem than conventionally chilled sides, and received higher marbling scores. These sides also had darker and softer lean as compared to conventional sides (Bowling et al., 1987).

Very fast chilling (VFC) has been defined as the achievement of a carcass temperature of –1°C within 5 h of postmortem chilling (Aalhus, Robertson, Dugan, & Best, 2002; Joseph, 1996). It has been proposed that toughening in lamb could be prevented by freezing in less than 4 h postmortem to cause surface hardening that restrains cold shortening (Joseph, 1996; Davey & Garnett, 1980). A study by Brown and James (1992) revealed that pork loin chops from ultra-rapidly chilled sides stored for 2 d were tougher than those from conventionally chilled sides. Joseph (1996) also identified the problem of variability in VFC meat because of storage temperature gradients produced in muscle during the VFC process. The practice of freezing lamb carcasses pre-rigor was researched by Watt and Herring (1974). These authors determined that pre-rigor freezing is known to produce toughening, and this type of rapid chilling can result in crust frozen carcasses that require extensive thawing time before fabrication can begin (Watt and Herring, 1974).

In the study by Watt and Herring (1974) on lamb carcasses, those that were chilled more rapidly had brighter lean and whiter fat, and experienced shrink savings that were maintained through shipping. This method of chilling resulted in a toughening of the *M. longissimus* up to 16%, and up to 7% in the *M. semimembranosus*, *M. semitendinosus,* and *M. biceps femoris*. Rapid chilling results in toughening in pork, but that can be improved using electrical stimulation (Gigiel et al., 1989). Chilling pork to internal temperatures of 20 to 25°C within 2 to 3 h postmortem can reduce pale, soft, and exudative characteristics, but muscle should not be chilled below 10°C in the first 5 h postmortem (Reagan & Honikel, 1985). Kerth et al. (2001) reported a reduced incidence of PSE meat from pigs carrying the Halothane gene when pork was cooled using accelerated chilling. Liquid nitrogen chilling was shown by Borchert and Briskey (1964) to prevent PSE conditions without affecting 24 h pH. Accelerated air chilling has been shown by some to improve water-holding capacity (WHC) in pork (Kerth et al., 2001; Taylor, 1971; Taylor & Dant, 1971), and to have no effect on WHC by others (Gigiel & James, 1984; Jones, Jeremiah, & Roberts, 1993). Bertram, Donstrup, Karlsson, Anderson, and Stodkilde-Jorgensen (2001) found increased WHC when using rapid tunnel chilling versus conventional chilling.

Sheridan (1990) reported that an ultra-rapid lamb chilling system was capable of producing tender loins after 7 d of storage by chilling at air temperatures of -20ºC for 3 to 5 h with an air speed of 1.5 m/s. This work led to the recommendation that lamb carcasses should not be chilled less than 12 to 14 h at 3 to 4ºC in order to prevent cold shortening (Sheridan, 1990).

Some studies paired the use of electrical stimulation with blast chilling in order to further prevent cold shortening, and therefore ensure more tenderness. In a study conducted by Aalhus, Janz, Tong, Jones, and Robertson (2001) that employed blast chilling and electrical stimulation in combination, shear force values in the *M. longissimus lumborum* (LL) of beef sides were decreased by 9.5% when compared to conventionally chilled sides. The proportion of extremely tough LL steaks also was reduced by 1.3%. The authors reported that blast chilling had no effect on marbling score, and blast chilled/electrically stimulated carcasses had brighter lean color when compared to conventionally chilled carcasses. Also, leaner carcasses experienced approximately 0.3% less cooler shrink when blast chilling was applied, and blast chilling was able to reduce the increased drip losses normally associated with electrical stimulation. As a result of these findings, Aalhus et al. (2001) was able to recommend to the industry the combination of blast chilling and electrical stimulation in order to reduce postmortem chilling times and shrink losses while continuing to produce meat quality.

Rapid chilling regimes produced significantly lower percentages of cooler shrink (Bowater, 1997; Aalhus et al., 2002) along with an increased perception of marbling, darker meat color, and increased drip loss in research conducted by Aalhus et al. (2002). Aalhus et al. (2002) found that for –20°C and –35°C blast chilling temperatures, shrink losses in beef decreased as time in the blast chill tunnel increased. After 7 h of –35°C blast chilling, cooler shrink was totally eliminated, and sides began to gain weight after 10 h of this treatment. Very fast chilling in this experiment was achieved in the *M. longissimus thoracis* after 7 and 10 h of –35°C blast chilling. The best combination they found was 10 h blast chilling with 6 d aging to produce low shear values and a high proportion of tender and probably tender steaks. Aalhus et al. (2002) identified the advantage of VFC as a reduction in the aging time necessary to achieve an acceptable product. Blast chilling of pork before the start of conventional chilling is reported to decrease shrinkage and give pork a darker and firmer lean (Jones et al., 1988).

Conclusions

Methods of chilling carcasses greatly impact the quality and palatability of meat with the results of these methods being very species-specific. In beef and lamb, employing chilling systems that minimize cold shortening should be a goal. Processes such as delayed chilling can successfully prevent or reduce the negative influence of cold shortening, however, food safety concerns and the need for maximum throughput in commercial facilities makes this system less applicable today. Commercial uses of electrical stimulation and alternative carcass suspension programs offer meat processors the opportunity to negate most or all of the effects of cold shortening when traditional chilling systems are used.

For pork, because of the role of elevated muscle temperature and low pH on the development of PSE, more rapid chilling systems have been employed to remove heat and slow the pH decline in an attempt to reduce the incidence of PSE. However, there still can be quality issues as a result of the differential between the extreme cold temperatures on the outside of the carcass and warm muscle temperatures in the deep regions of the carcass causing two-toned muscles (i.e., muscles that are darker in color externally and lighter in color internally).

COLOR STABILITY OF TRAY-PACKAGED FRESH PORK SAUSAGE LINKS IN LIGHTED DISPLAY

Acton, J.C., Grimes, L.W. and Skelley, G.C.

Department of Food Science & Human Nutrition, Clemson University, Clemson, South Carolina, 29634-0316 USA

Background

Fresh pork sausage is prepared with fresh or frozen pork, seasonings, and not more than 3% water or ice that may be added to facilitate chopping or mixing. Additionally, the finished product may not contain more than 50% fat (CFR, 2003). Manufacturers generally stuff the sausage in flexible films for linking as 0.45 kg chubs or in natural, synthetic, or collagen casings as small links that are typically utilized as a breakfast item. Fresh pork sausage also may be prepared in pattie form. An important step in preparation of this type sausage is maintaining a low temperature to prevent fat smearing when the fresh mix is coarsely ground or chopped and then stuffed. Particle definition of the lean and formation of oxymyoglobin are necessary to provide proper appearance in the finished sausage since it is marketed as a raw, uncooked product. With good sanitation programs and proper handling, low microbial counts are usually found (Surkiewicz *et al*., 1972). Most manufacturers ship the product frozen and thawing is conducted just prior to retail display. Shelf life expectations in display are generally in the range of 14-21 days (Anon., 2004, Sebranek *et al*., 2004).

Objectives

The purpose of this study was to evaluate the retention of fresh lean color of tray-packaged pork sausage links during lighted display as based on panel ratings and to provide an estimate of the range in shelf life when placed in display.

Materials and methods

Six fresh pork sausage mixes were prepared in a regional processing plant operating under USDA inspection. The mixes were stuffed in collagen casings yielding links of approximately 1.8 cm diameter and 9.3 cm in length. Individual links were then conveyed through a CO_2 freezer tunnel and frozen before being tray packaged. Fourteen links were arranged in a 7 link (column) x 2 link (row) array on foam trays and the trays were over-wrapped with film of high oxygen transmission rate (>10,000 cc/m^2/24 hr at 1 atm, 0% RH, 23^{o}C). Trays of frozen links from each mix were express shipped overnight from the plant to our laboratory, removed from the shipping container which contained dry ice, and placed in an onsite freezer (-16.2^{o}C) for 6 days. Each mix served as an experimental replicate (n = 6).

Two randomly selected trays from each coded sausage mix were placed in the dark at 2±1^{o}C and allowed to thaw for approximately 22 hr. The thaw period was designated day 0. After thawing, the 12 trays were placed in a display cabinet at 2±1^{o}C under 1615 lux of lighting provided by Cool White fluorescent lights. This day was designated as day 1. At 12 hr intervals, the trays were rotated between the lighted display and dark storage for the next 21 days. The last day of display was day 22.

Color evaluation was conducted by 9 panelists familiar with fresh pork sausage and prior evaluations for fresh meat color. Each panel member had previously been screened for color vision using the Farnsworth-Munsell 100 Hue test consisting of arranging 4 sets each of 25 colors in the correct hue sequence. Normal color vision observers make few mistakes in the arrangement. Two preliminary color evaluation sessions were also conducted using fresh and discoloured sausage link packages to familiarize panelists with the color rating system and display equipment. From day 1 through 22 within a 3 hr period (8 a.m. – 11 a.m.), each panelist rated the sausage color on an 8-point scale (8 = very bright red lean; 5 = slightly red lean; 4 = slightly dark red lean; 1 = extremely dark brown/grey of lean) and also selected the “best” 3 samples and “worst” 3 samples among the 12 trays. Color evaluations continued for the 22 day period excluding weekend days. Each day the 12 trays were randomly arranged in the display and assigned a new 3-digit numerical code, selected at random, to prevent panel members from associating any code with a particular sausage mix.

Preliminary statistical analyses involved general linear model analysis of variance (ANOV) (SAS, 1996). After establishing that the color rating fit a quadratic response over time as compared to a linear response, data were analyzed by least squares (LS) ANOV according to a randomized block split plot in time design. Polynomial regressions of rate on day were fitted for each sausage mix and the linear and quadratic coefficients (β_1 and β_2, respectively) were compared using linear contrasts. The regression used was as follows: $Y = y + \beta_1 (x - 11.022) + \beta_2 (x - 11.02)^2$ where Y = predicted color rating, y = LS mean of the sample color rating, β_1 = linear coefficient for "rate of change with time", x = day of sample display (from 1-22), β_2 = quadratic coefficient for "rate of change in the 'rate of change with time'", and 11.022 = day constant for days 1-22. LS means for the color rating for all sausages over all dates were also compared using linear contrasts.

Results and discussion

Preliminary analysis of the data by ANOV showed a significant ($P<0.001$) difference among panelists, sausage mixes, and days of display. Duplicate samples of the sausage mixes was not ($P>0.05$) a factor in color ratings over the evaluation period. Time (days of display) was the largest contributor to the sum of squares in the analysis. A number of interactions were significant (mixes*duplicates, mixes*days, mixes*duplicates*days), all involving the sausage mixes. Nonsignificant interactions were duplicates*days and panelists*mixes*duplicates, the latter serving as the error term for each component in the interaction.

The polynomial regressions coefficients for each mix are given in TABLE 1 with linear contrasts comparisons for significant differences determined using least significant difference (LSD) at $P = 0.05$. There was a significant difference ($P<0.05$) between the LS mean for color rating (y) for sausage mix 5 (highest LS mean of 6.10) compared to sausage mix 1 (lowest LS mean of 5.30). These extreme LS mean comparisons encompass the 22 day display period. Neither mix 5 nor 1 had a color rating different from the other mixes. This confirms that in following a sausage mix formulation involving different pork meat selections combined for mixing, seasoning, grinding, stuffing, packaging, storing frozen for shipping, thawing and then displaying for a 22 day period, five-of-six different production runs made for this study were not different in color ratings as judged by the panel members. The rate of change with time (β_1) shows that sausage mix 5 had the lowest rate of color loss ($\beta_1 = -0.151$) whereas mixes 1 and 4 had the highest rates ($\beta_1 = -0.242$ and -2.58, respectively). Other mixes (TABLE 1) were generally intermediate in rate in which color ratings decreased. No practical significance can be attached to the β_2 coefficient.

Data on panel selections for "best" and "worst" samples among the 12 packages evaluated over the 22 day period (TABLE 2) are consistent with the other findings in that sausage mix 5 was selected more frequently in the "best" category (29.9% of responses) and less frequently in the "worst" category (9.4% of responses). Opposite findings are present for sausage mix 1 which had the lowest LS mean for color rating and one of the highest rates of color change.

The average daily color ratings over all panelists from evaluations of the duplicate packages of sausage mixes 5 and 1, as examples of the extremes for fresh color retention, were plotted against the day of evaluation (FIGURE 1). The plot was then visually extrapolated to the approximate maximum number of days each sausage mix had an average color rating of 5.0 or higher (5 = slightly red lean). This provides an estimate of the range in shelf life for this product. Sausage mix 5 maintained a rating of 5.0 or higher for 16-17 days whereas mix 1 maintained the rating for 12-13 days. Other mixes would have expected color retention for time periods between the findings for these two mixes. Most manufacturers expect a display life of 14 days with a few additional days in the consumer's home for fresh pork sausage prepared and held as given in this study.

Conclusions

Fresh pork sausage links from 5 of 6 different production runs did not differ in rate of color loss over a 22-day lighted display period. Redness retention of the lean particles as rated by a trained panel indicated a product color life of 12-13 days to 16-17 days.

BEEF CHARACTERISTICS OF THREE MUSCLES FROM COW AND YOUNG BULL

Barge M.T., Destefanis G., Barge P. and Brugiapaglia A.
Dipartimento di Scienze Zootecniche, Università di Torino, Via L. da Vinci 44, 10095 Grugliasco, Italia

Background

The social evolution has brought the consumer to prefer products of a high and uniform quality. This is also true for beef, whose characteristics are anyway conditioned by intrinsic and extrinsic factors which increase its variability. In the retail sale, beef is still a quite undifferentiated product and this does not agree with the needs of modern consumers. It is therefore of great importance to know in a more detailed manner the characteristics of meat in relation to the affecting factors so as to provide correct information to the consumer.

Objectives

To study beef characteristics in relation to the animal category and muscle type.

Materials and methods

A portion of *longissimus* (the lowest thoracic vertebrae), the *semitendinosus* and the *supraspinatus* were taken at commercial slaughterhouses from half-carcasses of cattle of various breeds and crosses (14 cows aged between 39 and 143 months and 10 young bulls between 12 and 19 months). The samples were analysed for chemical composition, water-holding capacity (drip losses during 48h; cooking losses in water bath until an internal temperature of 70°C was reached), Warner Bratzler shear force (maximum value in kg and work done in kg cm) on cylindrical cores 2.54 cm in diameter obtained from steaks used to determine cooking losses; measured by an Instron 1011 equipped with a Warner-Bratzler shear device.
The data were subjected to the variance analysis (ANOVA of SAS), considering as sources of variation the category, the muscle and their interaction.

Results and discussion

For each examined parameter, table 1 shows the R^2 value of the model and the factors which have a significant effect, as well as the least square means of the subgroups and of the groups.
Water content appears to be influenced by both the muscle type - higher in SS than in ST, which in turn contains more water than LD - and the category, the meat of cows being less humid than that of young bulls. Also in the experiment by Destefanis *et al*. (2003), carried out on Piemontese young bulls, LT contained less water than ST and SS. Also in Piemontese and Belgian Blue and White hypertrophied young bulls (Destefanis *et al*., 1996) the water content was the highest in SS (77.40%), followed by ST (75.96%) and by LT (75,27%). The present data confirm that the decreasing order for water content in beef is the following: SS, ST, LD. In the study of Gerhardy (1995), the meat of young bulls in average showed a higher humidity than that of cows, the difference being significant in ST, but not in LD.
Category does not influence the protein content, which appears very similar for all three muscles, in accordance with the results of the study by Fiems *et al*. (2003), in which the mean for cows (22.2%) was very close to that of young bulls (22.1%). On the other hand, muscle type influenced the protein content, the LD and ST being richer in proteins than SS (less than 20%). The low protein content in SS and the similar values for LD and ST are consistent with the data reported in the bibliographic survey on muscle type by Barge et al. (2001) and with the results of Barge *et al*. (1993) and Destefanis *et al*. (1996).
Unlike the previous parameters of composition, lipid content was influenced by both factors (P=0.0001), which also interacted each other. Both in cows and in young bulls, LD appeared to be the fattest and ST the leanest. In young bulls, however, LD contained almost twice as much lipids than ST, whereas in cows almost three times. In young bulls, Destefanis *et al*. (2003) reported that SS was the fattest of the three muscles and ST the leanest, while Barge *et al.* (1993) reported that ST was significantly different from SS, with LT in between. Both studies indicated ST as the muscle with the lowest lipid content. On the contrary, Destefanis *et al.* (1996) observed no significant difference between the muscles, the low fat content of hypertrophied young bulls being comprised between 0.39 in LD and 0.46 in SS, with ST in the middle.

For all three muscles and more clearly for LD, the lipid content was higher in cows than in young bulls (2.93 *vs.* 1.35% respectively). A higher fat content in cows than in young bulls (2.3 *vs.* 1.1%) has recently been reported by Fiems *et al*. (2003), whereas our data only partially agree with the results of Gerhardy (1995), which showed a difference between cows and young bulls significant for ST, but not for LD, indicating the relevance of the former muscle for meat analyses. In both muscles, cows contained less than twice as much fat as in young bulls. It should be noted that general mean of all our 72 meat samples is 2.1%, indicating that, even if belonging to commercial carcasses, beef is not as rich in fat as sometimes mass media tend to show. Berg *et al.* (1985) stated "The concept that meat is high in fat and cholesterol is widespread. The effect of this perception has created an atmosphere of negative attitudes which … continue to be reinforced by the usage of outdated data on the nutrient composition of meats".

As far as the haeminic iron is concerned, the adopted model accounts for 58% of the variance and its content is influenced both by category and the muscle type (P=0.0001). Regarding the latter factor, the decreasing order of iron content is: SS, LD, ST. Also Destefanis *et al.* (2003) found SS richer in iron than LT and ST. Concerning the category, cow meat appears remarkably richer, the iron content being one and a half times greater than in young bulls. This is true for all three muscles, but it is particularly relevant in SS. The observation on the difference between the categories seems related to the fact that the quantity of pigment also depend on the age of the animals. In Renerre (1982) the increase in iron with age varied considerably according to the muscle examined and, in the opinion of the Author, these differences were due to the different metabolic type of the muscle fibres.

When studying the haeminic iron content in two muscles of cows and young bulls, Dumont and Bousset (1990) indicated average value of 20.05 μg/g for *longissimus thoracis* and 20.50 for *pectoralis ascendens* of cows and 11.8 and 13.5 for the same muscles in young bulls. In particular, the values of LT ranged between 9.20 μg/g and 15.9 for young bulls and between 15.80 and 26.10 in cows. We observed a similar slight overlapping of categories in SS, ranging from 9 μg/g to 16 in young bulls and from 14 to 28 in cows.

Drip losses - The factors significantly influenced this parameter, for which the general mean indicated a loss of 2% in 48 hours. The losses appeared to be greater for young bulls in all three muscles and especially in ST. Similar results were found by other Authors. In Barnier (1995), drip losses of muscular portion were greater in Friesian young bulls than in cows of the same breed, both in *longissimus* and in *semimembranosus*. Also Fiems *et al.* (2003) found drip losses inferior in cows that in young bulls.

As far as the muscle type is concerned, ST showed greater losses than the other two muscles. The results perfectly agree with other experiments. In Honikel and Potthast (1991) the muscle significantly affected the percentage of drip loss: the highest was in ST, the lowest in SS, in between lied LD. In Destefanis *et al.* (1994) drip losses were greater in ST than in LT, which in turn were greater than in SS. Hypertrophied young bulls showed a significant interaction between muscle and breed (Destefanis *et al.*, 1996). Anyway, drip losses tended to be greater in ST (4.44%) compared to LT (2.64%) and SS (2.51%).

Cooking losses - This is the parameter for which the highest R^2 was obtained, indicating that the adopted model accounts for over two thirds of variability. The considered factors of the model influenced and interacted in a significant way. Also for this parameter, cows showed a lower loss than young bulls, particularly in SS. In ST cows loose less fluid, but the difference was not significant. In LD the situation tends to be reverted, with slightly higher values for cows, even if not statistically different. Gerhardy (1995) found not significant differences between six cattle categories for cooking losses at 75°C both for LD and for ST. However, the data indicated a tendency to slightly greater losses in young bulls than in cows (33.41 *vs.* 32.67% in LD); on the contrary, statistically significant differences between categories appeared for cooking losses at 55°C only in LD. Also in the study of Fiems *et al*. (2003) young bulls showed statistically higher cooking losses than cows (25.1 *vs.* 23.6%).

As for muscles, the order for losses in both categories was ST, SS, LD. In young bulls, however, ST and SS were very close and did not differ much from each other. Similar results were obtained by Destefanis *et al*. (1996), with LT showing significantly smaller losses than SS and ST (similar to each other).

WB max - The category had a great influence (P=0.0001), showing average values of 15.72 kg in cows *vs.* 10.66 in young bulls. The muscle did not affect the parameter nor did it interact with the other factor. It should be noted that the values of the muscles are near within the category: from 10.22 in LD to 11.28 kg in SS for young bulls, and from 14.83 in SS to 17.13 kg in ST for cows. On the contrary, a lower shear force for LT was found by Destefanis *et al*. (2003). If we consider that the three muscles of the present study belong to cuts of different economic value, due to the assumed tenderness of the product, the proximity of the values of these muscles is quite remarkable.

WBw - The two factors had an influence on this parameter and interacted. The model accounted for a great part of the variability (54%). The meat of cows required a greater work than that of young bulls for all muscles, but the difference varied from 27% in SS to 40% in LD, up to 70% in ST. Gerhardy (1995) had reported significant differences between the categories of cattle for maximum shear force and for shear force done in LD only for the cooking at 55°C (mean values higher in cows than in young bulls and in heifers), whereas significant differences were found in ST (higher value in cows *vs.* young bulls for two out of three cooking methods). As for the muscle type, in young bulls the LSM ranged from 20.82 kg cm in LD to 22.60 in SS, values statistically not different. In cows, instead, the work necessary to shear ST (36.66) was higher than that for the other two muscles (about 29.00 kg cm). In each of the three muscles, WB max and WBw were higher in cows than in young bulls, with a slight difference in SS (+31 and +27%), intermediate in LD (+31 and +40%), greater in ST (+64 and +67%).
Gerhardy (1995) found significant differences between LD and ST for max shear force, for extension and for shear work done, being the values always higher in ST.

Conclusions

The fact that cows had a protein content similar to that of young bulls in all the three muscles examined, indicates that also the meat of cows is a good source of proteins. However, in comparison with young bulls, meat from cows was fatter (about twice and even more in LD) and showed a shear force about 1.5 times higher. In return, it contained one a half times as much iron. Young bulls showed a water-holding capacity less good than cows, loosing more drip and more fluid during cooking (significant difference in SS).
The muscle type significantly influenced many parameters. Among the three muscles used, *longissimus* is the poorest in water but the richest in lipids; it is the muscle with the lowest cooking losses, but most of all tends to low shear force. The *semitendinosus* is the leanest (mean <1.7% even in cows), but contains less iron, shows a poor water-holding capacity and, at least in cows, the highest WB max. The *supraspinatus* contains more water and less protein than the other two muscles, but is richer in iron and tends to loose less drip.
As well as acting on many parameters, at times the muscle interacted with the category, confirming the need to work also on muscles other than *longissimus*, every time that the effect of some factor or of a new technological treatment is being studied. Apart of the interest at research level, a punctual knowledge of the characteristics of beef would allow the consumer to choose the category and the muscle which better suit him, considering that the most valuable products are not necessarily the best with respect to chemical composition or water-holding capacity or shear force.
Instead of pursuing the probably utopian idea of the uniform quality, while keeping on selling beef as an undifferentiated product, perhaps it would be better to study methodically the different characteristics of the muscles, of the categories, etc. and inform the consumer, enabling him to choose according to his objectives.

LIPID OXIDATION AND 2-ALKYLCYCLOBUTANONESIN IRRADIATED TRADITIONAL PORK PRODUCTS

Battaglia A., Zanardi E., Dazzi G. and Chizzolini R.

Dipartimento di Produzioni Animali Biotecnologie Veterinarie, Qualità e Sicurezza degli Alimenti, Università degli Studi di Parma, Italy

Background

Irradiation is the treatment of food involving their exposure, either packaged or in bulk, to carefully controlled amount of ionizing radiation. Irradiation is considered a highly effective processing technology to achieve many technical objectives. Irradiation can kill harmful bacteria and other organisms in meat, poultry and seafood, disinfest spices, extend shelf-life of fresh fruits and vegetables killing insect eggs and larvae and control sprouting of tubers and bulbs such as potatoes and onions.
Similar to other food processes, irradiation has also technical and economic limitations that prevent its use on all foods under all circumstances. Low-dose irradiation treatments do not cause noticeable decreases in the nutritional quality of food, but the change in nutritional values depends on a number of factors: radiation dose, type of food, packaging and processing conditions such as temperature and oxygen exposure during irradiation and storage time (Crawford and Ruff, 1996). Irradiation causes certain chemical changes in food. Irradiation increased lipid oxidation in aerobically packaged meat and developed off-flavours (Ahn, *et al*., 2001b; Patterson and Stevenson, 1995).
Irradiation of fat-containing food generates also a family of molecules, namely 2-alkylcyclobutanones (2-ACB), that results from the radiation induced breakage of triglycerides. They are the only chemical compounds whose formation is thought to be specific for irradiation treatment of foodstuffs (Crone *et al*., 1992, 1993) and, for this reason they are useful for investigation of irradiated lipid-containing foods. These compounds contain the same number of carbon atoms as their precursor fatty acid and an alkyl chain of carbon atoms is attached to ring position 2. Due to the potential effects on human health the more investigated cyclobutanones are 2-dodecylcyclobutanone (2-DCB), 2-tetradecylcyclobutanone (2-TDCB) and 2-(5'-tetradecenyl) cyclobutanone (2-TdecCB). Their precursor fatty acids are listed in Table 1.
The Joint Expert Committee on the Wholesomeness of Irradiated Food of F.A.O., I.A.E.A. and W.H.O. concluded that irradiation of food up to an overall average dose of 10 kGy results in no toxicological hazard to humans. These organizations stated that irradiated foods are safe and nutritious (Joint F.A.O/W.H.O./I.A.E.A Expert Committee, 1981). Although irradiated foods have many known beneficial properties, the effect of long-term consumption of irradiated foods remains unknown. Lack of critical studies addressing the impact of long-term exposure to irradiated foods on human chronic diseases, such as cardiovascular disease, arthritis or various cancers, is considered a problem (Rao, 2003). Considering that some researchers underlined the problem about a potential toxicity of 2-ACB it is very important meanwhile to collect data concerning a wide variety of foods, wishing more investigations of this aspect.

Objectives

The aim of this investigation was to evaluate chemical effects of irradiation used as decontamination treatment on some typical Italian pork products. The research was focused in particular on the collection of preliminary data on the lipid oxidation and the formation of 2-ACB.

Materials and methods

The traditional Italian processed pork products investigated were: salame Milano, coppa and pancetta. Salame Milano is a typical minced, dry cured and fermented pork product; coppa is made up by the entire neck muscle, deboned, cured and afterwards matured in natural casing; pancetta is made up by adipose tissue of the ventral region of the pork and it looks layered alternatively fat and lean.
The products at the end of maturation were portioned and packed under vacuum in transparent plastic bags. For each kind of product the following groups were created: the control group (*Control*, n=5), the group irradiated at 2 kGy (*2kGy*, n=5) and the group irradiated at 5 kGy (*5kGy*, n=5). The treatment was performed using electron beam on refrigerated samples placed on cardboard boxes.

Proximate composition (AOAC, 1990) and fatty acid composition of total lipids (Zanardi et al., 2000) were determined on samples of *Control* groups. The samples belonging to *Control*, *2kGy* and *5kGy* groups were submitted to the following determinations:
- 2-thiobarbituric acid reactive substances test (TBARS test) as described by Tarladgis and Watts (1960), modified by Novelli et al. (1998). The procedure was based on the distillation of malondialdehyde and spectrophotometric determination at 534nm of the product of reaction between the distillate and 2-thiobarbituric acid;
- alkylcyclobutanones determination according the European Standard EN 1785: "Detection of irradiated food containing fat–Gas-chromatographic/mass spectrometric analysis of 2-alkylcyclobutanones".
Among the cyclobutanones, the 2-DCB, the 2-TDCB and the 2-TdecCB were considered in this investigation. The procedure involved a first step of lipid extraction, a second step of purification and concentration of alkylcyclobutanones and their analysis by gas chromatography-mass spectrometry (GC-MS). 12 g of well homogenized sample were mixed with 12 g of anhydrous sodium sulphate in a thimble placed in a Soxhlet extractor and the lipid was extracted by refluxing 160 ml of petroleum ether for a minimum of 6 hours. An aliquot of 200 mg of fat was then dissolved by 1 ml of internal standard (0.5 µg/ml of 2-cyclohexylcyclohexanone in n-heptane). It was applied to the column of 30 g of inactivated Florisil (PR 60/100 mesh, Supelco) and eluted with 150 ml of hexane followed by 150 ml of 1% diethylether in n-hexane. This latter fraction was collected separately, concentrated using a rotary vacuum evaporator and transferred in a test tube. The sample was further concentrated to dryness under a stream of nitrogen and resuspended immediately in 500 µl of n-heptane. GC-MS analysis was carried out on a gas chromatograph 6890N (Agilent Technologies) coupled with a Mass Selective Detector 5973 Network (Agilent Technologies). The column was a DB-5 (30mx0.25 i.d., 0.25 µm film thickness, Supelco). Mass spectrometric analysis was performed by electron impact mode and positive ions. Selected ion monitoring (SIM) was set for 2-DCB and 2-TDCB for ions m/z 98 and 112 and for 2-TdecCB for ions m/z 67, 81, 98 and 109. The retention time and ion ratio of the signals were confirmed to correspond to those of standards (Fluka and Alfa Aesar for 2-cyclohexylcyclohexanone). Quantitative determination of 2-ACB was performed by using the peak areas of ion m/z 98 because common to all compounds. Their concentration was reported as µg/g of sample. The limit of quantification (LOQ) was 0.01 µg/ml for 2-DCB and for 2-TDCB and 0.2 µg/ml for 2-TdecCB.
Analysis of variance (ANOVA) was carried out on the data and the Scheffé's test ($p=0.05$) was used for the evaluation of significant differences (SPSS 11.5 for Windows). Not detected values of 2-ACB, because under the LOQ, were considered as 0.

Results and discussion

General chemical parameters fall in a normal range for products of such a type (data not shown). Data on fatty acid composition of total fat are not reported because not complete.
The data of TBARS values are shown in Table 2. The lowest mean values were found in coppa and they ranged between 0.083 and 0.088 mgMDA/kg. Not significant differences were found between *Control* and treated groups. The highest concentration of TBARS has been found in pancetta. The samples irradiated at 2 kGy reached, indeed, average value of 0.311 mgMDA/kg whereas *Control* and *5kGy* groups scored 0.187 and 0.130 mgMDA/kg respectively. Because of the relatively high standard deviation, however, no significant effect can be attributed to the irradiation treatment. In Salame Milano the samples of *Control* group showed higher values (0.230 mgMDA/kg) compared to *2kGy* (0.135 mgMDA/kg) and *5kGy* (0.124 mgMDA/kg) groups. Despite the significance resulting by statistics analysis, the TBARS values can be considered similar also in the Salame Milano. The high variability of TBARS values among meat products, indeed, has been widely recorded in previous studies and seems to be linked to an intrinsic variability of raw meat. All the results, however, were lower than the suggested threshold for the appearance of rancidity off-flavours in fresh pork (0.5 mgMDA/kg) (Lanari *et al*., 1995). TBARS values were in line with the results of previous investigations (Novelli et al., 1998; Zanardi et al., 2000). The latter mentioned study reports, for example, TBARS values of Salame Milano and coppa around 0.280 and 0,110 mgMDA/kg, respectively, confirming the lower values in coppa. These values proved that, in this case, the irradiation does not accelerate lipid oxidation. This result could be explained by the vacuum packaging adopted in this research. Oxygen has a catalytic effect on irradiation-induced lipid oxidation (Lambert *et al.*, 1992). As has been suggested by some authors, the exclusion of oxygen should help reduce the extent of oxidation of fatty acid in vacuum packed cooked pork sausages compared to the same products packed in aerobic packaging

irradiated at 5kGy (Jo et al., 2003). The same effect of packaging has been observed on cholesterol oxidation in cooked pork (Ahn et al., 2001a). Moreover, the irradiation treatment was carried out on refrigerated pork products. Nawar and Balboni (1970) reported that the amounts of radiolytic products formed on irradiation are sensitive to the temperature at which the irradiation take place.
The data of 2-ACB content in salame Milano, pancetta and coppa are partially showed in Table 3. The three 2-ACB considered in this investigation were under the limit of detection (LOD) in all the pork products of *Control* groups. The irradiation dose 2kGy induced the formation of 2-ACB in all the three types of products. In particular the 2-DCB was observed in a range of values between 0.019 and 0.054 μg/g and the 2-TDCB between 0.029 and 0.039 μg/g in the samples of *2kGy* groups. The irradiation dose 5kGy did not further increase the content of both 2-ACB in salame Milano and coppa whereas induced a significant increase ($p=0.05$) of both 2-DCB and 2-TDCB in pancetta in which 2-DCB reached 0.123 μg/g and 2-TDCB 0.102 μg/g. When these concentrations of 2-ACB were plotted against irradiation doses, a linear response was observed both for 2-DCB and for 2-TDCB (Figure 1). These concentrations resulted also statistically higher ($p=0.05$) than those of 2-DCB and 2-TDCB in salame Milano and in coppa. Probably the difference among pancetta, salame Milano and coppa was due to the different fat content. The average percentage of fat in pancetta was, indeed, about 40%, whereas in salame Milano and in coppa was about 30%.
In Table 3, the values of 2-TdecCB were not included, because it was found occasionally. In all the samples of *Control* groups, in these ones irradiated at 2 kGy and in samples of coppa irradiated at 5 kGy the 2-TdecCB was not detected. These results could be explained by the high limit of quantification (0.2 μg/ml) due probably to the much greater fragmentation of 2-TdecCB in the ion source of the MS. 2-TdecCB was found only in salame Milano and in pancetta irradiated at 5 kGy. The average values were 0.355±0.224 and 0.969±0.422 μg/g respectively. These latter values were higher than the concentrations of both 2-DCB and 2-TDCB at the same dose of irradiation. This result was in line with Park *et al.* (2001) who detected the same 2-ACB in irradiated pork: 2-TdecCB showed the highest content for all irradiation treatments in the range of doses between 0.5 and 10 kGy. Compared to the data reported by the same author, the average content of 2-ACB on fat basis of the present study was lower. Due the absence of data on the use of irradiation of traditional pork products, the explanation of the results of the present investigation could be attributed also for 2-ACB to the packaging conditions. The absence of oxygen could reduce the induced radical species in the matrix.

Conclusions

The present study is a collection of preliminary data on the lipid oxidation and formation of 2-alkylcyclobutanones in some traditional pork products treated by ionising radiation as a decontamination process. The extent of lipid oxidation was not significantly influenced by ionising radiation at 2 and 5 kGy irradiation doses. 2-alkylcyclobutanones have been confirmed to be useful markers of identification of irradiated fat-containing food. 2-DCB and 2-TDCB can provide useful information to distinguish between treated and not irradiated food. 2-TdecCB could be used as an additional marker. Its high limit of quantification can not guarantee the distinction between treated and not irradiated food.
The conditions used during the treatment (vacuum packaging and refrigeration) seem influence both lipid oxidation and formation of 2-alkylcyclobutanones. The packaging can be considered a critical factor affecting the chemical quality of irradiated pork products.

FAT CONTENT REDUCTION IN PIG-SKIN SHEETS BY EXTRACTION WITH SUPERCRITICAL CARBON DIOXIDE

Sagrario Beltrán and Eva María Vaquero

Área de Ingeniería Química. Departamento de Biotecnología y Ciencia de los Alimentos. Universidad de Burgos. Plaza Misael Bañuelos s/n. 09001 Burgos. Spain. Tel.: +34 947 258810. Fax: + 34 947 258831. E-mail: beltran@ubu.es

Background

Collagen is the most abundant protein in animals. This fibrous protein is widely used in the Food Industry for various applications. Most often, it is obtained from cattle skin. However, it is always advisable to count on some alternative sources to eliminate strong dependences on one of them. Pig skin could be such an alternative; however, it has a high fat content that needs to be reduced to meet the specifications required by some of the applications of the food industry. Although there exist some methods to eliminate or reduce the fat content of animal skin, we propose in this work a mild method that can achieve very high reductions or even total elimination of the fat contained in pig skin to achieve a protein concentrate that can be used for most industry processes that need these type of proteins as raw material. This method consist in using supercritical carbon dioxide as a solvent that can selectively extract the fat without affecting the protein.
Supercritical fluid extraction (SFE) is a clean technique that can use low temperatures. Fat and oil extraction with supercritical fluids is widely reported in the literature from a large variety of natural sources such as different types of seeds, spices, meat or marine products (King et al., 1989). The most commonly used supercritical fluid is carbon dioxide due to its mild supercritical temperature and pressure and because it is a gas under ambient conditions what allows an easy separation of the processed products. It is also cheap and achievable with high purity; it is non toxic, non corrosive, non inflammable etc.CO_2 presents a large number of nice features to be used as a solvent for extraction processes. Its main inconvenient is its lack of polarity that makes it a poor solvent of polar solutes. However, it is a good solvent of fat (Bamberger et al., 1988), which is the solute whose removal from pork skin is to be studied in this work.

Objectives

The objective of the work was the search of the process conditions that allowed the highest yield for reducing the fat content of pig skin by using supercritical carbon dioxide. The skin was defatted as part of the treatment for its conditioning to be used as raw material to obtain the collagen paste that is used as casing of Frankfurt-type sausages. Different experiments were carried out to identify the resistance controlling the extraction process and to search for the process conditions that overcame such resistance and gave a high extraction yield.

Materials and methods

The experimental study was made in a semi-pilot SFE-plant whose flowsheet is presented in Figure 1. Pig-skin sheets, around 5 mm thick, were placed in the extractor. The skin could not be ground since, by doing so, the later treatment necessary to obtain the desired collagen paste could not be carried out. The solvent, CO_2, was pressurized up to the extraction pressure and then, it was circulated with a certain flow (F) through the skin trying to achieve a good contact skin-solvent for the extraction to be faster. The solvent was recycled after removing the solute in a separator where the solvent power of CO_2 was reduced by reducing pressure and increasing temperature.
Two types of experiments were carried out. In a first set of experiments, the extraction was carried out continuously during a certain extraction time in order to evaluate the influence of extraction pressure, temperature and time, and initial water content on the extraction yield. In a second set of experiments the extractor was depressurized several times during the extraction experiment in order to take a sample of the raffinate whose analysis allowed to follow the course of the extraction.

Results and discussion

The first set of experiments were designed to study the influence of the extraction pressure (p), temperature (T) and time (t) on the extraction yield as well as the influence of the initial water content. The influence of

pressure and temperature on fat extraction is showed in Figure 2. It can be observed that fat extraction increases slightly with temperature and pressure, but a maximum yield of around 40% was obtained. The maximum temperature assayed was 40 ºC since collagens experience denaturational transitions at temperatures above 40ºC (Privalov et al., 1979). The large error bars in the data are a consequence of the heterogeneity of the fat content of the skin. The results of some additional experiments carried out to study the influence of the extraction time are presented in Figure 3, where it can be observed that even fairly large extraction times did not allow a limit of 60% yield to be overcame.

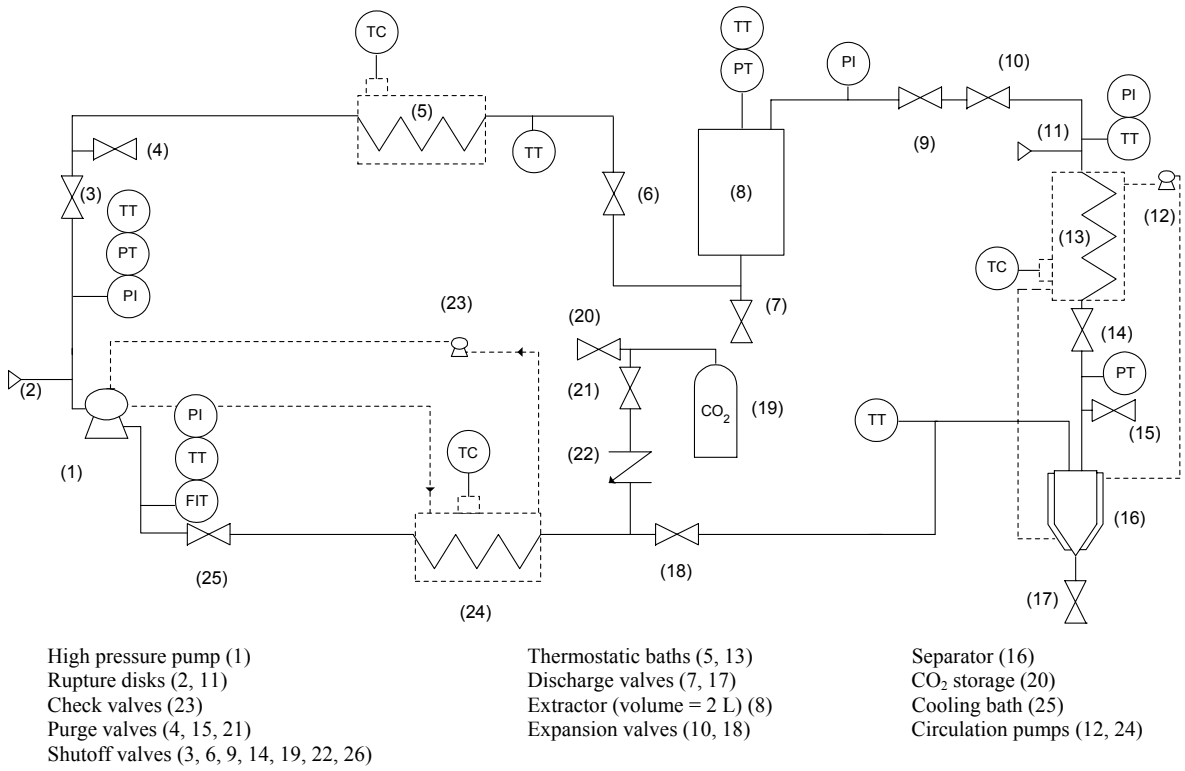

Figure 1. Flowsheet of the SFE semi-pilot plant of the Chemical Engineering Area of the University of Burgos. Maximum specifications: T= 200 ºC, p = 65 MPa and solvent flow, F = 20 kg/h.

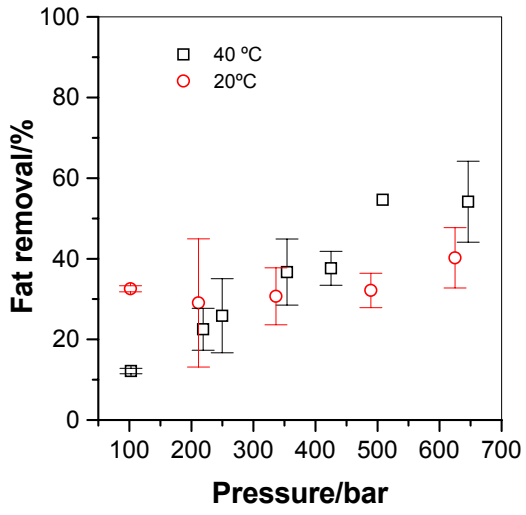

Figure 2. Fat extracted (%) versus pressure. F = 10 kg CO_2/h, skin sheets size = 2 cm × 14 cm, t = 60 min.

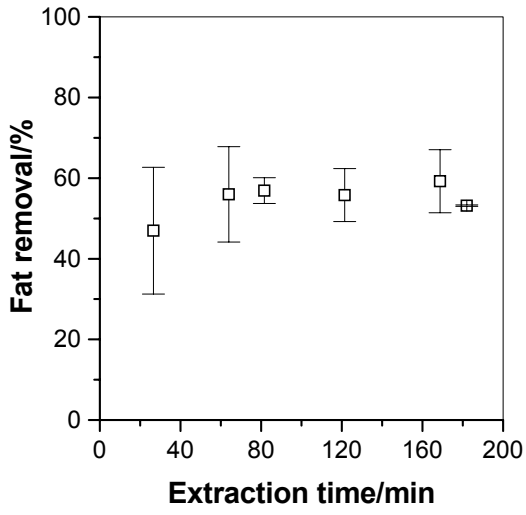

Figure 3. Fat extracted (%) versus extraction time. T = 40 ºC, p = 65 MPa, F = 10 kg CO_2/h, skin sheets size = 2 cm × 14 cm.

The influence of the skin water content on the fat extraction yield was also evaluated. The water content of the pig skin was reduced to different levels in a drier unit. The fat extraction yield obtained when using dried skin was also limited to an approximate value of 60%. Therefore, the study so far, proved that supercritical CO_2 removed the fat from pig skin, but the final concentration of fat was too high for this skin to be used to obtain the collagen-paste of interest. As an extraction temperature increase was not advisable and an extraction pressure or extraction time increase did not produce the required efficiency, a different extraction procedure needed to be assayed.

The fat is located all along the pig skin from the epidermis to the dermis and hypodermis (Compte, 1996). Therefore, it is reasonable to think that, when the skin is not ground, the external fat must be easily removed by the solvent but it must be much more difficult to extract the internal fat. In order to confirm or reject this assumption, some experiments were carried out to follow the course of the extraction process by determining the remaining amount of fat in the pig skin at different extraction times. In this experiments, the extractor was depressurized after some extraction time (called "cycle time") in order to take the skin sample necessary to determine its fat content.

The first observation made when analyzing the results obtained with this new experimental procedure was that the extraction yield of 60 %, that was the maximum obtained when working without depressurizing the extractor, was overcame and even total elimination of fat was achieved in some cases. That is, the successive and rapid depressurizations of the extractor seemed to be "exploding" the fat cell membranes and making the fat accessible to the solvent that extracted the fat much better. Therefore, two new variables that are going to influence the yield of the process have to be taken into account, i.e.: the number of cycles and the cycle time. Besides these variables, the influence of the initial fat content of the pig skin and of the solvent flow on fat removal was evaluated

Figure 4 shows the fat removal as a function of the number of cycles (a) and as a function of the total extraction time (b) for different cycle times. The experiments for cycle times of 10 minutes and 60 minutes were repeated to check for reproducibility of the tendencies. In the first 10 min cycle time experiment, sampling was made after every depressurization of the extractor and in the second experiment, after every three depressurizations. The two experiments carried out at a cycle time of 60 min differed on the initial amount of fat that is expressed in Fig, 4 as grams of fat per grams of protein. Figure 4a shows that fat removal increases when increasing the cycle time up to a cycle time of 60 minutes but larger cycle times do not improve fat removal. Therefore, a cycle time of 60 minutes was considered as the ideal time for the solvent to diffuse into the fat cells, so they explode with depressurization, and for extracting most of the fat accessible to the solvent after the previous rapid depressurizations performed in the extractor. A shorter cycle time required a larger number of depressurizations leading to a substantial loss of on-stream time, and a larger cycle time did not increase the extraction efficiency. Figure 4b shows that the tendencies were much more similar in all cases when the total extraction time was considered. Yields between 90 % and 100% were obtained in all cases after 4 hours of extraction.

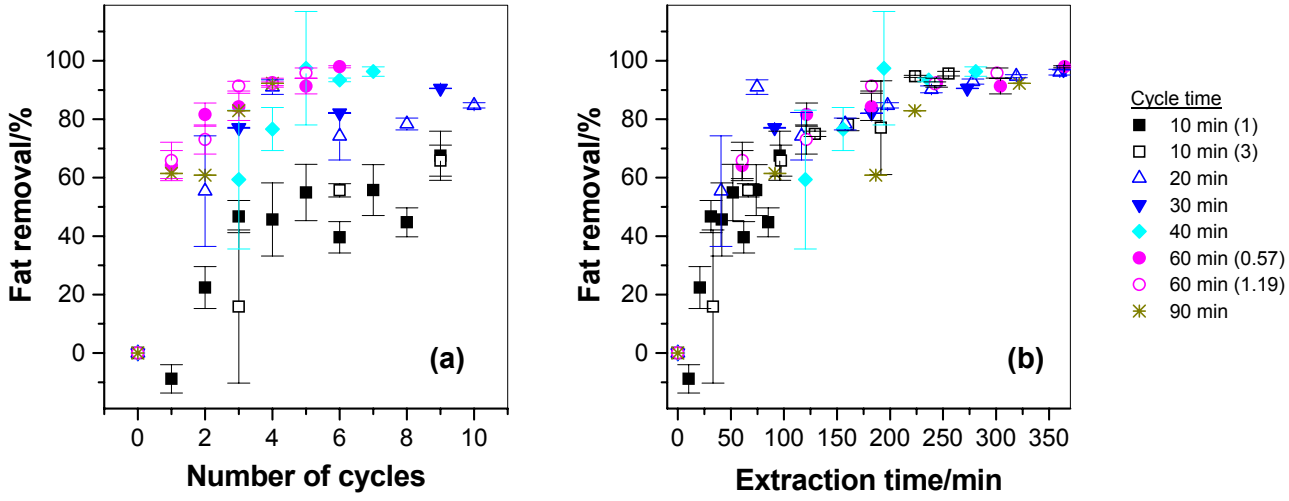

Figure 4. Percentage of fat removed against number of cycles for different cycle times (a) and as a function of total extraction time (b). T = 40 ºC, p = 35 MPa, F = 10 kg CO_2/h. skin sheet size = 15 cm × 14 cm.

Figure 5 presents the amount of fat in the skin, in a protein bases, as a function of the extraction time for different skin sheets with different initial fat contents. If fat removal was considered, there was no distinction between the two experiments indicating that the percentage of fat removed in a certain time is similar in both cases; however, Figure 5 shows that the fat content in the skin only reaches similar values for the two experiments after three hours of extraction. These experiments lead to the conclusion that the initial fat content in the skin is a variable to take into account. Therefore, the better the mechanical fat removal was performed, the lower the extraction time was for a given final fat content.

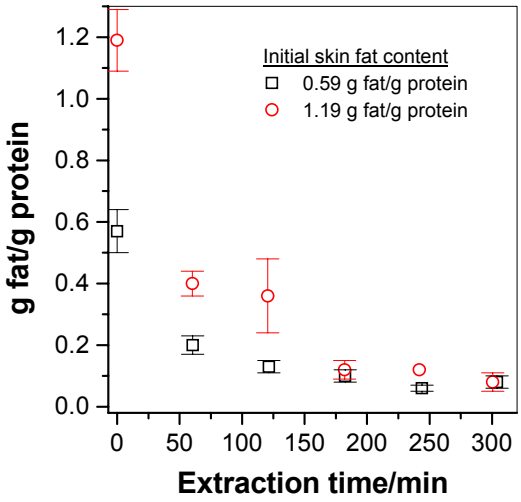

Figure 5. Fat content as a function of extraction time for different initial skin fat contents. T = 40 ºC, p = 35 MPa, F = 10 kg CO_2/h, skin sheet size = 15 cm × 14 cm, cycle time = 60 min

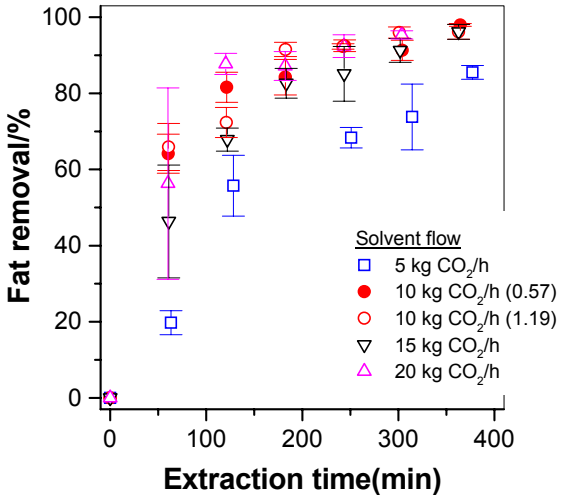

Figure 6. Fat removal as a function of extraction time for different solvent flows. T = 40 ºC, p = 35 MPa, skin sheet size = 15 cm × 14 cm, cycle time = 60 min

Figure 6 shows the fat removal as a function of extraction time for different solvent flows. It may be observed that when the solvent flow was low (5 kg/h) the extraction efficiency was also lower than in the rest of the cases indicating that the external matter transfer was important in the case. When the flow was equal or larger than 10 kg/h, the external matter transfer resistance seemed to be eliminated. Therefore it is recommended to work with a solvent flow of 10kg/h since using higher flows would only mean the use of a larger amount of solvent but not an improve of the extraction efficiency..

Conclusions

The results obtained showed that the internal matter transfer was the mechanism controlling the process; therefore, such resistance needs to be reduced or eliminated. A way of doing so, without grinding the skin, could be by "exploding" the fat cell membranes through rapid decompressions of the extractor where the skin sheets were previously swollen by the pressurized carbon dioxide. The optimum process conditions obtained after analyzing the influence of the process parameters were: extraction temperature 40 ºC, extraction pressure 350 bar; cycle time 60 min and solvent flow 10 kg/h.

Background

Meat from rabbit is one of the healthiest meats because its dietetics properties (Dalle Zotte, 2002), which make it recommendable by the WHO to children, older and unhealthy people nutrition. In spite of these characteristics, rabbit meat consumption is very low (less than 3 kg/person in Europe) and is therefore in need of a publicity campaign and appropriate distribution channels. Distribution could be improved by conservation in modified atmospheres (MA) in order to prolong shelf-life for a time longer than normal refrigeration allows.

Only the effect of CO_2 and N_2 atmospheres (Gariepy *et al*., 1986), and vacuum (Fernández-Esplá and O'Neil, 1993) have been evaluated in rabbit meat, and a lack of studies on modified atmospheres packaging for fresh rabbit meat is perceived (Dalle Zotte, 2002).

Objectives

The aim of this study was to evaluate some parameters of rabbit meat when is packed in modified atmospheres with different gas compositions, to suggest a package atmosphere that best preserves the initial characteristics of rabbit meat and would have better acceptation.

Materials and methods

Sixty-eight rabbits from the Cunicultura-Villamalea S.A. Company (Albacete, Spain) were selected and slaughtered using standard commercial procedures. Carcasses were chilled at 1ºC for a day, and after that were cut in half-carcasses.

One hundred and thirty-six half-carcasses (550 g), without liver, were grouped in 8 half-carcasses to study initial meat quality (1 d post-slaughter), and 128 half-carcasses to study meat quality evolution under MA.

Samples were randomly assigned (32 half-carcasses per MA) to one of the following four types of MA: *Atmosphere A*: 30% CO_2 + 70% O_2; *Atmosphere B*: 30% CO_2 + 30% O_2 + 40% N_2; *Atmosphere C*: 40% CO_2 + 60% N_2; and A*tmosphere D*: 80% CO_2 + 20% O_2

A thermoforming atmosphere packaging machine ULMA Packaging model Smart (Guipuzcoa, Spain) was used for packing. The samples were places in clear rigid trays (LINPAC Plastic), having an oxygen permeability (OP) rate of 3.2 cm^3 /m^2 /24 h at 1 atm and 23°C ,and a cover film with an OP of 4.1 cm^3 /m^2 /24 h at 1 atm and 25°C) with the correspondent gas mixture.

Samples were chilled at 1°C for up to 21 days post-slaughter (i.e. 5, 10, 15 and 20 post-packing).

Eight samples were examined per atmosphere type (A, B, C, D) and per sampling time to determinate off-odour, instrumental and sensorial colour and rancidity evolution on meat.

Sample rancidity was determined in duplicate from 2 g of the *Longisimuss dorsi* (LD) muscle as described by Botsoglou *et al.* (1994) by determining 2-thiobarbituric acid-reactive sustances (TBARS). Absorbencies were measured with a spectrophotometer Perkin Elmer Lambda 20 (Norkwalk, USA) at 532 nm. Results were expressed as mg malondialdehyde Kg^{-1} meat.

Colour measurements (*L*, a*, b**) were taken immediately after that the packs were opened and the measurements were taken on the surface of the LD, at the level of the fourth lumbar vertebra. Measurements were recorded using a Minolta CR200 colorimeter (Osaka, Japan) calibrated against a standard white tile.

Sensorial colour and odour were also assessed by a panel of five experts. Colour was categorised in closed packs, and odour inmediatly after opened its. For both colour and odour, samples were scored as 1= not acceptable, 2= acceptable or 3= very acceptable.

The data were analysed using analysis of variance to determine the effects of atmosphere type on colour and rancidity. When the differences among types of modified atmospheres were significant ($p< 0.05$), Tukey's test was carried out to check the differences between pairs of groups. The effect of time of storage in refrigeration for each MA was analysed using Tukey's test at a significance level of $p< 0.05$. Data were analysed using the SPSS 11.0.1 statistical software.

Results and discussion

Acceptability of packs according to visual evaluation was higher and longer in atmospheres type A and B (Table 1). By contrasts, samples packed in atmosphere C were not accepted at any time during this experiment due to poor colour. In agreement with Gariepy *et al.* (1986) a faster discoloration of samples stored with higher proportions of CO_2 was appreciated, which was more marked in packs without oxygen in their initial composition.

Table 1. Percentage of acceptable packs according to sensorial colour[1] and odour[2].

	Time post-packing	Type A	Type B	Type C	Type D
Colour	5 days	100	100	0	85
	10 days	100	100	0	100
	15 days	100	96	0	0
	20 days	100	50	0	0
Odour	5 days	100	100	100	97
	10 days	100	100	100	100
	15 days	100	100	100	100
	20 days	25	25	70	70

[1]Closed packs, [2]When packs were opened
Modified Atmosphere: Type A (30% CO_2 +70% O_2), Type B (30% CO_2+30% O_2 + 40% N_2), Type C (40% CO_2 + 60% N_2), and Type D (80% CO_2+20% O_2).
Samples were categorised (for both colour and odour) as 1= not acceptable (strong off-odour), 2= acceptable (slight off-odour) or 3= very acceptable (no off-odour).

Off-odour was developed faster in samples with more oxygen (Table 1). The inhibitory effects of CO_2 on the spoilage bacteria could be the cause of the better odour quality of samples containing high proportions of CO_2. Unacceptable odour has been attributed to bacterial growth over 10^6 CFU/g (Gariepy *et al.,* 1986), and after 20 days none sample from any MA presented counts higher than 10^5CFU/cm^2 (data not showed). Also Gariepy *et al.*(1986) reported no objectionable odour in rabbit carcasses packed under CO_2 for more than 20 days.

Initial values for L^*, a^* and b^* were 54.92, 3.62 and – 4.23, respectively. A significant increase in L^* values was observed in all treatments (Table 2), and this is usually attributed to the oxidation of hem-pigments (Fernández *et al.*, 2000). However there were significant differences among groups only from 15 days onwards, then the values of this parameter were higher in samples of type A (more oxygen).

Redness (coordinate a^*) increased during the first 5 days and then decreased ($p< 0.05$) in all MA treatments wiht time. Similar evolution on a^* values was reported in beef (Insausti *et al*., 2001). The decrease was more pronunced in type A, and could be the result of metmyoglobin formation (Insausti *et al*., 2001). Also, an increase in yelowness was observed in all MAs along the first 5 days. After that time, coordinate b^* took negative increasing values (more blueness), which were higher in type C the first 15 days. After that differences between b^* values were higher in samples from type D. Increases in blueness has also been reported in frozen rabbit meat by Cabanes *et al.* (1994, 1996).

Slight rancidity increases in rabbit meat were appreciated in all treatments along time (Fig 1), but the increase was only significant in atmosphere A ($p< 0.05$). After ten days of storage significant differences were appreciated among treatments in all times. The atmospheres with higher oxygen concentrations (type A and B) showed the highest rancidity rates ($p< 0.05$), and the atmosphere without oxygen (type C) the lowest ($p< 0.05$). In addition, at the end of this study malondialdehyde levels in these atmospheres (type A: 1.11 ± 0.61 mg/kg, and type B: 0.89 ± 0.51 mg/kg) were similar or inferior than those reported by other authors for refrigerated fresh rabbit meat (Corino *et al*., 1999; Castellini *et al*., 2000). According to some authors, at least 5 mg malondialdehyde/kg are required for rancidity detection (Insausti *et al.*, 2001). After 20 days the MA types A and B were inferior than this value. Studies about rancidity evolution of rabbit meat were scarce

and focused on other storage systems like vacuum packaging (Fernández-Esplá and O'Neill, 1993). As in vacuum packaging, the use of modified atmospheres with carbon dioxide allows the extension of rabbit meat shelf-life. Besides, meat samples packed in non-oxygen-MA were more stable to lipid oxidation, because the absence or the minimal residual oxygen concentrations (O'Grady *et al*., 2000; Insausti *et al*., 2001; Jeremiah, 2001).

Table 2. Values (means ± e.s.) of colour (*L, *a**, *b**) parameters of rabbit meat preserved in modified atmospheres with different gas composition.**

Colour	Time post-packing	Type A	Type B	Type C	Type D	ANOVA

Modified Atmosphere: Type A (30% CO_2 +70% O_2), Type B (30% CO_2+30% O_2 + 40% N_2), Type C (40% CO_2 + 60% N_2), and Type D (80% CO_2+20% O_2).
*,**: indicate significance levels at 0.05 and 0.01, respectively; NS: not significant
$^{a, b, c}$: values in the same column with different superscript are significantly different ($p < 0.05$); $^{x, y}$: values in the same row with different superscript are significantly different ($p < 0.05$).

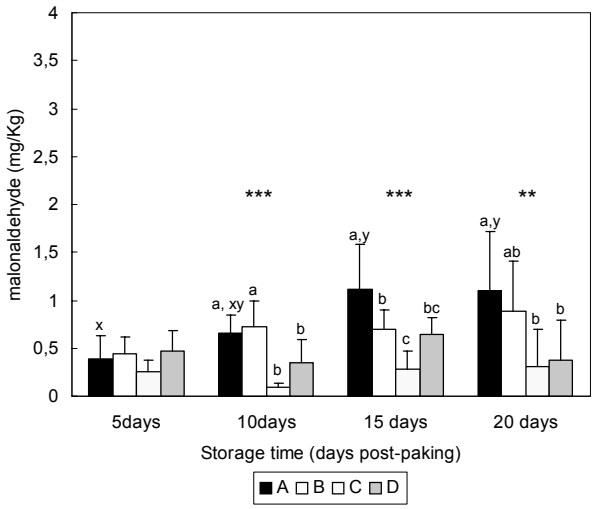

Figure 1. Rancidity levels (TBARS; mg malonaldehyde/Kg meat) in rabbit meat stored at 1°C in A: 30% CO_2 + 70% O_2 (black bars), B: 30% CO_2+30% O_2 + 40% N_2 (white bars), C: 40% CO_2 + 60% N_2 (pointed bars), and D: 80% CO_2+20% O_2 (cross bars). [**, ***: indicate significance levels at 0.01 and 0.001, respectively; $^{a, b, c}$: values in the same storage day with different superscript are significantly different ($p< 0.05$); ^{x,y}: values in the same colour bar with different superscript are significantly different ($p< 0.05$)].

Conclusions

According to colour samples from the atmosphere type A (30% CO_2 + 70% O_2) showed the best properties until the15th day; non off-odour were detected in any sample from this type, and although this atmosphere showed the highest levels of rancidity these numbers were always very inferior to the threshold level reported on the literature.

CHANGES IN IMMUNOELECTRON MICROSCOPIC LOCALIZATION OF CALPAIN IN MUSCLE INDUCED BY CONDITIONING AND HIGH-PRESSURE TREATMENT

Gerelt Borjigin[1], Shuhei Yamamoto[2], Toshie Sugiyama[3], Tadayuki Nishiumi[2] and Atsushi Suzuki[2]

[1]Department of Applied Biological Chemistry, and [3]Department of Agricultural Science, Faculty of Agriculture, Niigata University, 2-8050 Ikarashi, Niigata 950-2181, Japan

[2]Doctoral'l Program in Biosphere Science, Graduate School of Science and Technology, Niigata University, 2-8050 Ikarashi, Niigata 950-2181, Japan

Key word: calpain, immunoelectron microscopy, meat tenderization, meat conditioning, high-pressure treatment

Background

The most striking effect of postmortem aging is the improvement of meat tenderness, which is almost exclusively brought about by muscle endogenous protease that disrupts myofibrils. Especially, proteolysis of key myofibrillar proteins by calpain is the underlying mechanism of meat tenderization that occurs storage of meat at refrigerated temperatures. In general, calpain is widely distributed throughout the cytoplasm in a variety of cells. The calpains are present in two distinct forms, μ-calpain, a protease requiring 3-50 μM calcium ion for half-maximal activity; m-calpain, a protease requiring 400-800 μM calcium ion for half-maximal activity. The two calpain, μ- and m-calpain, are 110-kDa molecules each containing a 80-kDa and a 28-kDa polypeptide subunit. The 28-kDa subunit is identical in μ- and m-calpain; the 80-kDa subunits from two molecules differ, although they share 50 % sequence similarity.

It is well known that high hydrostatic pressurization is one of the new technology for reducing the conditioning period and improving the meat tenderness: there are many papers describing meat tenderization or acceleration of meat conditioning due to structural changes of the myofibrils caused by high pressure (Bouton et al., 1977; Locker & Wild, 1984; Macfarlane, 1985; Suzuki et al., 1992). Regarding calpain systems, Suzuki et al. (1993) provided direct evidence for the pressure-induced Ca^{2+} release from the sarcoplasmic reticulum from electron micrographs of the pyroanthimonate-fixed fiber bundles prepared from pressurized muscles. Ca^{2+} dispersion into myofibrils may cause the increase of activated calpain. Also Homma et al. (1995) indicated that the total activities of calpain in pressurized muscle appear to have been increased by the pressure and this may result in tenderization of meat.

There have been few reports describing the changes of calpain localization in muscle by high pressure treatment, and the behavior of the enzymes has not been clear. Many histological studies suggested that the calpain in the normal muscle localized primarily to Z-disk with smaller amounts in the I-band, A-band area, and between myofibrils. However, the changes in the localization of calpain in the muscle by conditioning or pressurization were not elucidated.

Objective

The objective of this paper was to investigate the changes in the localization of calpain in muscle exposed to high pressure by using immunoelectron microscopy, in comparison with those naturally observed in conditioned muscle.

Materials and methods

Tissue preparation: Lean meat was excised from the shoulder part of a culled-cow carcass 2 days after slaughter and stored at -25℃. As required, it was tempered overnight in a cold room (3 - 4℃) and divided into two parts, one for high pressure (100-400 MPa, 5min), and the other for conditioning at 2-4℃ 7 and 14 days. Muscle samples (1 mm^3) prepared from the pressurized and conditioned muscles were fixed with 0.25 % glutaraldehyde-PBS (0.1 M phosphate, pH.7.5, 8 % sucrose) for 30 min at room temperature, washed with PBS three times. After that the samples were dehydrated in graded alcohol (50 % and 75 %), and then were embedded in LR-White resin.

Immunoelectron microscopy: Ulrtrathin sections were cut onto 300-mesh grids and were incubated for 15 min in a PBS solution containing 5 % normal goat serum. After washing with PBS, the grids were

transferred onto drop of monoclonal antibody (Mouse anti-calpain small subunit (μ - or m-calpain) monoclonal antibody) (Chemicon) for 60 min. The monoclonal antibody was diluted 1:200 with PBS buffer. After incubation with the primary antibody, the grids were washed in PBS, and colloidal gold particle 10 nm in diameter conjugated with goat anti-mouse IgG+IgM (H+L) (Amersham) was added for 30 min at room temperature. The secondary antibody was diluted 1:25 (OD at 520nm of 0.1) just before use with PBS buffer. The grids were then washed in PBS, and the specimens were stained with 2 % uranyl acetate for 5 min. The stained specimens were examined with a CM 2000 Philips electron microscope at an operating voltage of 80 kV. Control sample was incubated with PBS in place of the primary antibody followed by incubation with the secondary antibody.

Results and discussion

To confirm the specific labeling for calpain, the muscle sample prepared immediately after thawing was first treated without anti-calpain antibody, then treated with colloidal gold conjugated anti-mouse IgG + IgM (H+L) (Fig.1). In which, non-specific labeling of the muscle was not observed. When the muscle sample was stained according to the procedure described in method, the immunogold particles were observed in Z-disk, I-band and A-band regions. This is proof that the anti-calpain small subunit (μ - or m-calpain) monoclonal antibody is specific to both μ - and m-calpain. But the immunogold particle seems to be concentrated primarily to Z-disk region than either I-band or A-band regions. This result agreed with those quantitative studies (Goll et al., 1983; Ishiura et al., 1980; Kumamoto et al., 1992) that calpain is located on the Z-disk with smaller amounts in the I-band and very little in the A-band area. When muscle was examined after postmortem, the calpain distribution was altered to being more diffuse throughout the sarcomere instead of concentrated at the Z-disk and between the myofibrils. As well as high density of immunogold particle was detected throughout the sarcomere, also disruption of myofibrillar structure was observed. The localization of the calpain may be involved in myofibril degradation and in membrane alterations of muscle cell.
When the muscle was exposed to pressure of 100 MPa or 200 MPa, a little more immunogold particle was detected in the sarcomere than that of unpressurizad muscle (Fig.2). With the increasing of the pressure up to 300 MPa applied to the muscle, detected high density immunogold particle throughout the sarcomere. Inversely, a few immunogold particle was detected in the sarcomere of the muscle exposed to pressure of 400 MPa. It seems to be due to the inactivation of calpain under high pressure. Also marked disruption in the regular structure of the myofibrils was observed in the muscle pressurized at 400 MPa as compared with the conditioned muscle. This disruption seems to be not due to the proteolytic degradation of myofibrils, but mainly due to the depolymerization of the F-actin, constituents of thin filament, as suggested by Macfarlane (1985)

Conclusions

From the results obtained in this experiment, it was clear that the changes in the localization of calpain in the muscle induced by high pressure were drastic in comparison with that in the muscle during conditioning.

THE EFFECT OF RIGOR-TEMPERATURE ON ISOMETRIC TENSION, SHORTENING, AND pH FOR OSTRICH *M. GASTROCNEMIUS, PARS INTERNA*

Background

A major commercial attraction of hot-deboning is the considerable reduction in time, space and refrigeration capacity required (Taylor *et al*., 1980-1981). With regard to the export of ostrich meat, a reduction in time from slaughter to vacuum packaging of muscles could be beneficial towards increased shelflife since the temperature decline in hot-deboned muscles is faster and more uniform than in muscles left on the carcass (Van Laack *et al*., 1992). The former is more beneficial for controlling microbial spoilage (Lawrie, 1985). The good eating quality of ostrich might be reduced by the risk of cold-shortening if hot-deboning is performed (Taylor *et al*., 1980-1981). Fortunately, the increased risk of cold-shortening can be avoided by controlled chilling, but it is suggested that the maximum saving in time is achieved when hot-deboning is combined with electrical stimulation. To avoid cold-shortening, it has been recommended to debone at temperatures between 5º and 15ºC and keep the vacuum packaged meat cuts at this temperature for at least 10 hours *post-mortem* (Lawrie, 1985). By measuring the sarcomere length, Sales (1994) found that cold-shortening were absent in ostrich muscles. Sales & Mellet (1996) and Sales (1994) found ostrich *M. iliofibularis* to have a very rapid pH decline until two hours *post-mortem*, after which the pH increased. Morris *et al.* (1995) found that the lowest *post-mortem* pH value for ostrich *M. iliofibularis* and *M. gastrocnemius* occurred within 30 minutes after slaughter (not hot-deboned). As illustrated by the results found by Sales and Mellet (1996), the risk of cold-shortening would be reduced in the *M. iliofibularis* since it reached a pH $\leq$ 6.20, at approximately 30 minutes after slaughter. Sales and Mellett (1996) found that the apparent ultimate pH was reached rapidly at two hours *post-mortem* in the *M. iliofibularis* (6.00 ± 0.09), and at six hours *post-mortem* in the *M. gastrocnemius, pars interna* (6.12 ± 0.06). Therefore, it was suggested that there is a risk of cold-shortening in the *M. gastrocnemius, pars interna* if this muscle would be separated from the carcass at 30-45 minutes *post-mortem*, but not in the *M. iliofibularis*.

Objectives

The aim of this study was to investigate the development of isometric tension, *i.e.* measuring tension while the muscle is prevented from contracting, and shortening in ostrich *M. gastrocnemius, pars interna* during *rigor mortis* at 7 and 37ºC respectively, in an attempt to determine the time course of rigor, pH decline, and degree and extent of shortening, *i.e.* occurrence of cold-shortening. This will allow one to decide how soon after death it would be safe in terms of eating quality to hot-debone and vacuum pack whole ostrich muscles.

Materials and methods

Ten rested, about 12 hours lairage, and two stressed ostriches, were slaughtered during February to April at the same EU approved abattoir. The two stressed ostriches were slaughtered on arrival at the abattoir. The right *M. gastrocnemius, pars interna* muscle were removed from the rested ostriches within one hour after death, and within 20 minutes from two rested and the two stressed ostriches. From these muscles, strips (1x1x3 cm) weighing between 1.5 and 3 g were cut for measurement of isometric tension, expressed as force (mN) per unit area, and shortening, expressed as percentage decrease in muscle length, during *rigor mortis* using two separate rigometers (Rigotech®) at constant temperatures of 7 and 37ºC, respectively. A SenTix 41 probe, connected to a portable pH meter 340i (WTW, GmbH & Co. KG, Weilheim, Germany), was inserted into a larger portion of muscle, which was also placed into the rigometers, for continuous measurement of pH every 10 minutes during the rigor process for a 24 hour period.

Results and discussion

Muscle pieces from rested animals reached maximum tension after 50 minutes for both 7 and 37ºC and maximum shortening after 170 min for 7ºC and 150 min for 37ºC, while a shorter time was observed for stressed ostriches (Figure 1). Muscle strips from rested ostriches, going into rigor at 37ºC, reached maximum tension and shortening sooner ($P < 0.001$) than those at 7ºC (Table 1). In addition, although tension showed no lag phase for either of the two temperatures, the mean lag phase for shortening onset was longer at 7ºC (42.22 min) than at 37ºC (17.78 min), indicating that the time course of *rigor mortis* is temperature dependant. Devine *et al* (1999) demonstrated that the time for bovine muscle to reach maximum tension was highly negatively correlated with temperature, as was the time to reach maximum muscle shortening.

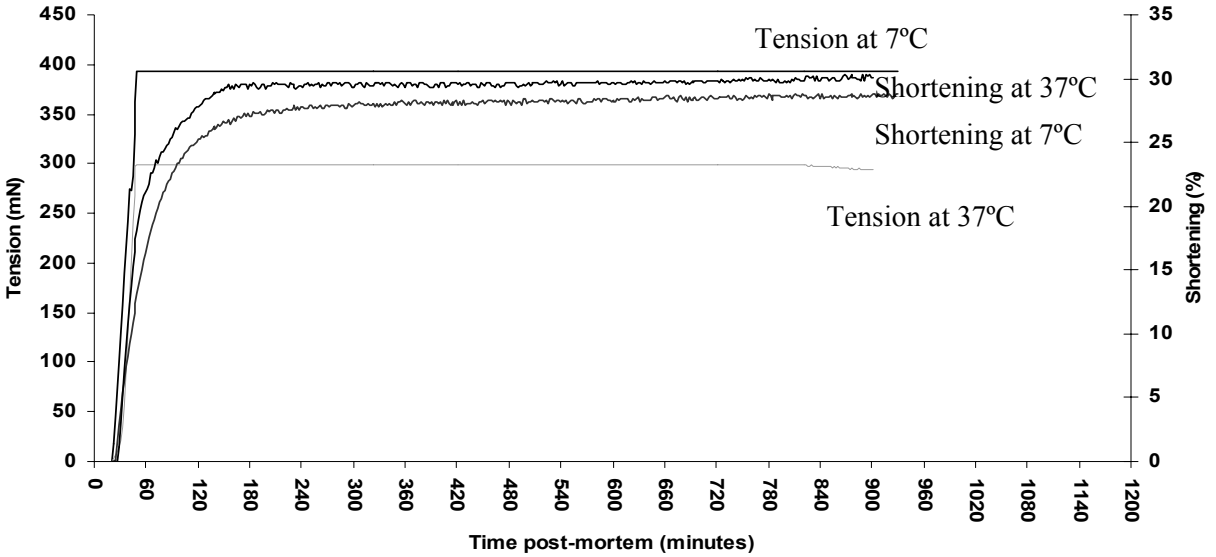

Figure 1. Measurement of isometric tension and shortening from the time (20 minutes after death) the muscle strips from the two stressed ostriches were placed in the rigometers and maintained at 7ºC and 37ºC, respectively.

Table 1. Mean times (minutes) for *M. gastrocnemius, pars interna* muscle from rested ostriches to reach maximum tension (mN) and maximum shortening (%)

Temperature (ºC)	Time (min) to maximum Tension (mN) (N = 8)	Time (min) to maximum Shortening (%) (N = 8)
7	679± 400	1400 ± 0.0*
37	183± 50	236 ± 40

*Shortening reached a high value at approximately 400 min, after which it continued to increased at a very slow rate up to 1400 min. without reaching a plateau.

The values for maximum tension and shortening were also temperature dependant, where maximum tension was higher ($P < 0.05$) at 7ºC (364 ± 50 mN) than at 37ºC (280 ± 70 mN), while in contrast, maximum shortening was higher ($P < 0.001$) at 37ºC (35.00 ± 5) than at 7ºC (11 ± 3%) (Table 2). This is in compliance with the findings of Devine *et al* (1999), demonstrating that muscle shortening decreases with decreasing temperature. Similarly, maximum tension was higher at 7ºC than at 37ºC, and maximum shortening was higher at 37ºC than at 7ºC in muscle strips from the two stressed ostriches. The occurrence of greater tension at low temperatures, with less shortening, than at high temperatures, could be explained by the release of calcium ions. Low temperatures (<15ºC) stimulate the release of Ca^{2+}-ions from the sarcotubular system, enhancing the contractile actomyosin ATP-ase (Lawrie, 1985). Actin and myosin interconnect but without the actin filament being pulled inwards, towards the centre of the sarcomere (causing the sarcomere to shorten), because of the lack of sufficient levels of ATP due to the decrease in enzyme activity at the low temperatures. There is thus tension due to the binding between actin and myosin, but less shortening since there is not enough energy to cause the sarcomere to shorten. The greater percentage of maximum shortening at higher temperatures could, on its turn, be explained by ATP levels (Hertzman *et al*., 1993).

Hertzman and co-workers found a high correlation between maximum shortening and the ATP level at the onset of the shortening rapid phase and explained the higher shortening at 37ºC compared to 15ºC due to the higher ATP level at this higher temperature. They further suggested that the release of Ca^{2+} at higher ATP levels (at 37ºC) could depend on the decreased stability of mitochondria to sequester Ca^{2+} under anaerobic conditions in conjunction with a faster decline in pH at 37ºC than at 15ºC.

Table 2. Maximum tension (mN) and maximum shortening (%) for individual *M. gastrocnemius, pars interna* muscle from rested and stressed ostriches at temperatures of 7 and 37ºC, respectively

In muscle strips from rested ostriches, the tension peak was followed by a decline in tension when rigor developed at 37ºC, while at 7ºC the maximum tension remained constant. The decline in tension at 37ºC could be explained by the initial ageing process (proteolysis) of the muscle at high temperatures. It might also be explained as relaxation due to transport of Ca^{2+} back to the sarcoplasmic tubuli. At 7ºC, after the lag phase of about 120 minutes, shortening increased rapidly during the next 180 minutes of measurement, then continued to increase at a very slow rate, reaching maximum values at about 24 hours *post-mortem*, although, not yet reaching a constant value. In contrast, maximum shortening at 37ºC was reached within the first 120-180 minutes and remained constant at this maximum value (Figure 2). Muscle tension showed no lag phase before onset at either of the two temperatures, and the muscle strips from the rested and the two stressed ostriches reached maximum tension before reaching maximum shortening.

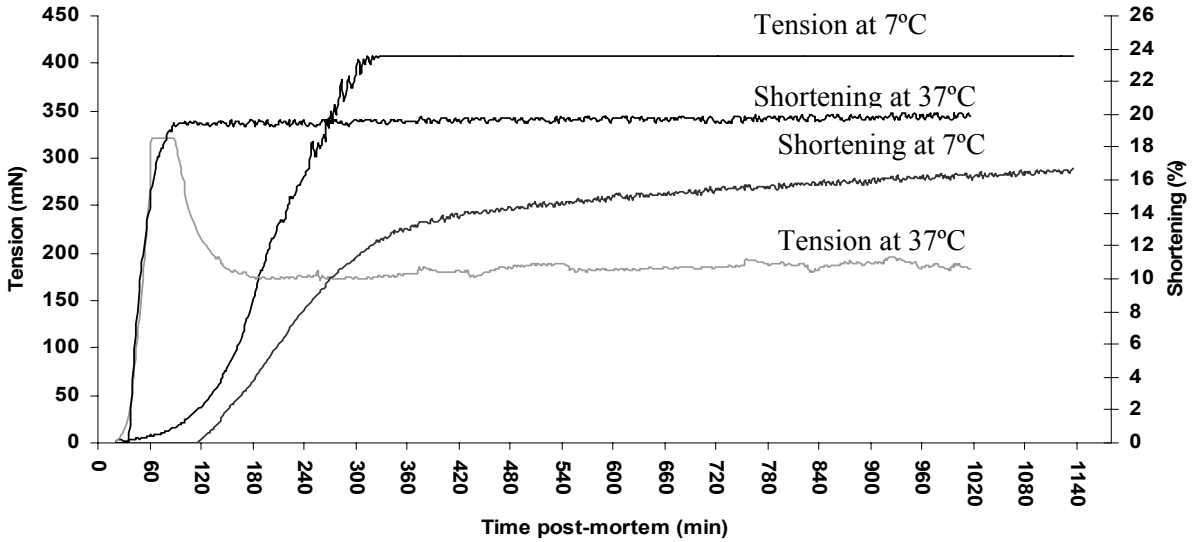

Figure 2. Measurement of isometric tension and shortening from the time (20 minutes after death) the muscle strips from two rested ostriches were placed in the rigometers maintained at 7ºC and 37ºC.

In general, the pH for intact *M. gastrocnemius, pars interna* from rested ostriches decreased from the start of pH-measurements (one hour after death) until about two hours *post-mortem* (reaching a minimum value of

6.0 ± 0.3), indicating a rapid fall in pH during the first 2-3 hours after death, after which the pH then increased (Figure 3). The change in pH for muscle strips from rested ostriches at 7ºC and 37ºC, showed a similar decrease in pH and subsequent increase. However, the time to reach the minimum pH at 7ºC was approximately four hours and approximately two hours at 37ºC.

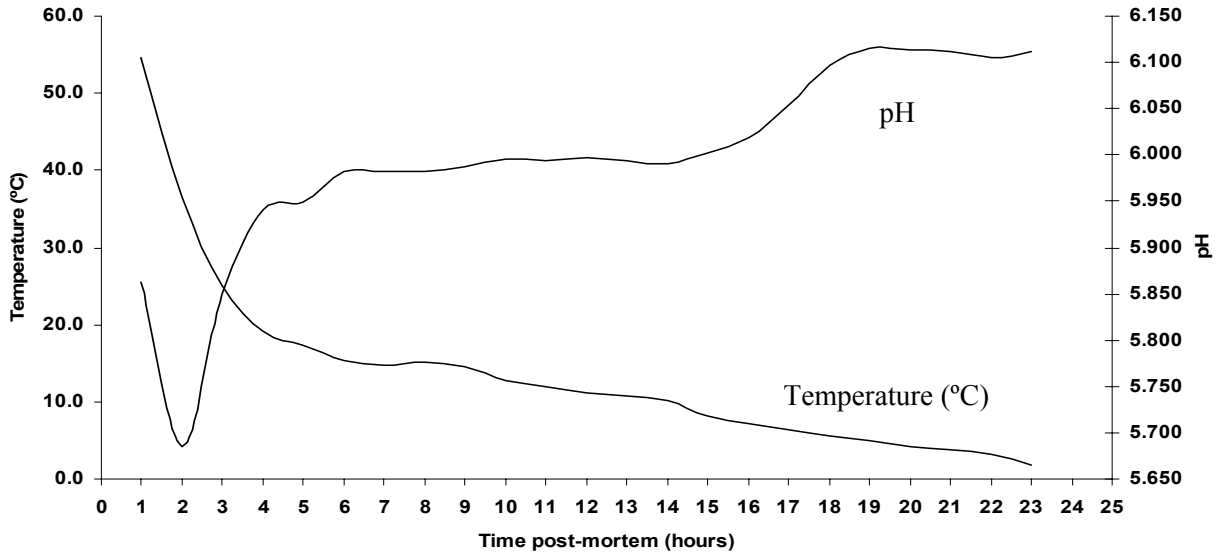

Figure 3. Representative measurements of temperature and pH change in intact *M. gastrocnemius, pars interna* from an individual rested ostrich.

Conclusions

The minimum pH obtained for ostrich *M. gastrocnemius, pars interna* seemed to be within 3-4 hours *post-mortem*, after which the pH increases. The reason for the increase in pH needs to be investigated. Cold-shortening occurs when muscles are exposed to low temperatures early *post-mortem* and when pH levels are still high. With the rapid fall in pH, the apparent absence of cold-shortening at low temperatures, and early onset of *rigor mortis* soon after death, it may be suggested that hot-deboning of ostrich muscles as early as 3-4 hours post-mortem would be without detrimental effects on the eating quality in terms of toughness.

PREDICTING AND SEGREGATING BEEF TENDERNESS AMONG URUGUAYAN STEER CARCASSES UNDER COMMERCIAL CONDITIONS USING *POSMORTEM* CARCASS TRAITS, PH, TEMPERATURE AND COLORIMETER READINGS

Gustavo Brito[1], Dean Pringle[2], Roberto San Julián[3], and Fabio Montossi[3]

Background

In the food industry consumer-oriented quality approaches are more and more used if we consider the large development of marketing. The perception of the quality could be defined prior to purchase (beliefs and attitudes), at the point of purchase (intrinsic and extrinsic cues) and upon consumption (sensory attributes). The National Beef Tenderness Survey conducted in US (1990), documented a relative high incidence of toughness problems among different beef cuts for sale and identified the need to improve retail beef tenderness (George *et al*., 1999). The US beef industry has made it a priority to address the inconsistency in beef tenderness and has been developed strategies to ensure that all beef has acceptably tender. The development of tenderness based classification systems makes possible to identify carcasses with superior tenderness and add value to these carcasses that are undervalued in current systems. Studies have demonstrated that consumers recognized consistently differences in tenderness and they are willing to pay for this attribute (Boleman *et al*., 1997). Most of these systems evaluated by research are based on the relationship between muscle pH (Purchas, 1990; Wulf and Page, 2000), color (Wulf *et al*., 1997; Vote *et al*., 2003) and temperature (Jones and Tatum, 1994) with meat tenderness. This strategy to improve consistency of meat palatability –tenderness as main factor- is also followed by principal meat export countries, such as Australia (Guarantee tenderness) and New Zealand (NZ Beef and Lamb Quality Mark). Uruguay, as a meat export country in South America ought to follow this approach making a diagnostic of the variation of this attribute and according to the information gathered identifying the critical control points along the meat chain to ensure the consistency on it.

Objectives

This study was conducted to determine whether carcass traits and objective measures of muscle color, pH and temperature are useful to predict tenderness on selected beef steer carcasses of unknown origin, and to determine whether the application of USDA quality grading standards to Uruguayan beef carcasses could improve their segregation by tenderness.

Materials and Methods

One hundred seventy four beef steer carcasses of unknown origin were selected at one packing plant in Uruguay. Carcasses were selected at the time of grading by the Uruguayan official system without electric stimulation. Hot carcass weight (HCW) and fatness are associated with the age, for this reason it was decided to study whether within age could exist differences in quality traits, considering two HCWs and two backfat thickness (0-2 teeth carcasses: HCW < and ≥ 225 kg and Fat < and ≥ 5 mm; 4 teeth carcasses, HCW < and ≥ 240 kg and Fat < and ≥ 5mm; and 6-8 teeth carcasses, HCW < and ≥ 265 kg and Fat < and ≥ 7 mm). Carcasses were segregated into appropriate fat thickness categories based on actual carcass backfat measured at the 11th rib surface. Two official classification systems were applied, the American (USDA, 1997) and the Uruguayan (INAC, 1997) at different moments. The pH and temperature of the *longissimus lumborum* (LL) was determined at three different times: 1, 3 and 18-24 (ultimate) hs postmortem. The pH and temperature at 1 and 3 hs *postmortem* were measured between the 10 and 11th rib on the left side of the carcasses, at a depth of 2 cm. The measurement of ultimate pH was realized at the 11th rib cut surface in the pistol cut. The muscle pH was measured using a hand-held pH meter (Orion A 230) with a probe type electrode (BC 200, Hanna Instruments), standardized against two pH buffers (4 and 7). The probe was cleaned with alcohol and rinsed with water between uses. The temperature was determined by a thermometer (Barnant 115) with stainless steel thermocouple (type E). Muscle color measurements followed the CIE color convention (CIE, 1986).

Color measurements were made using a Minolta Colorimeter (model C-10). They were recorded in triplicate from the exposed LL muscle between the 10-11th rib immediately following ribbing (left side). A 8-cm portion of the LL was removed from the left side of carcasses, labeled, vacuum-packaged and transported to the Meat Science Laboratory at INIA Tacuarembó for shear force analysis considering 7 and 14 days of aging at 2 - 4 ^{o}C. The steaks were cooked by immersion within a plastic bag in a water bath at an internal temperature of 70^{o}C for 75 min. The internal temperature was monitored using type E thermocouples placed in the approximate geometric center of the steak. Six cores (1.27 cm diameter) parallel to the muscle fiber orientation were removed from each steak. A single peak WBSF measurement was obtained for each core using a WBSF machine (G-R Electric Manufacturing Co, Manhattan, KS). Individual-core peak shear force values were averaged to assign a mean peak WBSF value to each steak. *Statistical analysis* Descriptive statistics were computed in this experiment for selected carcass traits, pH, temperature, colorimeter readings and WBSF values. The model used in this experiment was $Y_{ijkl} = \mu + A_i + B_j + C_k + ABC_{ijk} + E_{ijkl}$ being Y_{ijkl} = ijklth Warner-Bratzler shear force at 7 and 14 days of aging, μ = overall mean, A_i = effect of the ith dentition, B_j = effect of the jth hot carcass weight, C_k= effect of the kth fat thickness, ABC_{ijk}= interaction effect of ijkth dentition * hot carcass weight*fat thickness, and E_{ijkl} = residual error. Least squares means were calculated using PDIFF procedure. To better understand the relationship between the independent and dependent (WBSF values) variables the information was analyzed by correlation and regression procedures (stepwise procedures, SAS, 1990).

Results and Discussion

In this study, it was not detected significant differences (P>0.05) in WBSF 7 and WBSF 14 explained by dentition, HCW and Fat. The WBSF mean obtained for 7 and 14 days of aging were 4.06 kg (CV: 35.3%) and 3.42 kg (CV: 30.7%). These results agree with Lawrence *et al* (2001) who did not find significant differences in WBSF and sensory panel tenderness among five dental classes. These authors supported the concept that carcass classification based on dentition should not be used in place of USDA carcass maturity to segregate carcasses for *longissimus* steak tenderness. The carcasses were majority classified as Traces (35.1%) and Slight (55.2%) according to USDA marbling score and as A (76.4%) to USDA overall maturity category. QG scores varied from Utility to Choice, where 88.5% of the carcasses were classified as Standard (44.3%) and Select (44.3%). As it was expected, the pH values (pH_1, pH_3 and pH_u) were lower (P<0.05) and the T records were higher (T_1, P<0.01, and T_3, P<0.05) for the fattest group in each age group. The positive relationship between muscle temperature and subcutaneous fat thickness resulted from the insulation effect of fat. Correlation Analyses. YG was the main variable negatively correlated (P<0.01) with both WBSF 7 and WBSF 14 (Table 1). This could be explained by subcutaneous fat thickness, where higher levels of this variable would be associated to lower WBSF values. All correlation coefficients between muscle color and WBSF were negative. These findings have also been reported by Wulf *et al*. (1997), Wulf and Page (2000) and Vote *et al*. (2003), showing that dark color muscles could be associated to tough steaks. Lean maturity presented a low correlation with WBSF 7 and WBSF 14 (r=0.17 and 0.19, respectively). Studying the relationship between color parameters with some of the measured variables, lean L*, a* and b* were moderately and highly correlated (P<0.01) with pH_u, presenting a* the highest correlation (r=-0.81). This suggests the importance of lean a* as indicator of meat quality and especially of tenderness in the present study. Ledward *et al*. (1992) reported that the negative correlations between colorimeter readings and pH_u could be explained by the oxygenation of the myoglobin and the reflectance of the light. Lean L* was most closely related with lean maturity (r=-0.61, P<0.01). This result is concordant with the information reported by Vote *et al*. (2003) who found correlation values (P<0.05) between both characteristics in the range of -0.52 and -0.69 in different experiments using the CVS BeefCam color output. *Regression analyses* The application of the USDA quality grade factors to Uruguayan steers (Table 2) explained in most of the cases 4 to 6 % of the WBSF 7 and WBSF 14 variation, with the exception of WBSF 14 in 6-8 teeth carcass group where lean maturity explained 21% of its variation. Vote *et al*. (2003) reported a partial R^2 for lean maturity of 6 and 8% in the WBSF 14 variation for 2 different experiments. Marbling showed low correlation (P>0.05) to WBSF 7 (r=-0.13) and WBSF 14 (r=-0.14). Wulf *et al*. (1996) in a research containing mostly carcasses classified as USDA Select reported no correlation between variables (P>0.05) and Vote *et al*. (2003) considered that marbling score did not explain WBSF variation in Select carcasses. When it was ran multiple linear regression procedures using all the measurements to predict WBSF values, the main single variable in predicting tenderness for all evaluated carcasses was lean a* (Table 3). This colorimeter reading explained by itself 16 and 24% of the WBSF 14 and WBSF 7 variation, respectively. Vote *et al*. (2003)

considering Choice and Select carcasses found that lean a* from the CVS BeefCam explained 16% of the WBSF 14 variation. The lean a* parameter was followed by pH_u and T (T_1 or T_3) in entering into the model for all steer carcasses. This tendency was also observed in 0-2 and 4 teeth carcasses. However, for the 6-8 teeth carcass group, variables associated to yield as REA ($r=-0.37$, $P<0.01$), YG and HCW contributed to explain the tenderness variation. REA singularly account for 30% of the WBSF 14 variation. The REA has been related to carcass yield, however Wyle *et al*. (2003) and Vote *et al*. (2003) had observed a limited relationship between this variable and palatability and the possibility to identify tough steaks using REA from CVS BeefCam adjusted by carcass weight. In this age category (6-8 teeth) QG explained an additional 24% of the WBSF 14 variation.

Conclusions

The population of cattle utilized in this study was representative of slaughtered steers in Uruguay according to age. For these animals, objective measures of muscle color, specifically lean a*, was the most effective in predicting WBSF, which explained 24 and 16% of WBSF 7 and WBSF 14 variation. However, analyzing the information by age category, the prediction of WBSF in 6-8 teeth carcasses was better accounted for other variables like pH_3 or REA (for WBSF 7 and WBSF 14, respectively). The addition of the USDA QG standards to the Uruguayan steer carcasses grading would seem do not contribute to improve the effectiveness to sort carcasses into tenderness group, with the exception of WBSF 14 prediction in 6-8 teeth carcass group. For this population, ultimate pH and lean a* measured at ribbing might be useful in sorting beef carcasses likely to yield tough or tender steaks depending on the defined WBSF critical point. Further research should be conducted to better understanding the relationship between pH/color and tenderness and how to improve it for Uruguayan conditions.

CONSUMER'S PERCEPTION OF BEEF TENDERNESS

Destefanis, G., Brugiapaglia, A., Barge, M.T., Barge, P., Omento E.
Dipartimento di Scienze Zootecniche, Via Leonardo da Vinci 44, 10095 Grugliasco, Università di Torino, Italy.

Background

Tenderness is considered the most important palatability characteristic of beef and, consequently, the primary determinant of meat quality (Dikeman, 1987). It is also very variable, depending on several factors related to genetics, nutrition, *ante mortem* handling and *post mortem* technological treatments. As outlined by Koohmaraie (1996), tenderness variability is the main reason for consumer's dissatisfaction. In fact, today, the consumer requires food with quality characteristics standardized and adequate to the price.
Beef tenderness can be evaluated studying their intrinsic characteristics by instrumental analysis or by sensory analysis, using a trained panel. However, it is very important, even if more difficult, to know consumer liking of tenderness, considering that the consumer is the user of the product.

Objectives

The aim of this study was to determine consumer's ability to recognize differences in beef tenderness.

Materials and methods

A consumer panel of 220 people differing in sex and age was recruited from a broad range of socioeconomic background (table 1). The males represented about 58% of the panel. Concerning age, the individuals were allotted in quite a homogeneous way into the first three classes (28% 18 to 30 yrs old; 27% <45 yrs old; 31% < 60 yrs old), while the individuals over 60 yrs represented about 14% of the panel.
Tenderness evaluation was performed on 31 samples of *longissimus thoracis* taken between the 8th and 10th thoracic vertebra from the right side of the carcasse. The animals belonged to the most widespread commercial categories in Piedmont: milkfed calves (C; n = 10) and young bulls. The latter included dairy (DB; n = 10) and beef breeds (BB; n = 11). Meat samples were purchased at retail and transferred to the laboratory of Department of Animal Science of Turin, where they were divided in two further samples, vacuum packaged, frozen and stored at -25°C until of their utilization. The samples were thawed at 2°C and then cooked by roasting in an electric convection oven, preheated at 210°C, until they reached a final internal temperature of 70°C. The cooking temperature was monitored by an Iron/constantan thermocouple connected to a termometer and inserted into the geometric centre of the sample. The cooked meat was cut into 1.3 x 1.3 x 1.9 cm cubes for sensory analysis.
The tenderness sensory evaluation was carried out using a five point facial hedonic scale at the end-anchored by the words very tough/very tender (Cross *et al*., 1986; AMSA, 1995). The scale was: 1 = "very tough"; 2 = "tough"; 3 = "neither tough nor tender"; 4 = "tender"; 5 = "very tender".
The sensory analysis was performed at the laboratory of the Department and, in general, in each session the panelists evaluated three samples, one of each animal's groups for a total of 671 evaluation. Each consumer was involved in only one session.
The correspondence analysis was employed to study the sensory judgements distribution in relation to either the sex and age of the consumers or the category of the animals (SPSS, 1997).

Results and discussion

Table 2 shows that the distribution of the tenderness ratings was very similar in males and females (P = 0.75). Considering the consumers' age (table 3), a tendency of young people to give lower evaluations was observed, but the differences did not reach the level of significance (P = 0.49). Therefore the evaluation of beef tenderness seems not to be affected by consumer's sex and age. Similarly Huffman *et al*. (1996) did not observe significant effect of sex and age on sensory tenderness when the steaks were rated at restaurant, while reporting significant differences in tenderness rating across age groups in consumer's homes.
On the contrary, highly significant differences in rating distribution were observed according to the commercial categories of the animals (table 4; P< 0.001). Indeed, results show that meat of calves had scores

higher than meat of dairy (P<0.001) and beef (P<0.001) young bulls. The last two commercial categories did not differ in tenderness scores (P = 0.31).
Figure 1 shows that calves obtained more ratings in highest tenderness classes. In fact, 45% "tender" meat (class 4) and 55% "very tender" meat (class 5) belonged to calves, which also had lowest percentages in"very tough" (class 1) and "tough" (class 2) meat. Although meat from young bulls showed similar tenderness ratings, it must be, however pointed out that meat from young bulls of dairy breeds represented more than 50% "very tough" tenderness rating, whereas meat from young bulls of beef breed had a higher percentage in "very tender" rating (28% *vs* 16%).
The overall results can be represented in the correspondence analysis plot (figure 2). The dimension 1 explained the largest amount of inertia (95%). The calves and rating 5, showing the highest deviation from the origin, gave the main contribution to the inertia of this dimension. The calves placed to the right in the plot and near to ratings 4 and 5 differed from the young bulls placed on the left and near to ratings 1, 2 and 3. In particular, dairy young bulls were the closest to rating 1, while beef young bulls were the closest to rating 2.
These results are in agreement with the data by Boleman *et al*. (1995), Huffman *et al*. (1996), Miller *et al*. (1995), Wheeler *et al*. (2002) indicating that the consumers can detect differences in tenderness.

Conclusions

The results of this study show that, apart from sex and age, the consumers are able to consistently detect beef tenderness differences, when two commercial categories of animal are compared. In particular, ratings assigned by the consumers allowed to clearly discriminate the meat of calves from that of young bulls.
The large distribution of the meats of each commercial category of the animals in the tenderness ratings indicate that the meat sold at retail shows high variability. Consequently it is important for beef industry to promote the tender meat production.

Background

The marketing of meat in industrialised countries is conditioned more and more by the demand of quality on the part of the consumer, today, who are careful about a series of problems which, besides the aspects of the intrinsic surety of the food, finish up by involving all a togetherness of other aspects of the productive system. In the specific case of meat, it is known that the organoleptic qualities, i.e. smell, taste, colour, juiciness, texture and tenderness represent the principal factors able to condition drastically the choices of the consumers at the moment of purchase (Maltin *et al*., 2003; Sgoifo Rossi *et al*., 1999) therefore, the physical characteristics of the meat has a role of primary importance regarding the qualification of the product (Destefanis, 1988). The physical characteristics of the meat are influenced by different factors such as: age, sex, race, system of breeding, methodologies of transport, slaughtering and ripeness (Villaroel *et al.*,2002). In the light of these observations and given the importance and the vastness of the subject, the Agriculture and Forest Regional Assessorship of the Sicilian Region, with the project: Quality and traceability of the Sicilian beef meat, co-ordinated and carried out by the Consorzio di Ricerca Filiera Carni (CoRFilCarni), has in progress the realisation of a detailed map of the quality of the meat produced in Sicily, so as to individuate the eventual critical points and therefore to set up the adequate strategies of intervention.

Objectives

The specific objective of this part of research is to study the physical characteristics of the beef meat produced in Sicily, derived from different genetic types kept in ordinary breeding conditions.

Materials and methods

The research was carried out on 200 male yearlings, weaned in a natural way, belonging to the following genetic types : 20 Belgian Blu (BBL) x half-bred (MTT); 26 Charolaise (CHL) x half-bred (MTT); 45 Limousine (LMS) x half-bred (MTT); 29 half-bred (MTT); 20 Charolaise (CHL); 20 Limousine (LMS); 20 Charolaise (CHL) x Belgian Blu (BBL); 20 Limousine (LMS) x Belgian Blu (BBL).
The animals, up to age of 8±1 months were kept in extensive conditions with their mothers and they utilised the available pasture for feeding. Only 6±1 months before slaughter, at a body weight of 300±20 kg, they were bred in intensive conditions, in boxes provided with external paddocks, and fed with 1.3 kg/100 kg of body weight and with wheat straw *ad libitum*. The chemical composition of the feeding (table 1) was determined according to the A.O.A.C. (2000) official methods.
All the subjects at the age of 14-16 months, at a homogeneous fattening condition, were slaughtered after fasting for 12 hours, but not from water. On each half carcass, 45' (pH_1) and 24h (pH_u) after slaughter pH value of the *Longissimus dorsi* muscle was measured with pH meter (WTW).
A sample cut of meat carrying out of two perpendicular sections at the vertebral column in correspondence with the cranial margin of the X (T10) and the XI (T11) rib (Hankins & Howe, 1946) was taken from the right half carcass of each subject, after 48 hours of refrigeration at a temperature of 4°C and relative humidity of 80%.
After the dissection of the sample cut, a slice 2,5 cm thick of the *Longissimus thoracis* muscle was prepared for the determination of colorimetric parameters (CIE L*: Lightness; a*: redness index; b*: yellowness index) using a spectrometer of imagine Spectral Scanner (DV s.r.l. Tecnologie d'avanguardia-Italia) and successively for the measurement of the Water losses and of the tenderness (Warner Bratzler Shear Force-WBS) using the INSTRON 5542.

Data obtained were subjected to the analysis of variance using the GLM procedure of the SAS (Version 8.1, 2001).

Results and discussion

The results obtained in table 2, pointed out the uniformity of the physical characteristics of the meats of different genetic types; in particular, no statistically significant differences were observed among the parameters investigated.

The values of pH_u observed (Tab. 2) indicate a good progress of the process of acidification (Hoffmann 1994) even for the BBL x MTT, CHL x BBL, LMS x BBL genetic types that are characterised by a greater muscular hypertrophy and therefore more sensible to stress (Schakelford *et al.,* 1994; Destefanis *et al*., 1993).

The L* and a* parameters show a good lightness and red index (Lizaso *et al*. 1996). This could be due to a greater concentration of myoglobin at a muscular level for the breeding system which determines a greater physical activity of the animals.

The Water losses (Tab. 2) show normal values according to Bultot *et al*. (2002) and Offer and Knight, (1988).

The values of WBS (Tab. 2) permit us to classify the meat of these genetic types as tender showing values less than 4.54 kgf/cm2 (Shackelford *et al*., 1991).

Conclusions

Following the guidelines of a system for the qualifications of the zootechnical productions (CoRFilCarni), this preliminary study has pointed out that, the employment of bulls for meat (BBL, CHL, LMS) in the cross-breeding with Sicilian half-bred (MTT) has produced meat characterised by good physical characteristics, comparable to those of the best races specialised for meat.

SENSORY EVALUATION OF BEEF LOIN STEAKS STORED IN DIFFERENT ATMOSPHERES

Ina Clausen
inc@danishmeat.dk, Danish Meat Research Institute, Maglegaardsvej 2, 4000 Roskilde, Denmark

Background

Case-ready fresh meat packaging is a fast growing segment (Zilbermann, 2003), and it is therefore important to optimise the packaging method to ensure a good eating quality including a long shelf life. In Denmark, most centrally wrapped consumer unit packages of fresh beef are Modified Atmosphere Packed (MAP; usually in 70-80% O_2 and 20-30% CO_2) or vacuum-skin packed (VSP). Although oxygen maintains the desirable red colour of the fresh meat it also promotes oxidation of lipids and may therefore be detrimental for the taste. A few studies have demonstrated that sensory properties decrease during MAP storage (Jayasingh, 2002; Toerngren, 2003). Furthermore, a few studies have demonstrated that beef stored in high oxygen atmosphere develops a well-done appearance at temperature much below than expected (Hunt et al., 1999; Toerngren, 2003).

Objectives

The purpose of the present study was to examine sensory quality of beef loin steaks packed with 6 different packing systems.

Whole cuts (longissimus dorsi) were 1) aged in vacuum, sliced to steaks and re-packed to 3 different atmospheres with different oxygen content, and 2) beef loin steaks were aged in 3 different atmospheres - O_2/CO_2, N_2 and under vacuum.

Materials and Methods

Source of meat: Six animals (cows and heifers) of Danish Friesian, Red Danish and Crossbreds, approx. 2-4½ years old, carcass weight (263-304 kg), were slaughtered at a Danish slaughterhouse, low voltage electrically stimulated and chilled so that no part of the carcass reached <10°C in the course of 12 hours after stunning. The carcasses were selected according to pH (5.5-5.6) and stored at 2°C for 3 days before boning. *Longissimus dorsi* (LD) was then excised from each carcass half and separated for different packaging systems, Table 1.

Table 1. *Packing systems and cut used during ageing and display*

Ageing conditions (2°C)			Display conditions, steaks (2°C)			Abbreviation
Cut	*Atmosphere*	*Days*	*Repacked*	*Atmosphere*	*Days*	
loin	Vacuum	19*	Yes	Air	2	Vac + Air
loin	Vacuum	14*	Yes	50% O_2/ 50% CO_2	6	Vac + 50%O_2
loin	Vacuum	14*	Yes	80% O_2/ 20% CO_2	6	Vac + 80%O_2
steaks	100% N_2	19*	Only top film	Air	2	N_2 + Air
steaks	50% O_2/ 50% CO_2		No		21*	50%O_2
steaks	Vacuum-skin pack		No		20*	VSP

* From packaging. Meat was packed 3 days after slaughter
Air capacity: approx. 79% N_2, approx. 21% O_2

Packaging and storage conditions: LD muscles (left and right side) were cut into 3 parts and randomised with respect to packing systems. LD was cut into steaks (2 cm thick) after boning or after aging. Storage temperature was 2 °C from boning to analysis. All steaks were moved to light surroundings (1,110-1,249 lux) for 2 days prior to the analysis (22-24 days after slaughter).

Vacuum bags for loins were made of transparent plastic with max. O_2 permeability: 4 $cm^3/m^2/d$, bar, (Bemis, Packagervej, Denmark APS). Vacuum: 5-10 mbar vacuum.

The *vacuum-skin packing (VSP)* consists of an upper co-extruded film with barrier properties and a bottom semi-rigid film usually in the form of a tray that maintains the original form of the product: Max. O_2 permeability (upper film and bottom): 2 cm^3/m^2/ x d x bar (Cryovac, Sealed Air Corporation). Vacuum: 5-10 mbar (Multicvac packing machine).

MAP (O_2): Tray (13x18x4 cm) covered with transparent film, O_2 permeability: 10 cm^3/m^2/d, bar (Cryovac. Sealed Air Corporation). Flowpack, BDF, Fuji.

MAP (N_2): Tray (12x16x3,5) in transparent bags (23x30 cm, NEN 40 HOB/LLDPE 75, AMCOR, oxygen permeability: 0,45 cm^3/m^2/ d, bar). One O_2 scavenger was placed in each pack (AGELESS, Mitsubishi Gas Chemical Company, INC). Multivac A300/16 packing machine (5 mbar vacuum, 750 mbar filling). Two days before the analysis, the bags were removed and the steaks exposed to air through O_2 permeable film.

Traditionally wrapped (Air): Tray (12x16x3.5) and transparent high O_2 permeable film (PE).

Atmosphere content was measured at time of packing and before analysis for MAP packed steaks (Check Mate 9900, BPI Dansensor)

Vacuum packed loin

MAP steak

VSP steak

Cooking and sensory evaluation: Steaks were equilibrated after storage at room temperature (approx. 20°C) to an internal temperature of max. 15°C prior to cooking on a preheated frying pan (155°C), turned every 2 minutes until an internal temperature of 62±1°C had been reached. Steaks were cut and served in pieces of 2½ x 3 cm. Samples were evaluated by 8 trained assessors using a 15-point non-structured line (0=slight and 15= intense). The attributes were tenderness, juiciness, Warmed Over Flavour (WOF), meat-flavour and doneness (internal colour).

Statistic: Data were analysed in an analysis of variance model (mixed procedure, SAS version 8.2). Fixed effect in the model were main effects.
Sensory data: $Y_{ijk} = \mu$ + packing systems $_i$ (fixed) + animal $_j$ (random) + assessors $_k$ (random) + e $_{ijk}$

Results and discussion
Results of the sensory evaluations are shown in table 2.

Tenderness: There were significant differences between packing systems ($P<0.0001$). Steaks aged and displayed in MAP (50% O_2/50% CO_2) gained the lowest score for tenderness: 6.5 point, which is 3 points lower than the traditionally aged and displayed steaks (vac+air: 9.5 point). Only steaks aged in N_2 (display packed in air) gained the same high levels of tenderness as the traditionally packing system. These results are in agreement with Jayasingh et al. (2002; ground beef) and Toerngren (2003; beef steak) who also found that MA-packing with O_2 and CO_2 decreased tenderness. It is expected that O_2 is responsible for the reduced tenderness in MAP, since Toerngren did not find that ageing in 50% CO_2/50% N_2 decreased tenderness. The

explanation for the negative effect of O_2 on tenderness could be protein oxidation. Rowe et al. 2004 found that increased oxidation of muscle proteins early postmortem could have negative effects on meat tenderness.

Beef steaks aged in vacuum-skin pack (VSP) were less tender than beef steaks aged in N_2. In an earlier study (Clausen et al. 2003) we also found that VSP steaks were less tender than the corresponding meat vacuum aged as a whole cut (app. 2 kg). The difference was significant at 4 and 11 days after packaging (meat was packed 3 days after slaughter). Vázquez et al. (2004) also found that the meat tenderisation process was slowed down in VSP beef steaks compared to traditional vacuum packed beef steaks.

Juiciness: There were significant differences between packing systems ($P<0.0001$). Beef steaks exposed to O_2 in higher concentration than normal air were less juicy. The reduced juiciness is probably caused by O_2 since Toerngren (2003) found that ageing in 50% CO_2/50% N_2 did not reduce juiciness compared to traditional packaging (vacuum aged and packed in air for two days). Jayasingh (2002) also found ground meat packed in 80% O_2/20% CO_2 tasting less juicy than the control.

Warmed Over Flavour (WOF): WOF varied between packing systems ($P<0.0001$). The highest degree of WOF was found in steaks aged and display packed in 50% O_2 for 20 days (8.4 point). Also steaks display packed in O_2 for 6 days scored high in WOF (50% O_2: 5.9 point 80% O_2: 5.7 point). As seen from table 2, development of WOF varied from 1.9 to 12.3 between animals (50% O_2 for 20 days). WOF is primary known from stored and reheated cooked meat and is caused by oxidation of fatty acid (Konopka and Grosch, 1991). However, in this experiment it appears that the oxidation already occurred in the raw meat stored in MAP with high oxygen content. Jakobsen and Bertelsen (2000) and Jayasingh (2002) also found increased lipid oxidation during storing in O_2 atmosphere. The degree of WOF probably depends of antioxidant content like tocopherol in fresh meat. Consumers sensitive to WOF will probably dislike O_2-MAP meat with high WOF.

Meat flavour: Meat flavour differed between packing systems ($P<0.0001$). Once again, steaks packed in MAP with O_2 deviated from the others and with less meat flavour, too.

Colour: Visual internal colour of the steaks (cooked to 62°C±1°C) varied between packing systems ($P<0.0001$). Steaks stored in MAP with O_2 for 6 or 20 days appeared well done (high score), and the VSP steaks scored the lowest points and had the most reddish-pink color. Hunt et al. (1999) demonstrated that patties containing the myoglobin forms oxymyoglobin and metmyoglobin turned brown at 55°C. These results indicate that oxygen penetrates beef steaks and oxidizes deoxymyoglobin in 6 days. Toerngren (2003) found that loin steaks looked nearly well done after two days' storage in MAP with 80% O_2 and well done after 18 days. MA-packed steaks with 80% O_2 were less brown than beef packed with 50% O_2. The explanation could be that CO_2 helps O_2 to penetrate into the meat as CO_2 is dissolved in meat (Jakobsen & Bertelsen 2002).

Conclusions

Beef steaks packed and stored in modified atmosphere containing O_2 (50 or 80%) for 6 and 20 days at 2°C were less tender and juicy, had less meat flavour and more warmed over flavour than steaks exposed to normal air for two days. Furthermore, steaks exposed to O_2 (50 or 80%) looked well done, even if they were cooked to an internal temperature of only 62°C.

After 20 days' of ageing, vacuum-skin packed beef steaks were less tender than steaks aged in N_2.

Table 2. Mean (incl. min. and max.) sensory score (8 trained assessors using a non-structured line scale, anchored to the extremes; 0= slight, 15=intense) of beef loin steaks stored in 6 different packaging systems (see table 1) (n=6).

VOLATILE CHARACTERIZATION OF BLOOD SAUSAGE "MORCILLA" DE BURGOS

González, L.; Diez, A. M.; Collado, M., González-sanjosé, M.L., Jaime, I.; Ena, J. M.; Rovira, J.

Department of Biotechnology and Food Science. University of Burgos. Pza. Misael Bañuelos s/n. 09001. Burgos. SPAIN.

Background

"*Morcilla de Burgos*" is a popular cooked blood sausage (black pudding) produced in the region of Burgos, in the north of Spain. It consists of a mixture of chopped onion, rice, animal fat, blood, salt and different spices such as black pepper, paprika and cumin. According to a general scheme, onion and frozen fat are chopped at low temperature; also rice (raw or pre-cooked according to local procedures), salt, spices and blood are added and mixed. Then, the mixture is stuffed in natural casings of around 35-45 mm of diameter, which have been preserved with salt and are rinsed in clean water prior to use. The product is boiled for around 1 h at 94-95 ºC, air cooled to 8-10 ºC and finally store chilled at 4 ºC. This product is commercialised in local markets as a fresh product with a shelf-life of around 8-10 days.

Previous studies have been made about composition, physic-chemical and sensory characterization of this product. Depending on the amount of onion (between 15 and 70%) and the mixture of spices used, it is possible to distinguish between three different types of *morcilla*: type I, around 15% of onion and little spiced; type II elaborated with around 40% of onion and high spiced, and type III with an amount of onion between 45 to 70% and half spiced. These three types of *morcilla* are distributed in different geographic zones of Burgos, type I in the North, type II in the South and type III in the centre (Santos 2001, Santos et al., 2003). The presence of onion could be an important and characteristic feature in the flavour profile of *morcilla de Burgos*, together with the spices mixture that can be the key point to distinguish this type of blood sausage from others made in other places.

Objectives

The purpose of this study was to determinate the volatile profile of the blood sausage *morcilla de Burgos* by Solid Phase Micro Extraction (SPME) and GC-MS and determinate the influence of the percentage of onion in the total volatile profile.

Materials and methods

Sample preparation: Seven blood sausages of different manufacturers, four of them belonging to *morcilla* type III, 2 from the type III, and 1 from the type I were used in this study. All samples were vacuum packaged and were purchased from different local supermarkets. Each analysis was performed twice for every producer and each blood sausage was analysed for duplicate.

After peeling the sausages, they were homogenised in a lab blender, and 2 g of this homogenised were introduced in a headspace vial and heated at 70ºC (optimal consumption temperature) in a water bath for 5 min and allowed to equilibrate for 10 min with a 2 cm x 50/30 µm divinylbenzene/carboxen/polidimethylsiloxane (DVB/Carboxen/PDMS) Stable-Flex SPME fibre (Supelco. Bellefonte, USA). The fiber was conditioned prior to sampling at 270 ºC for 1 h. The SPME fibre was then injected into the GC injection port, and thermally desorbed in the GC injection for five minutes.

GC-MS Conditions: Gas chromatographic analyses were performed with an Agilent Technologist 6890N Series GC System (Agilent Technologist, Palo Alto. CA. USA) coupled to a Waters Autospec mass spectrometer (Waters. Milford, USA). The SPME fiber was injected into the GC injection port, and thermally desorbed at 150ºC. Compounds were separated on 30 m length x 0.25 mm I.D fused silica capillary column coated with 0.25 µm film thickness of silphenylene polysiloxane (Quadrex Corporation. New Haven. USA). The temperature of the column was programmed starting at 30 ºC after injection for 5 min, afterwards temperature was increased at a rate of 3 ºC/min from 30 to 120 ºC and held there for 5 min. Helium gas with a flow of 0.9 L/min was used as the GC carrier gas. During desorption of the SPME fibre the injector split valve was closed. The effluent from the capillary column went directly into the mass spectrometer, operated in the electron impact (EI) mode with an ionisation voltage of 70 eV.

Compounds were identified by comparing their mass spectra with a NIST spectrum library. These compounds were related to the different ingredients used in the elaboration of *morcilla* de Burgos, by

comparing them with previous published spectra obtained from different *Allium cepa* L. varieties, and spices (see references on table 1), and also from samples analysed, in the same conditions mentioned above, and belonging to the same onion variety and the same spices used for the elaboration of the product taken from one of the producers factory (data not shown).

Results and discussion

The results obtained show 60 different volatile compounds found in *morcilla de Burgos*, taking into account all the compounds that appear in all different samples analysed. Forty six of these compounds have been tentatively identified using the NIST library, and they are listed according to their appearance time in Table 1. As it was expected, all seven samples of *morcilla* presented a different volatile profile due to the particular way each producer elaborates their product, although all samples belonging to the same geographical area show more similarities in their profiles than to the others. In table 1 is also shown that *morcilla* type III has the higher number of volatile compounds (33), followed by *morcilla* type II with 25 and finally *morcilla* type I with 22. Only 10 of the compounds found were common to all three types of *morcilla*, four of them have been related to the presence of onion (2-methyl 2-pentenal, dipropyl disulphide, 1-propenyl propyl disulphide and dipropyl trisulphide), 3 could be related with black pepper (β-myrcene, 3Δ carene and δ limonene), 2 with oregano (see table 1) and one has not been associated to any ingredient. Dealing with the number of compounds becoming from onion, it has been shown that their number increase with the percentage of onion in *morcilla* composition. In that sense, eleven compounds were found in *morcilla* type III, which have a percentage of onion between 50 and 70%, 6 of these compounds appear in blood sausages belonging to type II, and finally only 4 of these compounds are recognised in *morcilla* type I, the one with a low percentage of onion in their composition (around 15%). In general, the most abundant compounds are those related with some spices, as black pepper (δ limonene), oregano and so on, and those associated with onion, such as dipropyl disulphide, which is the more abundant in some *morcilla* type III, as it is shown in Figure 1. However, it is remarkable that only few volatile compounds are related to rice and fat, and none have been identified related to cooked-blood. This feature can be due to the high intensity and high number of compounds associated with spices and onion, that can mask other volatiles, as well as the extraction method and column used in the present work, which is very specific to detect sulphured compounds.

Besides these general features, it is possible to see that some specific and characteristic compounds appear in the three different *morcilla* types that seem to agree with the different spices mixture used in their manufacture. In *morcilla* type I apart from some compounds, related to oregano and black pepper, appears the volatile, 1,3,8 p-menthatriene, which is characteristic from parsley (Belitz and Grosch, 1999), this spice is typically used in the north zone of Burgos. Moreover, in this type of *morcilla* appears decanal, 2-propanol 1-butoxi, and hexanal that could become from rice (see table 1), which is more abundant than in blood sausages elaborated in the other geographic zones. In *morcilla* type II it has been identified the compound cuminaldehyde, which is the more abundant substance in the chromatograms and it is related to cumin that it is used in abundance in that southern zone of Burgos. Finally, *morcilla* type III present some compounds such as 2-butenal 2-methyl, 1,3-butanediol or benzene 1,2-dimethyl that several authors had associated to paprika (Mateo et al., 1997; Guadayol et al., 1997). Together with these compounds, the presence of volatile compounds derivate from onion is also characteristic of *morcilla* belonging to this zone, as it has been mentioned above.

All these results agree with those obtained by Santos et al. (2003), where a trained sensory panel characterised *morcilla* type I by the blood flavour, black pepper predominant taste and by the abundance of rice, *morcilla* type II where characterised by the strong spicy taste, mainly by the addition of cumin and other spices, together with a background flavour and taste of onion, and *morcilla* type III by their strong onion flavour, with some burn notes due to paprika.

Conclusions

According to the results obtained in this study, it can be conclude that *morcilla de Burgos* has a volatile profile characterized by the presence of flavour notes becoming from onion, black pepper and oregano, as common feature of all different *morcilla* types of the region, although each producer present a slightly different volatile profile according to the kind of ingredients and percentages of raw material employed. Volatile onion compounds are mainly sulphur derivates, and they are more abundant in *morcilla* type III (11 compounds found), followed by *morcilla* type II (6), and finally by *morcilla* type I (4), in accordance with the percentage of onion used for elaborating the blood sausage in the different zones of production described.

It is also possible distinguish the *morcilla* of each zone by some characteristic spices used. In that sense, *morcilla* type I is not so spicy and only it appears a slightly note of parsley. In *morcilla* II the characteristic spicy among others used to be cumin, and in *morcilla* type III paprika.
More studies should be done to obtain more evidence to this preliminary study and to compare the volatile profile of *morcilla de Burgos* with other blood sausages elaborated in Spain and other countries.

FACTORS AFFECTING THE WATER CHANGES IN MEAT DURING TENDERISATION

Devine, C. E., Wells, R. W. and Lowe, T. E.
Bioengineering Sector, Hortresearch PB 3123 Hamilton, New Zealand

Background

Kristensen and Purslow (2001) showed that the water-holding of pork gradually decreased immediately post *rigor mortis* during ageing followed by an increase as ageing continued. They interpreted this as being due to degradation of the cytoskeletal proteins. They suggested that when the cytoskeletal proteins degrade, free water appears to be lost more readily during the first part of post mortem storage after which the water holding capacity increases to levels one day post mortem. It is not clear whether the water is directly associated with the cytoskeletal proteins or degradation of the protein assists with water appearance over time.

It is possible that the increase in water arises from connective tissue squeezing water as the structure of the meat is degraded through the breakdown of the cytoskeletal proteins. However an alternative view is that the water involved in the tertiary protein structures is released and this is the source of water rather than that from other compartments within the muscle. The degradative changes in the cytoskeletal proteins over time (ageing) results in increased drip and such changes are also likely to be those associated with meat tenderisation. In this study we explore the changes in drip and bound water associated with shear force changes as the meat ages.

It is now generally regarded that changes in the proteins holding the meat together termed structural or cytoskeletal proteins are responsible for shear force changes as the meat ages or tenderises. These proteins, desmin, titin, nebulin and others are affected by the action of endogenous proteases (calpain) in such a way to affect the tertiary structure altering water binding.

Objectives

To determine the relationships between centrifuge-expressed water, tightly-bound water, ultimate pH_u and meat tenderisation.

Materials and Methods

Animals

Lambs (n=24, approximately 12 months old), were processed in a commercial abattoir. The animals were electrically stunned followed by throat cut to sever carotid arteries and jugular veins and the *m. longissimus thoracis* (LT) from one side between 5th rib (T5) and 6th lumbar vertebra (L6) was removed immediately after stimulation and tightly wrapped by rolling in 4 layers of polythene cling film (11mm, GLAD wrap Clorox, New Zealand Ltd., Auckland New Zealand) and placed in a polythene bag (Devine et al, 2002). The wrapped muscle was chilled initially at 15°C until *rigor mortis* was complete.

Meat ageing

Following *rigor mortis* muscles were cut into four equal pieces along the length of the muscle, beginning at the lumbar end, placed in polythethene bags and held in air at 15°C and aged for 0, 5, 24 and 72hours as described previously (Lowe *et al.*, 2002). The meat samples were frozen at the specified times to stop further ageing. Thermocron iButton, Dallas Semiconductor Corp., Dallas Texas, USA) were placed both in the muscles to ensure the required temperatures were maintained. The ultimate pH (pH_u,) was measured with a Mettler Toledo pH meter with a combination puncture electrode (Mettler Toledo GmbH Process Switzerland) at approximately 24 hours post *rigor mortis*.

Cooking

Meat samples obtained for shear force measurement were stored at -20°C and cooked from the frozen state in an 85°C water bath to an internal temperatures of 75°C and then cooled rapidly in ice. The shear force was determined from six 1 cm x 1 cm samples sheared perpendicular to the orientation of the muscle fibres using an Instron with a tooth-shaped head to conform to the specification of a MIRINZ tenderometer (Graafhuis, *et al*., 1991).

Water binding measurements

At *rigor mortis* (0 ageing) a sample from the middle of the LT sample was weighed (approximately 2 g) and was cut so that the muscle fibres were vertical. The piece was transferred to a plastic centrifugation tube with the same orientation into which were placed 5 mm diameter polycarbonate beads and centrifuged for 15 min at 1800 G (Hettich Zentrifugen Tuttlingen, Germany). The duration of centrifugation was based on the extensive data from Kristensen and Purslow (2001) for pork. The same speed and duration of centrifugation was used throughout all experiments.

The centrifugation loss (free water) was the difference in weight before and after centrifugation. The remaining meat post-centrifugation, was then dried in a 105°C oven for 24 hours and the water loss determined. The water remaining was termed "bound water" for our purposes. The total water lost was the difference from original weight and final dried weight.

The procedure was undertaken at ageing times 0, 5, 24 and 72 hours. This gave shear force values, centrifuge loss (free water), a bound water compartment and total water changes over time.

Curves were fitted using the statistics function in Sigma Plot.

Results and Discussion

There was a large scatter in the results that appeared to be unrelated to measurement procedures and is in line with the observations of Honikel and Hamm (1984) showing that water binding of meat from different animals is highly variable. The pH_u over the range 5.4-6.16 was plotted against centrifuge-expressed water (analogous to free water or drip) at 72 hours (Fig 1 a) indicating that as the pH_u increased the centrifuge-expressed water decreased and this was in part responsible for the variability. The data was sorted into a low pH_u values (5.43-5.55) and normal to intermediate pH_u values (5.56-6.16) giving two sets of curves for each attribute (Fig 1b-1d). The two samples with pH_u values of 5.86 and 6.16 were left in the calculations, and form part of the discussion, although they were at the extreme edge of the relationships (Fig. 1 a) – with these included the significance between the low pH_u and normal pH_u attributes was not altered.

The centrifugation loss (Fig 1b) and total water loss (not shown) increased exponentially, whereas bound water (Fig. 1 d) and shear (Fig. 1 c) decreased exponentially. As the duration of ageing increased, the centrifugation loss increased (Fig 1 b) but changes with regard to the water content past this period were not considered in relation to factors such as re-uptake (Kristensen and Purslow, 2001). Final shear force values were achieved at 72 hours at 15°C (Fig 1 c).

There was a significantly ($p< 0.05$) greater (1.5 times) increase in free water 24 hours for meat of a low pH_u than for the normal to intermediate pH_u meat and a significant two-fold significant increase at 72 hours ($p< 0.05$).

For the shear force the curves for low pH_u meat were significantly more tender than for normal to intermediate pH_u meat at 24 hours and 72 hours ($p< 0.05$) (Fig. 1 c). The absence of a difference at 0 hours is expected as shear values start from the same point whatever the pH_u and in the case of sheep age to similar values but intermediate pH_u meat ages more slowly (Watanabe *et al*., 1995: Watanabe & Devine, 1996).

The bound water retained upon heating to 105°C also decreased over the ageing duration and there was significantly less water bound at 72 hours for the low pH_u group (Fig 1 d) than for the normal to intermediate pH_u group.

The total water (bound plus free) (range 75-90%) released also increased with ageing, with more being released for the low pH_u group.

When the two samples with pH_u values of 5.86 and 6.16 were removed from the calculations the relationships and significance between the low pH_u and normal pH_u attributes did not change.

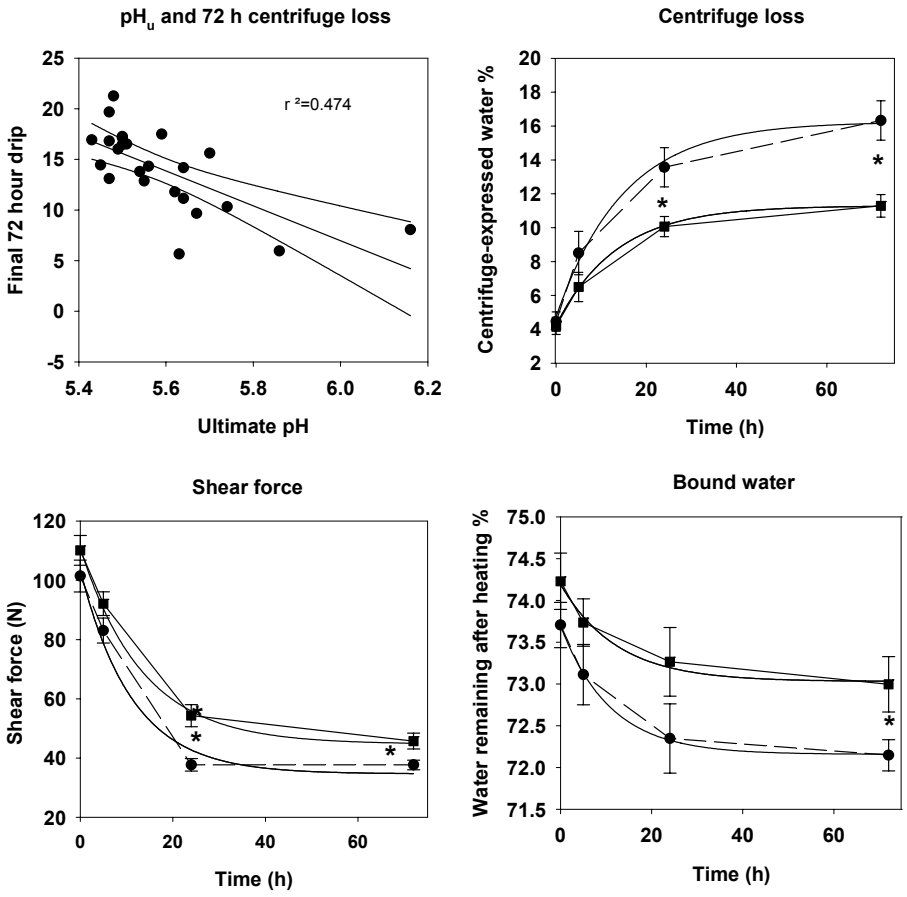

Figure 1. (**a**) The relationship between pH_u.and centrifuge-loss at 72 h ageing. The subsequent graphs are obtained from attributes sorted on the basis of low pH_u (5.43-5.55) (filled circles dashed line) and normal to intermediate pH_u values (5.56-6.16) (filled squares solid lines). (**b**) The increase in centrifuge-loss (free water) over time as the meat ages. (**c**) The reduction in shear force over time. (**d**) The decrease in the water retained in the meat after drying over time as the meat ages (bound water). The * indicates significant difference between the points on the curves at $p< 0.05$). The error bars are ± se and the fitted curves are derived from exponential functions.

The changes over time for free water, bound water and the shear force, are described by fitted exponential curves. It is difficult to establish causative interrelationships because such relationships could be fortuitous. However, the present experiments are consistent with changes in the water components being affected by degradation of cytoskeletal proteins. Free water expressed as drip, naturally increases over time, but the amount produced is also sensitive to various *prerigor* temperature effects (Offer *et al*., 1991) and as the temperatures were similar in this study, the relationship between centrifuge-expressible water and shear force is not unexpected.

The contractile proteins, actin and myosin, are components that are intimately bound to water in their tertiary structure and release of this water is a consequence of changes in interfilament spacing and protein denaturation related to the *prerigor* temperatures, sarcomere length and pH conditions (Honikel *et al.*, 1986; Offer *et al*., 1991). After *rigor mortis* is achieved, the myosin is protected to some extent through the formation of actomyosin (Offer *et al*., 1991), but the consequences persist while the meat ages. The characteristics of water binding by myosin, affected by temperature, pH_u and processing conditions, not only provides the initial drip (analogous but not identical to the centrifuge-expressed water) from meat, but this drip increases over time supplemented from the water associated with the breakdown of cytoskeletal

proteins. The bound water changes are still smaller that the changes that occur in free water. Previous studies by others have only been concerned with the water that comes out as drip rather than water associated with cytoskeletal proteins.

The water released over time includes the contribution from centrifuge-expressed water and bound water and suggests that the water content of meat known as drip is significantly affected by ageing duration. All sources of water are not known at this stage, while some is likely to be water located in the muscle fibres other water is likely to come from components of the extracellular matrix such as hyaluronan (Fraser & Laurent, 1996) that also bind water.

Conclusions

The increase of free water over time is an inevitable consequence of meat tenderisation, with low pH_u meat having more free water, less bound water, greater tenderisation than meat with an increasingly elevated pH_u. The water release during tenderising may be directly related to breakdown of the cytoskeletal proteins.

PERFORMANCE DURING RETAIL DISPLAY OF BEEF AND BISON STEAKS AFTER STORAGE UNDER VACUUM AND MODIFIED ATMOSPHERE PACKAGING

Dhanda, J.S., Pietrasik, Z., Shand, P.J. and Pegg, R.B.

University of Saskatchewan, Department of Applied Microbiology and Food Science, 51 Campus Drive, Saskatoon, SK, S7N 5A8, Canada

Background

The colour of meat is the single most important factor that influences the buying decision of the consumer. Myoglobin, sometimes referred to as dexoymyoblogin (DOMB), is the main pigment of meat and has a purplish red colour. When a freshly cut surface of meat comes in contact with air, DOMB is oxygenated and converted to oxymyoglobin (OMB); this gives beef a bright cherry red appearance and this colour is normally used as an indicator of freshness by the consumer. If only small quantities of oxygen are present, such as in a partial vacuum or a sealed semi-permeable package, DOMB is converted to metmyoglobin (MMB) via oxidation giving the meat a brown appearance. Development of this brown pigment is a serious problem in merchandising meat, because most consumers associate it with a product that has been stored too long. Bison meat is traditionally viewed as having a dark red colour. This colour is not as acceptable to consumers who are conditioned to the bright cherry red colour of beef. The colour of the meat can be controlled, if the factors influencing it are better understood. In the meat industry, vacuum packaging (VP) is employed to maximize the shelf-life of meat, whereas modified atmosphere packaging (MAP), containing high levels of oxygen, is widely used to attain the bright red colour of meat through oxygenation of DOMB.

Objectives

The objective of this study was to assess the influence of injection, packaging and storage conditions on the colour stability of beef and bison steaks during retail display.

Materials and methods

Fresh beef and bison loins (*longissimus lumborum*, LL - 4 each) were procured from local sources. Each LL was divided into two sections. One section was injected with brine containing NaCl and sodium tripolyphosphate (0.5% and 0.3%, respectively in the finished product) to achieve 20% extension by weight, while the other section was kept as a non-injected control. Then, each loin was divided into as many steaks (2.54 cm thick) as possible. These steaks were randomly allocated to storage atmospheres (MAP and VP), storage temperatures (-1 and +4°C) and storage interval subgroups (overnight, 1 and 2 weeks; and 1, 2 and 3 weeks for MAP and VP, respectively). The steaks (n=48) for VP treatment were individually packaged in ethylene/vinyl acetate copolymer polyvinylidene-chloride (PVDC) laminate bags. After making 2 holes through the over-wrap film for free exchange of gases, the steaks (n=48) for MAP were masterpacked in high oxygen using Cryovac B series bags. The headspace was evacuated, filled with a mixture of 70% O_2/30% CO_2 and then sealed. VP and MAP steaks were stored at designated temperatures for set periods. After removal from the main packaging following the designated storage interval, steaks were re-packaged on styrofoam trays over-wrapped with an oxygen permeable film and then placed in a retail display case (under 24 h fluorescent lighting with average light intensity of 975 lx) maintained at 3.0±1°C. Colour (L*, a* and b*) and absorbance was measured using a HunterLab Miniscan XE colorimeter daily for 5 days. Different forms of myoglobin (*i.e.*, OMB, MMB and DOMB) were calculated as described by Hunt *et al.* (1991).

Results and discussion

As is typical of most game animals, bison meat appeared darker than beef, yet was of similar initial pH (5.3). It has a negligible amount of intramuscular fat, which could be a possible reason for its darker appearance. In the present study, bison meat bloomed quickly with a dark red colour, but it tended to loose its brightness readily on storage compared to that of beef. The ability of different muscles to resist MMB formation during aerobic storage varies greatly and depends upon the species in question, anatomical location within the carcass and most importantly variations in the rate of DOMB oxidation and the ability of muscle to consume

oxygen; *i.e.*, muscles with high activities of oxygen-utilizing enzymes, that allow little penetration of oxygen into the tissue, tend to discolour more rapidly.

HunterLab colour values, particularly a* values, are a good indication of the redness of meat: the higher the a* value, the redder the meat. The change in colour of beef and bison steaks was monitored for 5 days. For beef, the decline in a* values was gradual and significant ($p<0.05$) between day 0 and day 5, whereas for bison the steaks held a bright red colour for only the first 2 days. After which, discolouration of bison steaks became evident; most of the steaks had to be discarded before the completion of the retail display study. As expected, steaks stored at the lower temperature (-1°C) held better colour than those stored at the higher temperature (+4°C). Because the maximum storage life of meat is attained at the lowest possible temperature, without freezing the meat (*i.e.*, between -1 and -1.5°C), any increase in this optimum storage temperature will result in a proportional decrease in the storage life (Gill and Shand, 1993). The rate of change in redness or discolouration increases with a rise in storage temperature (Jeremiah and Gibson, 2001). Injection had a beneficial effect on the colour stability of steaks during retail display; however, this positive effect was more pronounced for bison steaks compared to those of beef. Steaks stored overnight under MAP (MAP-OV) prior to retail display maintained the highest a* values (*i.e.*, a brighter red colour) for up to 5 days compared to those stored under vacuum (VP1, VP2 and VP3). Bison steaks stored for 2 weeks under MAP were grossly discoloured by the end of the storage period and were discarded from the retail display study (data not shown).

Figs. 1 and 2 depict the effects of injection treatment, temperature, packaging type and storage in the retail display case on the relative proportions of OMB. Beef steaks maintained significantly ($p<0.05$) higher proportions of OMB compared to bison steaks: darker and less redder bison steaks (*i.e.*, lower a* values) compared to beef ones complemented these results. Injected steaks and steaks stored at the lower temperature (-1°C) had significantly ($p<0.05$) higher OMB levels compared to non-injected steaks and those stored at the higher temperature (+4°C), respectively. Present results clearly show the detrimental effects of storage and display on OMB content: MMB formation increased, while OMB proportions decreased with increasing storage time in the retail display case and corresponded to the changes observed in HunterLab values. The decrease in proportions of OMB for steaks in the retail display case was dependant upon injection treatment and storage temperature, as injected steaks and those stored at -1°C were generally redder and contained more OMB. This clearly demonstrates the beneficial effects of a lower storage temperature and antioxidative properties of phosphates on muscle colour stability. MAP-OV steaks maintained the highest OMB content for up to 5 days during retail display compared to those stored under vacuum (VP1, VP2 and VP3). A continued supply of oxygen in the headspace was responsible for oxygenation of DOMB, hence, the bright red colour. Nevertheless, OMB levels were significantly ($p<0.05$) lower in bison steaks compared to those of beef irrespective of packaging treatments.

Conclusions

Marination had a beneficial effect on the colour stability of steaks during retail display, but this positive effect was more pronounced for bison steaks compared to those of beef. The results obtained from the present study support the view that MAP containing a high oxygen concentration is not suitable for long storage; however, such packaging is well suited for display applications when the time between packaging and display is short. High oxygen-containing modified atmospheres tend to stabilize the oxygenated state of DOMB for relatively short periods, whereas VP is a better option when prolonged storage is required.

Background

Beef is losing ground to sales of other meats and it is important therefore to try to determine the origins of this declining consumption. The origins can be found in both the intrinsic qualities of the beef on offer and consumer expectations. Concerns about healthier eating and the recommendation to reduce the consumption of saturated fats from animal origin that may be related to cardio-vascular disease could impact on meat consumption or on the choice of leaner meats. Changing life-styles, with smaller households and less time spent in meal preparation may also influence the type of food chosen with an increase in prepared meals and eating out. The knowledge of the importance of these factors could be crucial in predicting future trends in consumer consumption of beef and in providing a basis for future strategic planning in the beef industry.

Different approaches have been used to determine the intrinsic factors governing consumer choice. Surveys have been conducted on choice in relation to external fat cover and marbling in Canada (Jeremiah, 1981 and 1982) and, more recently by questionnaires, on Belgian consumers' perceptions of beef (Verbeke and Viaene, 1999) and the importance of characteristics of beef as quality indicators in the shop (Glitsch, 2000) in six European countries. These studies all show importance of various beef appearance characteristics, of which fat cover and marbling were included, however they do not investigate the actual preferred levels of fatness in beef.

In 1955, Pomeroy (1956) undertook a survey at the (now) Royal Smithfield Show in England to determine consumer preferences for beef in terms of fatness. Fatty beef rib joints (with 40% of the cut surface visible as fat) were preferred by 63% of consumers. In 1982, Dransfield (1983) repeated the survey using similar joints and observed that the preference had fallen to 24% and that most consumers preferred the leanest rib cut with only 30% visible fat. In 2002, the opportunity arose to restage the study on consumer preferences for fatness thus giving evidence of changes in preferences over half a century.

Objectives

- Determine British consumer preferences according to the level of fatness in beef.
- Determine the changes in consumer preferences over half a century by comparing the results with studies performed in 1982 and 1955.
- Relate consumer choice to socio-demographic categories.

Materials and methods

Both previous surveys were undertaken at the (now) Royal Smithfield Show, a renowned Agricultural show held every 2 years in London. As Dransfield believed in 1982, those attending the show might not statistically represent consumers in the whole UK population, however the opportunity to re-stage the surveys conducted in 1955 (Pomeroy, 1956) and 1982 (Dransfield, 1983) greatly outweighs any disadvantages of a restricted sample of consumers.

The procedures and analyses used here followed as closely as possible those used in 1955 (Pomeroy, 1956) and 1982 (Dransfield, 1983) to facilitate comparison of results. However, unlike the earlier studies, the fatter beef rib joints, with a cut surface of 40 and 48% visible fat, could not be obtained locally at supermarkets, butcheries or abattoirs. As an alternative, photographs of beef rib joints were made, following those published previously (Pomeroy, 1956; Dransfield, 1983). Digital images of these beef photographs were

computer modified to achieve the fatness levels (48, 40, 37 and 30% of the cut surface) and the lean to fat ratios (1.05, 1.36, 1.52 and 2.22, respectively for the given fatness levels) similar to those used in the two previous studies.

Four different beef rib cuts were photographed and each image was computer modified to give the four levels of fatness for each rib giving a total of 16 (4x4) photographs. Four A3 posters were made, each showing four images: the four different ribs of beef, each with a different level of fatness. The order of the level of fatness and the rib was randomly placed in the poster and each rib was randomly assigned a three digit number.

The posters of raw beef ribs were randomly presented to consumers at the Royal Smithfield Show in London, England in November 2002. Each poster was seen by approximately equal numbers of consumers on each of the four days of the show. The consumers were asked to rank the beef samples in order giving their first, second, third and fourth preferences. Place of residence, occupation, age, number of children and marital status were also asked of each consumer.

Significant differences in the ranking of the four fat levels were observed using Friedman test (SAS, 1999). Links between the consumers' first choices and socio-demographic information were determined using χ^2 test (SAS, 1996).

Results

1. Consumers

The survey was completed by 1064 consumers, all over 15 years old, of which the majority (987) were from Great Britain. This compares with 565 in 1955 and 1880 consumers in 1982.

Comparisons of the socio-demographic information about the consumers showed that a lower proportion of consumers from North East, London and Home Counties regions of England participated than had in the two previous studies and might be explained, at least in part, by changes in regional boundaries and the recent importance placed on attracting participation from all regions of the UK. Greater proportions of consumers were observed from Scotland and overseas.

The age distribution of participants was similar to that in 1982 but with a greater proportion of participants under 30 years of age than in 1955. A greater proportion of farmers and a lower proportion of butchers completed the survey in 2002 than in 1955 or in 1982. There were also a greater proportion of participants without children and fewer with 3 or more children than in 1982 (number of children was not available for the 1955 survey).

In the current survey, the proportion of single/divorced/widowed was similar to that of married/co-habiting people and there were almost four times as many men as women. These statistics were not available for the 1955 and 1982 surveys.

2. Consumer preferences

The consumer rankings of the four fatness levels are given in Table 1. The 2002 first choice rankings differed significantly (Friedman's test; $P<0.01$) from each other for all four fatness levels.

The leanest sample (with 30% of the surface as fat) was the most preferred cut, being the first choice for 53% of consumers. This was a slightly lower percentage than that (60%) obtained in 1982. In 1955, this leanest cut was ranked only third in preference.
The second most preferred cut in 2002 (placed first by 31% of consumers) was the second leanest (37% fat), followed by third leanest (40% fat chosen by 13% of consumers). In 1982, the inverse ranking of these two fatness levels was observed.

The biggest shifts in the first choice preferences from 1982 to 2002 were the increase in the percentage of people preferring the 37% fat and the decrease in those preferring the cut with 40% fat. Thus there had been a decrease in preference for fatness at these levels over the past 20 years.

In all three surveys, the fattest (48%) beef cut was the least popular selection, but, even at this low preference, a trend was evident. It was placed as first choice by fewer and fewer people, decreasing from 6 to 4 to 3% of consumers for the 1955, 1982 and 2002 surveys, respectively. The largest change over this half century was a decrease in first choice preference for the rib cuts with 40% fat. The percentage of consumers giving this as their first choice decreased from 63% in 1955 to 24 % in 1982 and to only 13% in 2002 (Table 1).

Table 1. Percentage of consumer ranking their preference for the four fat levels in surveys conducted in 1955, 1982 and 2002

Fat level (% cut surface)	First choice - preferred 1955	1982	2002	2nd choice 2002	3rd choice 2002	4th choice 2002
30	**12**	**60**	**53**	26	13	8
37	**17**	**12**	**31**	47	19	3
40	**63**	**24**	**13**	23	56	8
48	**6**	**4**	**3**	4	12	81

Second and third preferred choices, and by default the least preferred, were only available from 2002 survey (Table 1). In this, the most preferred second choice (for 47% consumers) was the 37% fatness level. The leanest (30% fat) and the 40% fatness level were selected each by a quarter of the consumers as their second choice. The third choice was most often (56% of consumers) the 40% fatness level and the last choice, or least preferred, for 81% of consumers, was the fattest rib (48% fat).

3. Preferences and socio-demographic data

From 1955 to 1982, and similarly from 1982 to 2002, the decrease in the proportions of consumers selecting either of the two fattiest beef cuts as their preferred was similar for all socio-demographic categories. A slightly higher proportion of consumers aged 50 years or over preferred one of the two fattest ribs in both 1955 and 1982 than the other age categories, although this tendency was not observed in the 2002 survey. Indeed there was a lower proportion of those 50 years and over for the fattest (48%) rib than for the other fatness levels. Of those choosing the fattest beef (48% fat), none of them were in the youngest (15-20 year old) age category.

There were few effects of gender on choice, except for the fattest beef which was placed as first choice by 30 people (3% of the whole consumer sample) of whom 28 were men.

Discussion

While fat is the only factor studied here, it is acknowledged that it is not the only factor considered in choosing beef by the consumer or in the purchase decision. However, fat content is, and clearly has been for the last 50 years, an important factor not only for consumer preference but also in purchase.

Considering only the surveys in 1982 and 2002, the proportion of consumers choosing the leanest rib had changed little, but fewer people chose the intermediate level of fatness in 2002. Considering all three surveys, the number of people choosing the two leanest cuts of beef has increased from 29% in 1955 to 72% in 1982 and 84% in 2002. The fattest rib cut (48% visible fat) was the least preferred in all 3 surveys. Although not unusual in 1955, it is unlikely that this high level of fatness in beef would be readily available nowadays.

Choice is likely to include other factors which may involve the consumer in a relatively extended problem solving and intensive evaluation of beef attributes in making the purchase (Verbeke, 2000). When purchasing meat in the UK in 1958 (see review by Jeremiah, 1982), 60% of consumers considered colour of lean, 36% leanness, 28% marbling, 25% quality of fat, 10% bone and 4% firmness. So, at that time, colour appeared to be more important although fatness played an important role. The reasons for this are unclear but

may be due to the variations on offer in the shop and the importance at that time placed on colour as an indicator of freshness and quality. The greater importance of fatness nowadays is supported by consumer studies conducted in different European countries (Glitsch, 2000) in which consumers were asked to rank "quality in the shop". Irish and UK consumers ranked leanness as one of the most helpful characteristics and marbling was one of the second choices. German and Spanish consumers ranked leanness as one of the second most helpful characteristics.

This study concerned only beef but other studies suggest similar tendencies in preference for leaner lamb and pork. However these other studies are punctual, whereas this survey on beef is the first time qualitative studies have been compared over such a long period. As far as we are aware no longitudinal studies have been performed on preferences for different types of meats.

Finally, it is interesting to note that the increasing preference for leaner meat since 1950s is in contrast to the trend of an increase in the proportion of over-weight people in the UK.

Conclusions

- Fatness in beef has been an important characteristic in the consumers' choice for the last half century, but the majority of today's British consumers preferring leaner meat to their predecessors.

- Since the first meat congress (now called The First European Meeting of Meat Research Workers) in 1955, the percentage of British choosing cuts of beef with less than 40% visible fat has increased from 29% to 84% today.

- The percentage of people choosing the leanest cut offered (30% of the surface area) has stabilised but fatter beef was chosen by fewer people than in previous surveys. The preference of UK consumers for lean cuts of beef is likely to continue in the future.

- Modern production methods should take into account this continued trend in consumer preference for lean beef.

TENDERNESS IN *M. LONGISSIMUS DORSI* FROM COWS – EFFECT OF PELVIC SUSPENSION AND AGEING TIME

Enfält, A.-C., Lundesjö Ahnström, M., Svensson, K. Hansson, I. & Lundström, K.

Department of Food Science, Swedish University of Agricultural Sciences (SLU), P.O. Box 7051, S-750 07 SWEDEN, e-mail: lotta.enfalt@lmv.slu.se

Background

Tenderness is found to be the most important trait when meat is judged from a sensory point of view (Koohmaraie, *et al*., 1998). Meat from older cows is often rejected because it is considered tough. Madsen (1997) found that the age of the cow (2–9 years) did not substantially affect the tenderness in *M. longissimus dorsi* when it was aged for 14 days. Thus, it is of value to study the quality of meat from cows.

Most studies evaluating meat tenderness are done on meat aged for a standardized time, then frozen until heat treatment. However, in the fresh meat marketing of whole steaks, most meat is aged and sold fresh without freezing. Shanks *et al*. (2002) showed that freezing positively affected tenderness compared with meat stored fresh. This indicates the importance of a correct and consistent treatment when meat tenderness is evaluated and implies that results from studies on frozen meat might not be directly applicably to meat marketed/consumed fresh.

An alternative method to enhance tenderness in beef meat is the use of pelvic suspension, instead of Achilles suspension. Pelvic suspension has been reported to improve tenderness in young bulls (Lundesjö *et al*., 2001; Sørheim *et al*., 2001), steers (Hostetler *et al*., 1972) and heifers (Jeremiah *et al*., 1984; Lundesjö *et al*., 2002, Lundesjö Ahnström *et al.*, 2004). Moreover, pelvic suspension was also found to decrease the variation in tenderness. To our knowledge, no studies evaluate the effect of pelvic suspension on meat from cows and it is therefore of interest to evaluate pelvic suspension and different ageing times in cows.

Objectives

The aim of this study was to evaluate the effect of pelvic suspension and ageing time on shear force in fresh *M. longissimus dorsi* from cows. In addition, the effect of freezing on shear force was also studied for meat aged for 7 days.

Materials and methods

Animals. Twelve cows of the Swedish Red and White breed, selected at a commercial slaughter plant, were used. The background of the animals was unknown but only cows in good condition were included in the study. The average slaughter weight and age at slaughter was 315 kg (range 265 – 375) and 68 months (45 – 80), respectively. *M. longissimus dorsi* (LD) from both sides of the 12 carcasses were used.

Slaughter, cutting and preparation of samples. The animals were slaughtered according to the standard routines at the slaughter plant. All carcasses were electrically stimulated, 20 min *p.m*. Left sides were rehung in the pelvic bone, after splitting (app. 45 min *p.m*.), by attaching a rope in ilium. The right sides were used as control, and were kept hung in the Achilles tendon. The carcasses were chilled 30 min in a chilling tunnel (–2°C, –4°C, –2°C), and thereafter in a chilling room (+2-4°C). After 24 h chilling, the carcasses were divided in fore and hindquarter between the 8th and 9th rib from the cranial part. At 48 h *p.m*. LD from both sides were collected, packed in plastic bags and transported to the laboratory. pH was registered to avoid samples with DFD (pH>5.8) (pH-meter WTW pH 340, Germany; electrode Knick SE 104 Germany).

Length and weight of the muscles were registered and each LD was separated into six 10-cm pieces for texture analyses. The pieces were randomized for ageing at 4°C for 2, 4, 7, 14 or 21 days, and also for 7 days followed by freezing at –20°C. All samples were weighed and packed in vacuum bags. Within each carcass, samples were given the same treatment in both left and right side. The sample aged for 2 days was heat treated immediately at the laboratory. A 1-cm piece for analysis of intramuscular fat content (IMF) was

packed in vacuum and stored in –20°C until analysis. A separate 5-cm sample was also packed in vacuum for measurement of pH during storage and kept at 4°C.

Instrumental tenderness. Frozen samples (aged 7 days) were thawed overnight at 4°C. The samples were weighed before further preparation. All samples were kept in a room-tempered water bath for 120 min, before weighing, repacking and heat treatment in a water bath (70°C) during 120 min, until an internal temperature of 69.5°C was reached. Thereafter, the samples were chilled in cold running tap water for 20 min. The samples were stored at 4°C until shear force measurements were performed. Heat-treated samples were room tempered in a water bath for at least 2 h before shear force analysis. Maximal shear force values (WB_{max} in N) was registered on strips (10*10*40 mm) cut parallel with the fiber direction, using a Stable Micro Systems Texture Analyzer HD 100 (Godalning, UK), equipped with a Warner-Bratzler metal blade (1 mm thick; speed 0.83 mm/s) (Honikel, 1998).

IMF, pH and water losses. IMF was analyzed after hydrolysis, using petroleumether for extraction (Soxtec System H^+ equipment, Tecator AB, Höganäs). pH measurement at 2 days *p.m*. was performed when the LD were divided into the different treatments (pH-meter WTW pH 340, Germany; electrode Knick SE 104 Germany). The following pH registrations after 4, 7, 14 and 21 days of ageing were made on the same sample. Water loss was expressed in percentage of initial weight and was calculated as *purge* [(initial weight – weight before heat treatment)/initial weight *100] and *total loss* [(initial weight – weight after cooking)/initial weight *100]. Freezing loss for the frozen samples was calculated as [(initial weight – weight after freezing)/initial weight *100].

Statistical analysis. Data were analyzed with the MIXED procedure in Statistical Analysis System (Version 8e, SAS Institute Inc., Gary, NC, USA). The model used included the fixed effects of ageing time, suspension method, their interaction, and the random effect of animal.

Results and discussion

Pelvic suspension changed the shape of the cuts because loins from the pelvic suspended carcasses were 3.6 cm longer that those from carcasses suspended by the Achilles tendon ($p=0.001$), which equals to a 5.0% increase. This was also found by Lundesjö *et al*. (2001) in *M. semimembranosus* from young bulls. Both suspension method ($p=0.039$; least square means 47.9 and 50.9 for pelvic and Achilles, respectively) and ageing time ($p<0.001$) significantly affected meat tenderness measured as WB_{max}. The overall effect of pelvic suspension independent of aging time was 5.9%, which is lower than previous findings for heifers (12.5%) (Lundesjö *et al*., 2002). Young bulls of the same breed as the cows in this study had as much as 21% decrease in shear force in *M. semimembranosus* after pelvic suspension and 7 days of ageing (Lundesjö *et al*., 2001; 2002).

Suspension method did not significantly interact with ageing time ($p=0.818$). It was, however still interesting to evaluate the combined effect of the two treatments, and therefore, each subgroup is presented in Table 1. Despite the overall effect of suspension method, with a higher tenderness for pelvic vis-á-vis Achilles suspension, no obvious differences could be found between suspension methods within each ageing time. With 2 days of ageing, shear force values tended to be lower for the pelvic suspended group ($p=0.083$). This difference was reduced by ageing time, giving equal values between suspension methods after 14 and 21 days of ageing. A lowering of the shear force values as an effect of pelvic suspension tallies with earlier results in other sexes (Hostetler *et al*., 1972; Jeremiah *et al*., 1984; Sørheim *et al*., 2001; Lundesjö *et al*., 2001; Lundesjö *et al*., 2002; Lundesjö Ahnström *et al*., 2004).

Shear force values declined over time, indicating a higher tenderness with longer ageing time, independent of suspension method (Table 1). This is in agreement with the findings by Sañudo *et al.* (2004). In the present study, both suspension methods had significant lower WB_{max} values at 4 days than at 2 days, but no difference between 4 and 7 days of ageing. However, the difference between 4 and 14 days was significant, but not between 14 and 21 days. With Achilles suspension there are larger differences between 7 and 14 and 21 days compared with the pelvic suspension. It can thus be concluded that with pelvic suspension, tenderness after 21 days ageing is already reached within 7 days even though there is a slight, but not

significant increase in tenderness with time. On the other hand, with normal suspension, it takes 14 days of ageing to reach the same value as with 21 days of ageing.

By freezing the samples after 7 days of ageing, shear force values were significantly reduced (see Table 1). The same effect was found for both suspension methods. This reduction gives meat with the same tenderness as for the meat aged for 14 or 21 days. It is, however, not clear if the improved tenderness as a consequence of freezing is accompanied by a lower juiciness. This could be assumed, as a consequence of the finding of higher freezing loss compared with purge from fresh meat stored for the same time. Shanks *et al*. (2002) also found a significant effect of freezing on tenderness and concluded that results for frozen samples might not be transferable to meat stored fresh. This needs to be further investigated.

pH increased in the samples during ageing, from 5.39 at day 2 to 5.50 at day 21 ($p<0.001$). This might be explained by a degradation of proteins during storage, giving a buffering effect in the meat. The overall water loss increased significantly with ageing time ($p<0.001$) (Table 2), but was not influenced by suspension method ($p=0.436$). Purge also increased with ageing time ($p<0.001$) and was lower for pelvic suspension than Achilles suspension ($p=0.030$). Within subgroups, the only difference was found at 14 days of ageing, with a lower loss as a result of pelvic suspension ($p=0.015$). The small effects found on water loss by suspension method in cows found here are in contrast to a larger effect reported earlier in young bulls and heifers (Eikelenboom *et al*., 1998; Lundesjö *et al*., 2001; Lundesjö *et al*., 2002). The frozen samples had higher water loss compared with those stored fresh, both with pelvic ($p=0.011$) and Achilles suspension ($p=0.001$). Higher water loss as a result of freezing was also found by Shanks *et al.* (2002).

Conclusions

In conclusion pelvic suspension gave a more tender meat, measured as lower shear force values, at 2 days of ageing, compared with normal hanging (Achilles). This difference was not found at longer ageing times and thus, pelvic suspension, does not seem to have a great influence on meat tenderness in LD from cows. The tenderness increased during ageing, from 2 to 21 days, in the same way with both pelvic suspension and Achilles suspension. Freezing the meat after 7 days of ageing gave higher tenderness, compared to fresh stored, and gave the same tenderness as meat aged for 14 and 21 days.

Background

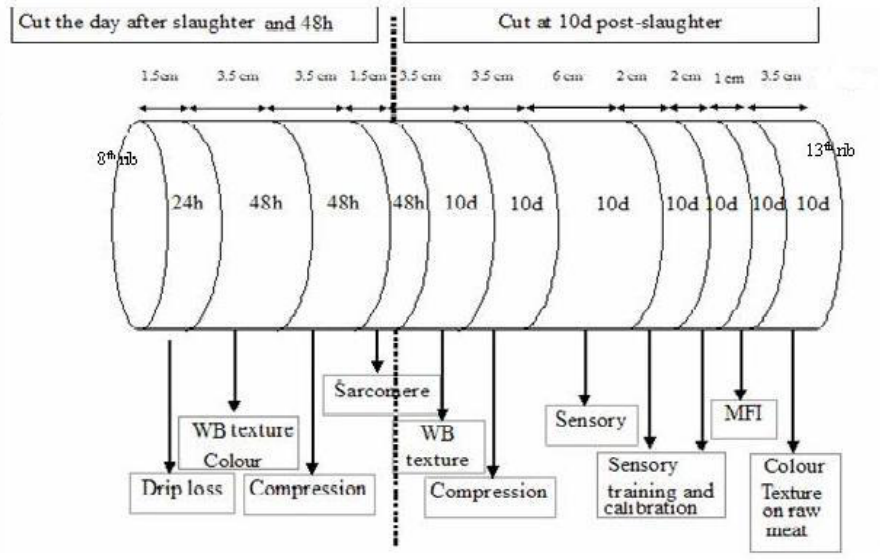
This research is a part of an European Union ongoing project aiming to compare carcass and meat quality of young bulls from several European cattle breeds (both dairy and beef), raised under standardized conditions to minimize environmental differences. *In vivo* measurements, covering production, slaughter data, meat and carcass quality parameters (both physical and chemical) and qualitative traits and their relationship with meat quality characters were investigated.
Some peculiarities of the different European cattle breeds are renowned, but we still need to improve our knowledge of their meat quality to understand the genetic background of these traits, to facilitate the design more efficient breeding programmes.
In particular, the extrinsic quality traits of meat, mainly tenderness and colour which are more appreciated by the consumer. These parameters are dependent on many *ante mortem* and *post mortem* factors, which need further study to understand the mechanisms determining their variability.

Objectives

Assess differences in instrumental meat quality traits (colour, water holding capacity and texture) in eight beef breeds from three European countries.

Materials and methods

The research was carried out on 243 young bulls from 8 different European beef breeds: Asturiana de los Valles, Asturiana de la Montaña, Avileña-Negra Ibérica and Pirenaica from Spain, Piemontese and Marchigiana from Italy, and Limousine and Charolaise from France. Diet and slaughtering methods were standardized for all the animals and are described in Sañudo *et al.* (2004).
At 24 hours after slaughter the *Longissimus thoracis* muscle was removed from carcass and stored at 3+/-1°C until 48 hours and then a section was subdivided in three slices and frozen, the other section was aged for 10 days and then was subdivided as shown in figure. The samples were frozen at -18°C. In this paper only the data performed at 10 days and water loss and pH at 24 hours are reported.



The water loss, by the drip method of Barton-Gade *et al.* (1994), and pH, by putting the probe into the muscle, were performed on fresh meat, then on samples aged 10 days thawing losses were recorded.
On the raw meat samples colour and compression tests were

performed. Colour coordinates were measured at ten points on the surface of slices, 3 cm thick according to Cassens *et al. (*1995). After exposure to oxygen for 1 hour, lightness (L*), redness (a*), yellowness (b*), chroma (C) and hue (H) were calculated with CIEL*a*b* System using D65 illuminant using spectrophotometer Minolta CM-2600d; reflectance spectra between 360 and 740 nm (by steps of 10 nm) were also measured.
On ten samples 1 cm^2 of cross section, with fiber direction paralleled to length (long axis), maximum load, stress at 20% and 80 %, maximum compression were measured with an Instron 4301 machine, using a modified device which avoids transverse elongation of the sample (Campo *et al.*, 2000).
Shear force was measured on raw and cooked meat. Samples were cooked in a waterbath at 80°C to an internal temperature of 78°C, then cooled in running tap water for 45' and stored in a refrigerator for 4 hours. Cooking losses were later calculated as percentage. Shear force was measured by a Warner Bratzler device mounted on an Instron 1011, on ten cores with section 1x1 cm for each animal, both of raw and cooked meat. Analysis of variance using breed as a factor was performed using GLM procedure of SAS package.

Results and discussion

pH and water losses
The pH at 24 hours (Table 1) showed that Limousine had significantly the higher values (5.90), than all other breeds. The Asturiana de la Montaña was significantly different from other breeds with mean pH values of 5.82. The lowest values were found in Charolaise, Pirenaica and both the Italian breeds (5.58 in average) which did not differ significantly, whilst the pH values of Avileña and Asturiana de los Valles were intermediate. A similar trend was found in the thawed meat aged 10 days, except for Limousine, which unlike the data at 24 hours, showed a lower pH, however close to the mean value of all breeds.
A low pH was generally found in the animals with a more marked beef aptitude, in particular Piemontese, while the more rustic breeds had a higher pH, even if within the norm, showing muscular fibres with a lower glycolytic power.
The drip losses (Table 1) showed a definitely lower value in Asturiana de la Montaña (1.11%) followed by Avileña (1.91%), while intermediate values were found in Marchigiana and Asturiana de los Valles, whilst Pirenaica, Piemontese and the French breeds had higher losses. Also with regard to thawing losses Asturiana de la Montaña gave the lowest value (6.85%), while the Avileña mean value did not differ from the other breeds. Cooking losses were generally lower than those reported in bibliography (Destefanis *et al.*, 1996) for the relevant losses caused by thawing, mainly in Limousine, Pirenaica and Asturiana de los Valles which showed the lowest value for cooking loss, while Charolaise and Italian breeds lost higher percentages of liquids. Water losses were higher in animals with a relevant muscular development and a slight adipose covering (Sañudo *et al*., 2004).
The pH and in particular its rate of fall in the first 48 hours after slaughter was highly correlated with water losses and shear force, this is in accord with Thompson (2002).

Colour
Analyzing colour (Table 2), a group of breeds, Italian and French, did not differ in lightness and hue, higher than the others, but were lower than other breeds in redness (a*), ranging from 14.74 to 15.84, except for Asturiana de los Valles which showed similar values (15.51). The opposite conditions (the lowest L* and H and the highest a*) were found in Asturiana de la Montaña and Avileña-Negra Ibérica. The remaining two Spanish breeds (Asturiana de los Valles and Pirenaica) showed intermediate values for L* and H and only Pirenaica for a*. The same group, which had lighter meat, showed a higher yellowness (b*): Charolaise was significantly different from Limousine (15.72 vs 15.03), and showed intermediate values with the Italian breeds and Pirenaica, with respect to the whole group. The remaining Spanish breed had lower b* values, particularly Asturiana de la Montaña compared to Asturiana de los Valles and Avileña-Negra Ibérica (13.51 vs 14.34 and 14.44 respectively). The latter had higher chroma being definitely different from the others, whilst Charolaise and Pirenaica had intermediate values, but different only from Limousine and Asturiana de Valles. Piemontese, Marchigiana and Asturiana de la Montaña had an intermediate chroma value and differed significantly only from Avileña-Negra Ibérica.

Texture
The Spanish rustic breeds and Charolaise presented a higher value of shear force on raw meat (Table 3), in particular compared with Piemontese. However, in these breeds a low shear force on cooked meat was

observed, together with Pirenaica, differing from Marchigiana, which was significantly tougher than the others on cooked meat, also if it showed intermediate value in raw meat.
With cooking Asturiana de los Valles and Piemontese meat became tougher, it is possible that excessive water losses and a marked shrinkage effect by the muscle contraction during cooking undervalued the Asturiana de los Valles and Piemontese, which had lean meat, with a greater development of muscle fibers, being hypertrophic animals. In particular Piemontese meat is commonly deemed as tender by the consumers and is consumed rare or raw (carpaccio).
Compression at 20% values, which can be related with myofibrillar resistance (Lepetit and Culioli, 1994), were in general low (near of 4 N/cm^2), showing an adequate tenderization through ageing (10 days in our study). The differences between breeds were not important, which showed the natural tendency of homogenizate myofibril resistance differences among breeds or individuals with ageing time. According to previous results (Sañudo *et al*., 2004), the highest values were found in Marchigiana breed, in correspondence with its shorter sarcomeres and its higher shear force values.
Compression at 80% values, which is probably due to the connective component resistance, showed important variability among breeds. This was expected since their differences in precocity and subsequent collagen characteristics (Campo *et al*., 2000), whereby the lowest values in Piemontese were related with the collagen composition of high muscularity animals. Conversely, two rustic type breeds and Charolaise gave the highest values (up to 40 N/cm^2), which are more characteristic of unimproved breeds.

Conclusions

Breed has an important effect on instrumental meat quality characteristics.
In particular, Asturiana de la Montaña shows very good water holding capacity and tenderness, while Italian and French breeds are characterized by their lightness and bright red appearance, appreciated by the consumer.
The data variability of these animals made us hope in the possibility of improving some quality traits, obtaining products appreciated by the consumer.

EFFECT OF CARCASS WEIGHT ON SENSORY QUALITY OF YOUNG HOLSTEIN BULLS

Linda Farmer[1], Bruce Moss[1], Terence Hagan[1], Laurence Majury[1], Griff Kirkpatrick[1], Raymond Steen[2], Desmond Patterson[2], Richard Kirkland[2], David Kilpatrick[1] and Sally Dawson[1]

[1]Department of Agriculture and Rural Development, Newforge Lane, Belfast, BT9 5PX, UK
[2]Agricultural Research Institute for Northern Ireland, Hillsborough, BT26 6DR, UK.

Background

A considerable proportion of beef produced in the UK is a byproduct of the dairy industry. In Northern Ireland, approximately 50% of beef animals slaughtered derive from the dairy herd while nearly 20% of animals are entire bulls. Young animals from this source are generally regarded as low in quality, especially at the lower weight ranges, receiving low EUROP grades for conformation and providing poor remuneration to the farmer. Meat from animals of this type is usually destined for the commodity minced (ground) beef market.

Previous research has studied the effect on the eating quality and other attributes of young bulls of diet and finishing, age at slaughter and genotype (e.g., Sinclair *et al.* 1998, Vestergaard *et al.* 2000). However, little of this research has focused on young dairy animals. This preliminary investigation forms part of a larger investigation on the rearing and use of young dairy bulls for beef production.

Objectives

This work aims to determine the effect of final live-weight of young dairy bulls on the eating quality of the beef from *biceps femoris* (silverside), chosen as it is a commonly used roasting joint of intermediate quality.

Materials and methods

Husbandry and slaughter

Ninety-three weaned Holstein bull calves were purchased from farms in Northern Ireland and housed at the Agricultural Research Institute for Northern Ireland. At approximately 15 weeks of age, calves were grouped into blocks of four animals according to similarity of live weight and age. One animal from each block was allocated at random to one of four treatments with different target slaughter weights, namely 400 (T3), 450 (T4), 500 (T5) and 550 (T6) kg. Animals were housed in pens accommodating between 4 and 9 animals within each slaughter weight treatment group. All animals were offered concentrates (maize meal, sugar beet pulp, vitamin/mineral premix, barley, and soyabean meal) *ad lib* with a restricted quantity of barley straw (nominally 0.5 kg/head/d). Of these animals, 48 were selected for assessment of eating quality, 15 in each of the heavier treatments and only three in T3. Data from this lightest group was excluded from statistical analysis due to the small number of animals.

The animals were slaughtered on seven different dates at the same plant with no electrical stimulation and the sides hung by the Achilles tendon. Treatments T4 to T6 were each slaughtered over four to six of these dates. The silverside joints were removed from the carcass at 24h *post mortem* and vacuum packed.

Preparation of meat

The joints were transported to the laboratory in a refrigerated van and aged at 2ºC for a total of 21 days from slaughter. After this time the joints were frozen and stored at -20ºC for a period of 3 to 4 months. Prior to sensory analysis the *biceps femoris* muscles were cut into 3 pieces cutting across the longitudinal axis of the muscles whilst still frozen, the joints were re-vacuum packed and returned to the freezer. The pieces were denoted A (proximal), B (centre), and C (distal). Only joints A and B were used in this study

Sensory Analysis

Joints were allowed to thaw in their vacuum packs at 4ºC for a period of 24h. Joints A and B (mean weights of 1720 and 2160kg) were prepared for roasting by removal of all fat and epimysium. The joints were browned on all sides before being placed in uncovered stainless steel dishes in an electric fan assisted oven (Falcon) at 180ºC for an estimated cooking time of 30 min per 500g, with start times adjusted to give similar finish times. All the joints were cooked to an internal temperature of 74 ºC. The outer surface was trimmed

from the cooked joints and the inner roast meat cut into portions (30-40g) for sensory analysis. The samples were held in a warm oven (95 to 100°C) before being served warm to the panellists within 5 minutes.
Panellists were volunteers from University and DARD departments who were untrained but had experience of participating in taste panels. The panellists assessed 96 joints from 48 animals over 36 sessions. Samples were allocated to the taste panels sessions using a balanced design (PSA Systems Version 3.3, Oliemans, Punter and Partners, Utrecht, The Netherlands) where each panellist was presented with a total of six samples. Panellists scored the first three samples (from three joints) for the subjective attributes, acceptability of aroma, flavour, texture, and overall acceptability, in this order, using a 10cm line scale anchored at each end (dislike extremely – like extremely) and at 50%. Panellists were advised that the central point differentiated between acceptable and unacceptable. Panellists were also asked to rate the sample on a four point category scale as being unacceptable (1), satisfactory everyday quality (2), better than everyday quality (3), premium quality (4), similar to that used in the Australian MSA system (Polkinghorne *et al.* 1999). Panellists then assessed three more samples from the same joints for the objective attributes, intensity of aroma, intensity of flavour, tenderness and juiciness, again on a 10 cm line scale. Each sample was tested by 10 consumers. Statistical analysis was conducted using a mixed model analysis of variance.

Results and discussion

Table 1 lists the live-weight of the animals used in this study together with those carcass characteristics that might be considered to influence eating quality. The groups of animals achieved their target mean live-weight at slaughter but there was some variation in the weights of individual animals. As expected, increasing live-weight and age gave a slight improvement in EUROP grade and an increase in fat grade and cover. These aspects will be discussed fully elsewhere. Table 2 shows the mean sensory scores for the subjective and objective sensory attributes of *biceps femoris* (silverside) from young Holstein bulls.

Table 1. Characteristics of animals belonging to the four groups used for eating quality assessment.

Treat-ment	No. anim-als	Mean live-weight (kg)	*SD*	Mean carcass weight (kg)	*SD*	Mean age (days)	*SD*	Conformation (EUROP grade)	Mean fat grade	*SD*	Mean fat cover (mm)	*SD*

Effect of liveweight

Only small differences were observed between roast beef from animals reared to different live-weights. There were no significant differences in texture or flavour. Meat from the smaller animals (T4) was, apprently, significantly more juicy but had a less acceptable aroma and was a little less acceptable overall than that from the animals reared to 500 or 550kg (T5, T6). However, the three animals reared to 400kg (T3) did not follow the same trend and the observed effect may be related only to group T4. Sinclair *et al.* (1998) reported that age at slaughter had no significant effect on the tenderness of meat from several muscles, including *biceps femoris*, from young bulls.

Effect of position in muscle

The most significant effect on eating quality was that of joint or position within the *biceps femoris* muscle, with highly or very highly significant effects observed for all sensory attributes. The greatest differences were in aspects of texture. The joint from the proximal portion of the muscle (A) was much more tender than the centre portion (B) and also had more acceptable texture. Differences in overall acceptability reflected this texture difference. Significant but smaller differences in the same direction were also observed for juiciness, intensity of flavour, and acceptability of flavour. Sensory trials with untrained panellists frequently show

Table 2: Effect of carcass weight and position in joint on subjective and objective sensory scores for eating quality of roast beef from *biceps femoris* (silverside) from young Holstein bulls.

[a] SED = standard error of difference, shown in brackets. *, **, *** = significant at P<0.05, 0.01, 0.001 respectively. ns = P≥0.05

[b] Data from 400kg group were not included in statistics as comprises only 3 animals.

correlation between flavour, juiciness and texture, perhaps due to the difficulty of separating these attributes completely and possibly due to inter-relationships between, for example, juiciness and flavour release. In this study, many of the attributes were highly correlated (P<0.001) with one another even though assessments were conducted on two separate samples. It is interesting that the panellists were able to differentiate between these joints for intensity of aroma and acceptability of aroma. As these attributes were assessed first, before the panellists had taken the sample into their mouths, these differences appear to be small but real and suggest that joint A gave a greater concentration of key odour volatiles when roasted, probably also contributing to the observed difference in flavour.

Live-weight x joint interactions

Seven of the eight attributes showed significant joint x live-weight interactions, suggesting that the size of the animal was important for the eating quality differences observed between the joints. Most affected was

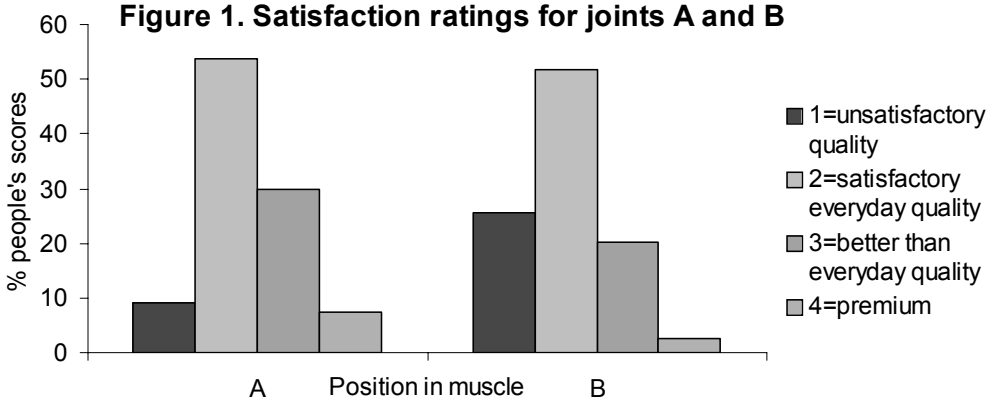
acceptability of texture, together with overall acceptability and intensity of odour. However, all the attributes followed a similar trend; joint A scored higher than joint B for the 450kg and 500kg animals but this difference was considerably reduced or removed in the 550kg animals. The data from the three 400kg animals also followed the same trend. Overall, this increased difference between the joints at the lower weights represented both a slight decrease in quality of joint B and a slight increase in the quality of joint A at these lower weights. As the muscles were aged to 21 days, the observed tenderness differences brtween joints may be due to differences in collagen content or sarcomere length. Such differences may be caused by differences in pH/temperature fall and size or fat cover of the muscle, or by differences in muscle development. Table 1 shows that the difference in fat class and cover between treatments T4 to T6 is small and would not appear to explain these results. Further work is required to determine the reason for these effects.

An exaggeration of sensory differences at the lower live-weights was also observed by Vestergard *et al.* (2000). Beef from young bulls reared to 360kg showed a greater difference in eating quality between beef from extensively and intensively reared animals than that from animals reared to 460kg. However, in this case, this effect was attributed to an intensive finishing period given to the older 'extensive' animals.

Satisfaction scores

The satisfaction ratings provide an indication of how the panellists in this trial assessed the overall quality of the *biceps femoris* roast beef presented to them (Figure 1). For both joints, most samples assessed to be 'satisfactory everyday quality' but, for joint A, a higher proportion of assessments were at the higher grades.

Figure 1. Satisfaction ratings for joints A and B



These preliminary results suggest that the eating quality of aged *biceps femoris* from these young dairy bulls is not poorer than that of roast beef joints purchased at retail and assessed previously. This observation concurs with the conclusion of Sinclair et al. (1998) that beef from young bulls, in their case of beef breeds, can be at least as good as the UK standard product. Further studies will be conducted to study the eating quality of a range of muscles from young dairy animals and to determine whether extensive aging is necessary to achieve acceptable eating quality.

Conclusions

This preliminary study indicates that the eating quality of *biceps femoris* (silverside) is affected significantly by the position within the joint but only slightly by live-weight. However, the sensory differences between joints are largely non-existent at 550kg but are exaggerated at the lower live-weights. Further research is needed to establish why this effect occurs and whether it can be managed to enable high quality beef to be obtained from young dairy bulls.

CONSEQUENCES OF USING DENTAL CLASSIFICATION AS INDICATOR OF MATURITY AND BEEF TENDERNESS

Grigera Naón, J.J., Schor, A., Cossu, M. E. and von Bernard, H.

Departamento de Producción Animal, Facultad de Agronomía, Universidad de Buenos Aires,
Avenida San Martín 4453, C 1417 DSQ, Buenos Aires, Argentina

Background

Usually decreased meat tenderness has been associated with increased cattle age (Tuma *et al*., 1963 and Wulf *et al*., 1996), this fact has led to include dental classification in current grading systems (Aus-Meat, 1998). Lawrence et al (2001 a) suggested that it was more accurate to assess maturity by sorting carcasses through the number of permanent incisors present at slaughter rather than by visual appreciation of ossification. However, Wythes and Shorthose (1991) and Lawrence et al. (2001 b) found that the dentition status of steers had no effect on Warner-Bratzler shear force and tenderness of *M. longissimus* assessed by sensory panel . Therefore, there exists some contradictory conclusions referred to the relationship between beef cattle maturity and meat tenderness.

Objectives

Our objective was to determine the relationship between tenderness and age, assessed by dentition status, of steers commercially produced in Argentina.

Materials and methods

Fifty five Angus steers were used, the number of permanent incisors were recorded previous to slaughter. Twenty animals had no permanent incisors, twenty had two and fifteen had four. Animals fell into two fat classes, having respectively 4 to 5 mm (class 1) and 6 to 7 mm (class 2) subcutaneous fat depth between the 12^{th} and 13^{th} rib, measured at the abattoir. Samples of *M. longissimus dorsi* were removed from each left carcass. Half of each sample was kept for 24 hours at $3\ ^0$ C previous tenderness determination and the other half, also kept at 3^0 C, was analyzed after 96 hours. Tenderness was measured with an Instron 4442 Universal Testing Machine (Canton, MA, USA) with a Warner-Bratzler shearing attachment on samples boiled for 50 minutes, in a water bath, to an internal temperature of $70\ ^0$C. Data were analyzed using GLM procedure of SAS (SAS Inst. Inc,. Cary, NC, USA).

Results and discussion

After 24 hrs in cold storage, meat from steers with two incisors was more tender ($p < 0.05$) (Table 1), than from those with no permanent incisors, differences were not detected ($p > 0.05$) neither between two and four nor between four and zero permanent incisors. After 96 hrs ageing, meat from all the dentition groups showed enhanced tenderness, meat from animals with two and four permanent incisors was more tender ($p < 0.01$) than meat from less mature steers. These results partially agree with Wythes and Shorthose (1991), who reported no differences among dentition groups attributed to contraction of myofibrils in unstimulated muscles. In our case, carcasses underwent electrical stimulation, but ageing period was shorter, it was at the very most 96 hours. Lawrence *et al*. (2001) in a very accurate experiment did not find, among five dentition groups, differences in tenderness of muscle *longissimus* aged for 14 days. They do not explain the possible causes of such finding. Our results contradict those reports and an indirect relationship is established between maturity and improved tenderness (Tuma *et al*., 1963, Shorthose and Harris, 1990 and Wulf *et al*., 1996). This leads to suggest that more research is needed to determine if dentition can be used as a reliable predictor of tenderness. Correlation between fatness and shear force was significant ($r = - 0.34$, $p < 0.05$).

Conclusions

Ageing improved tenderness irrespective of dentition group. After a short ageing period, meat from steers with two and four permanent incisors proved to be more tender than meat from those animals showing no permanent incisors.

EFFECTS OF VARIOUS PRESLAUGHTER HANDLING TREATMENTS ON THE COLOUR OF DIFFERENT PORK MUSCLES

Hambrecht, E. and Eissen, J. J.
Nutreco Swine Research Centre, P.O. Box 220, 5830 AE Boxmeer, The Netherlands

Background

Colour is one of the most important quality attributes of pork because colour can be easily assessed by both producers and consumers. In addition, colour is related to other important quality aspects. Various phases during preslaughter handling, such as transport (Leheska et al., 2003), lairage (Pérez et al., 2002) and stress immediately before slaughter (Hambrecht et al., 2004b) may affect pork colour. Due to its size and accessibility, the LM is the most frequently assessed muscle. However, muscles consist of various fibre types that determine the metabolic properties of a muscle. It can be expected that muscles, depending on their anatomical location and metabolic profile, react differently to the physical and psychological stressors associated with preslaughter handling. In agreement, Warner et al. (1993) found that the longissimus, a predominantly glycolytic muscle, was a reliable pork quality indicator for other muscles when its colour was dark and exudate low. However, when its colour was pale and exudate high, quality of the longissimus muscle was only related to the major ham muscles and not to the shoulder muscles that have a more oxidative metabolism.

Objectives

The objective of the present experiment was to investigate whether the effects of transport, lairage, and preslaughter stress on colour are different in various, commercially important pork muscles.

Materials and methods

All pigs were commercial halothane-free end products of the *Hypor* pig breeding company. Pigs (n= 384) were assigned to one of eight treatments in a 2 × 2 × 2 factorial arrangement, with two types of transport (short (50 min) and smooth or long (3 h) and rough), two lairage durations (long (3 h; considered as optimal) or short (<45 min; considered as sub-optimal)) and two stress levels immediately before slaughter (minimal or high). Eight groups of 48 pigs, all originating from the same commercial farm, were processed during eight weeks on various days. Long and short lairage alternated between consecutive weeks. Transport types and preslaughter stress levels were varied within the same slaughter day. Pigs were electrically stunned in a fully automated, head-to-heart stunning system at a commercial plant. At 23 h post-mortem pork cuts were harvested for colour measurements. All measurements were done after a 10-min blooming period with a Minolta Portable Chroma Meter (Model CR 210). L* (lightness), a* (redness), and b* (yellowness) values were assessed in the *longissimus lumborum* muscle (**LL**) at the level of the third lumbar vertebra, in the *longissimus thoracic* muscle (**LT**) at the level of the 6th thoracic vertebra, in the *serratus ventralis* muscle (**SV**), and in the *semimembranosus* muscle (**SM**). Data were analysed by the mixed-model procedure (PROC MIXED) of SAS. Tests of multiple comparisons of least squares means were adjusted according to the TUKEY-KRAMER method to ensure the overall significance level of $P = 0.05$. The model applied included the fixed effects of muscle type, transport conditions, lairage duration, and stressor level, as well as their 2-way interactions, and the random effect of slaughter day nested within lairage.

Results and discussion

Effects of transport

Results are presented in Table 1. Long and rough compared with short and smooth transport decreased ($P < 0.05$) the yellowness of the meat. No other main effects or interactions between the transport treatment and muscle type were observed. The meat was darker (i.e. lower L* values) when transport was long and rough and pigs were additionally subjected to the short lairage treatment (transport × lairage interaction; $P < 0.05$; results not shown). This effect was similar for all muscles but the largest effect was observed in the SV muscle. Transport had no effect on the redness in the minimal preslaughter stress group. In the high stress group, however, long as opposed to short transport increased the redness in the LT and SM muscles but

decreased the redness in the SV muscle ($P < 0.05$; results not shown). LL redness was not affected ($P > 0.05$). These effects on redness are probably related to differences in the relative proportions of the various myoglobin forms (Lindahl et al., 2001) but remain difficult to explain. The physical exercise and psychological stress that is associated with transport varies depending on the type of transport. Transport in general was shown to be stressful for pigs (Geverink et al., 1998) and even more so in rough as opposed to smooth transports (Bradshaw et al., 1996). As a consequence, both the physical exercise and the psychological stress level was probably higher in the long and rough compared with the short and smooth transport treatment. Oxidative muscle fibres are preferentially recruited at low intensity exercise levels (Køpke et al., 1984; Lacourt and Tarrant, 1985) and were shown to be more sensitive to adrenaline (Górski, 1978; Fernandez et al., 1995) which is secreted in response to psychological stress. Consequently, it was expected that the SV, a more oxidative muscle compared with the other muscles, would show a larger response. This was only partly true, which is probably related to the small differences in exercise and stress level between the two transport treatments.

Effects of lairage

For the lairage treatments there was for all colour values an interaction between lairage and muscle type noted ($P < 0.05$). For the L* value, this was probably due to the relatively large decrease ($P < 0.05$) in lightness in the SV muscle, whereas the response to the short lairage duration was small in the LT and intermediate in the SM and LL muscles ($P > 0.05$). Regarding the a* value, the SV was again the only muscle that showed a difference ($P < 0.05$) between long and short lairage with a decreased redness after a short lairage period. None of the pair wise comparisons were significant for the b* values, but both the LL, SM and SV muscles appeared to exhibit a, numerically, lower yellowness for the short lairage treatment whereas there was no difference in b* values noted for the LT. Lairage is not a stress factor itself but is meant to provide a rest for pigs to recover from previous transport stress. Lairage times shorter than 45 min are usually considered as too short for recovery (Milligan et al., 1998; Pérez et al., 2002) whereas 3 h is often regarded as optimal for pigs (Warriss et al. 1998; Pérez et al., 2002). In agreement with the above mentioned higher adrenaline sensitivity and recruitment at low exercise intensity of oxidative muscle fibres, the oxidative SV muscle showed a somewhat larger response to the short lairage treatment. Another reason may be the heavier involvement of the shoulder and neck muscles in activities such as posture holding during transport, exploring and fighting due to mixing of foreign pigs and, as a consequence, an increased need for rest compared with other muscles.

Effects of stress

For all colour values, there were interactions between the stressor treatment and muscle ($P < 0.001$). High stress compared with minimal stress resulted in paler meat in the LT ($P < 0.05$) whereas the SV muscle became darker in response to high stress ($P > 0.05$). Meat was less red ($P < 0.05$) in both the LT and the SV for the high stressor treatment while SM redness seemed to be increased ($P > 0.05$). Whereas LL lightness and redness appeared to be hardly affected by preslaughter stress, the yellowness of the LL was, similar to SV yellowness, decreased ($P < 0.05$). No effect on yellowness was seen in the SM but LT yellowness was increased ($P < 0.05$) in response to high stress. The high stressor treatment was previously tested and shown to be associated with a high level of both physical exercise and psychological stress as well as large effects on pork quality (Hambrecht et al. 2004a,b). In agreement with the previously mentioned differences in adrenaline sensitivity, response to exercise intensity and involvement in physical activity, effects of the stressor treatment depended on muscle type. Barton-Gade and Olsen (1987) compared stress-susceptible pigs with stress-resistant pigs and found an increased incidence of PSE in glycolytic muscles such as the LM whereas oxidative muscles, including the SV, showed an increased incidence of the DFD condition. These results are supported by the effects of the high stressor treatment in the present experiment. Additionally, the present study shows that considerable variation exists for pork colour measured within the longissimus muscle. The high stressor treatment produced different and larger effects in the LT compared with the LL muscle. The reasons for these differences within the longissimus muscle are unknown. But results are in agreement with Lundström and Malmfors (1985) who showed a higher incidence of PSE in the shoulder part of the loin, compared with the mid-loin and the ham site of the loin.

Conclusions

Effects of preslaughter treatments depend on the muscle that is studied. The metabolic profile but also the location of a muscle play a crucial role. High stress levels associated with preslaughter handling may promote PSE development in some glycolytic muscles whereas more oxidative muscles will rather develop DFD pork. Effects of preslaughter handling on pork quality should be assessed not only in one but in several muscles.

SENSORY AND INSTRUMENTAL ANALYSIS OF LONGITUDINAL AND TRANSVERSE TEXTURAL VARIATION IN PORK *LONGISSIMUS DORSI*

Stine Hansen[a,]*, Thomas Hansen[a], Margit Dall Aaslyng[b], Derek V. Byrne[a]

[a]The Royal Veterinary and Agricultural University, The Department of Dairy and Food Science, Rolighedsvej 30, DK-1958, Frederiksberg C, Denmark
[b]Danish Meat Research Institute, Maglegårdsvej 2, DK-4000 Roskilde, Denmark

Background

Longitudinal and transverse textural variation in pork *longissimus dorsi* has been widely reported (e.g. Onate and Carlin, 1963; Rust et al., 1972; Alsmeyer et al., 1965; Weir, 1953; Møller and Vestergaard, 1986). It is essential to understand this variation when measuring different aspects of meat quality such that what is measured is the actual difference between treatments and not differences within muscles.

Objectives

The objective of the present study was to investigate the texture variation in pork *musculus longissimus dorsi* (LD) through sensory and instrumental analysis. Specifically, the aims were to determine how the transverse and longitudinal texture varied within and between left and right muscles. A further objective was to determine the dynamic nature of texture variation occurring in and between left and right muscles of pigs and as a function of ageing. Overall, in the present case the predictive and causal association of these methodologies was considered paramount, such that confusion and misrepresentations as to what textural variation in pork meat means from a sensory perspective versus texture measurement from instrumental perspective.

Materials and methods

Twenty seven pigs were selected at random from an abattoir production line with regard to weight at slaughter (73-79 kg), lean meat percentage (58-62%), and ultimate pH (5.5-5.8). Both left and right *Longissimus dorsi* (LD) from the pigs, a total of 54 muscles, were excised. During excision subcutaneous fat and bones were removed. The LD muscles were divided into two halves at the 13th rib (cranial and caudal ends) and vacuum packed in oxygen impermeable bags. The muscles were aged for 0, 4, and 7 days respectively at 4˚C before they were frozen at -20°C.

Both the cranial and caudal ends of the loins were sliced into 20 mm thick chops from the 13th rib upwards and downwards (producing 9 chops in each direction). The pork chops were pan cooked in neutral oil (grape seed oil) at 155˚C for approximately 8 minutes until a core temperature of 65˚C was reached.

The transverse sample cores for the sensory descriptive texture profiling were excised by using a template (4×5 cm) and then divided into three equally sized pieces (approximately 17 mm wide, 20 mm thick, and 40 mm long). For instrumental analysis transverse sample cores were excised parallel to the muscle fibre orientation to the cut chop surface as recommended in AMSA (1995). The cores from each chop were denoted according to their position on the chop from inner to outer edge, a (nearest spinal column, dorsal), b (medial), and c (lateral).

The samples were measured using sensory descriptive texture profiling (ISO 11036, 1994; Meilgaard et al., 1999) and a Texture Analyser (Stabel Micro Systems, UK) mounted with a Volodkewich shear blade.

In the present study a special use of 'two block' Partial Least Squares Regression (PLSR) known as APLSR (the 'ANOVA like use of PLSR') was utilised. This form of PLSR projects the response variables onto the design variables in order to determine to which degree each of the design variables in **X** contribute to the variation in the response variables **Y** (Martens & Martens, 2001).

In relation to significance testing at the 5% level, i.e. $P \leq 0.05$, a re-sampling technique termed 'jack-knifing', which is part of cross-validation, was utilised. All multivariate analyses were performed using the Unscrambler Software, Version 8.0 (CAMO ASA, Norway).

Results and discussion

In the sensory determined transverse muscle variation a trend (non-significant) in decreasing tenderness from the dorsal position (nearest the spinal column) to the medial position was found. Instrumental analysis showed that hardness increased from the dorsal to the lateral position, both being significant. It should however be mentioned that the medial position could not be ascribed any significance level. The sensory and instrumental analysis agreed that the dorsal position was the most tender, but neither method was able to determine if the medial or the lateral position was the least tender of the three positions investigated (see Figure 1). The reason for the dorsal position being most tender can be attributed to the anatomic location. This position is supported by the spinal column, thus less work is performed in this muscle area.

Transverse variation was better described instrumentally than from a sensory perspective, in that significance levels could be ascribed. This was most likely because fibre orientation when assessed in sensory analysis was more inconsistent in its orientation when physically placed in the mouth by panellists.

In the sensory determined longitudinal muscle variation a significant decrease in tenderness was found from the anterior to the posterior part of the muscle. The reason for the cranial end being the most tender was most likely related to the anatomical location of the muscles. The cranial end is strongly supported by the ribcage and thus less work is performed in this muscle part. Instrumental analysis showed a trend (non-significant) in decreasing hardness when approaching the caudal end of the muscle.

Variation between individual chops was found when assessed by the sensory panel but not when measured instrumentally. Because the instrumental measurements lacked information about the longitudinal texture variation, specific examination of the texture was only carried out using data from the sensory analysis (see Figure 2).

When tenderness ratings were determined as a function of individual chops for each of the three ageing periods it appeared that the first 7 chops showed similarity in tenderness level for 0, 4, and 7 days respectively. A marked decrease in tenderness took place at the region near the end of the ribcage. Below the ribcage the tenderness was rated as being constant or tending to slightly increase. As tenderness decreased hardness was found to concurrently increase. The turn-over point in tenderness could be applied to a general textural turn-over point in that hardness and juiciness also showed marked changes in this specific region of the muscle. A markedly higher difference between individual chops was seen in the cranial versus the caudal end at 0 days of ageing. When the meat was aged, larger individual chop variation occurred in the caudal end. It seemed that the individual chop variation in the cranial end decreased, whereas the variation in the caudal end concurrently increased when the meat was aged.

Marked differences between left and right muscles were observed. Right muscles showed bigger internal variation throughout the loin, when compared to left muscles. Moreover, it appeared that the longitudinal variation was more distinct and interacting in the right loins compared to the left loins. Qualitatively left and right loins displayed the same trends but differed quantitatively in the levels of variation. A plausible explanation may be that the majority of the pigs in the present study were ‘right-footed’. If this was the case, right muscles would perform more work than left muscles which may explain why the right side muscles varied considerably more internally than the left side muscles.

Both sensory and instrumental analyses were able to differentiate significantly between 0, 4, and 7 days of ageing. As expected 0 days of ageing was positively correlated to hardness. Ageing for 4 and 7 days respectively resulted in equally tender meat. The sensory analysis revealed that 4 and 7 days of ageing were differentiated by the levels of crumbliness and cohesiveness, 7 days of ageing leading to more crumbly and less cohesive meat.

Sensory and instrumental data revealed significance differences between left and right muscles. The left muscles were found to be significantly more tender than the right muscles in both the sensory and instrumental analysis.

The textural variation lengthwise was better described when assessed by the panel compared to when measured instrumentally. Of considerable importance regarding this discrepancy the shear force apparatus only measured deformation in terms of force (Newton) used for compression of the sample, whereas the sensory profiling described what caused the differences in the longitudinal variation.

Sensory and instrumental measurements were found to be predictive indexes of each other (see Figure 1) however these methods did not measure the same textural properties in the muscles. This is due to the fact that texture testing instruments are calibrated to respond linearly to the intensity of the tested mechanical property, which does not apply in the human perception of texture (Szczesniak, 1987). According to Spadaro et al. (2002) linearity will only occur if the biological material is homogeneous.

Conclusions

A trend of decreasing tenderness from dorsal to medial transverse positions was found in sensory analysis. Instrumentally determined transverse variation was found to significantly decrease from dorsal to lateral position, though the medial position did not display significance. Overall, the dorsal position was the more tender of the three positions (dorsal, medial, and lateral).
It was clear that the cranial end was significantly more tender than the caudal end when evaluated from a sensory perspective. However, no significance could be applied to the instrumental measurements hereof.
The individual chops in the left and right sides generally showed a gradual change in tenderness from cranial to caudal end of loins. Significance was found for most sensory evaluated individual chops, which again could not be derived from the instrumental analysis. A marked change in texture was observed at the end of the rib cage. Instrumental analysis was found unable to predict lengthwise texture variation. Sensory analysis was found to consistently describe the longitudinal variation.
An effect of ageing on the transverse variation could not be assigned. A greater decrease in tenderness between individual chops was seen in the cranial than in the caudal end at 0 days of ageing. When the meat was aged more pronounced individual chop variation occurred in the caudal end. Ageing was found to be similar qualitatively in left and right LD
Transverse and longitudinal variation was found to be more distinct in right LD compared to left LD. Furthermore, the decrease in tenderness longitudinally, was markedly higher and more defined into stages in the right loins. The cranial ends were more similar in tenderness from both left and right side of the animals than the caudal ends.

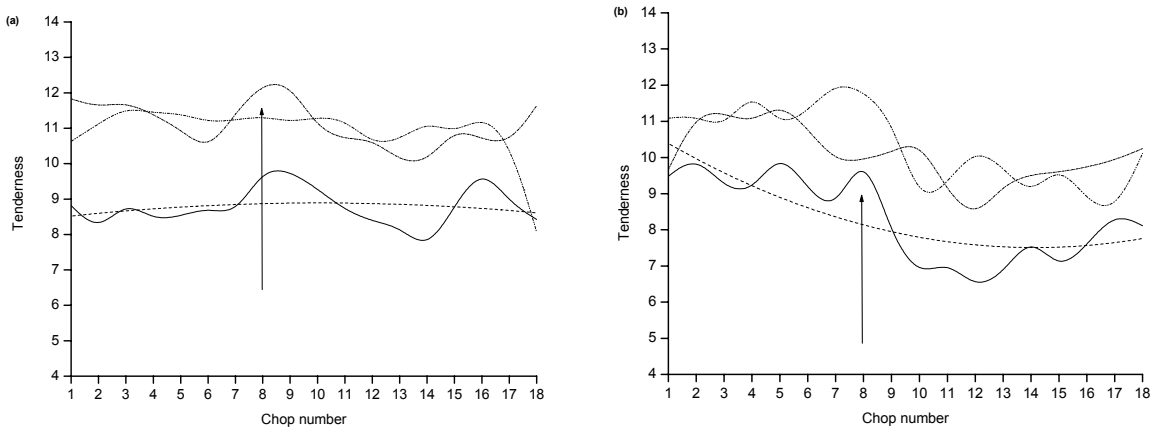

Figure 2. Longitudinal variation of tenderness in (a) left and (b) right loins within each ageing period. muscles respectively, at 0 The solid line represent 0 days of ageing. The dashed and dotted (–¨–) line represent 4 days of ageing. The dotted (¨) line represent 7 days of ageing. The dashed (---) lines represent the average of changes in left and right muscles respectively at 0 days of ageing. Data is averaged over transverse sample positions (a, b, and c) within each chop. Arrows indicate the change point at chop 8.

MODIFICATION OF VERY LONG CHAIN n-3 PUFA IN CHICKEN MEAT

Ivanković S.[1], Kralik, G.[2]
[1]Faculty of Agriculture, University of Mostar, Trg hrvatskih velikana 1, 88000 Mostar, Bosnia and Herzegovina,
[2]Faculty of Agriculture, Josip Juraj Strossmayer University of Osijek, PO Box 719, 31000 Osijek, Croatia

Background

The content of PUFA n-3 in chicken meat is of great importance for human nutrition. The ratio of n-6/n-3 PUFA in meat should be as narrower as possible (Okuyama and Ikemoto, 1999). This recommendation is based upon the fact that PUFA n-6 and PUFA n-3 affect differently the immunological functions and inflammatory processes in humans and animals (Caldor, 2001). PUFA n-6 acts pro-inflammatory, while PUFA n-3 has anti-inflammatory effects. Within n-3 PUFA group, EPA and DHA are more important than precursors of α-linolenic acid (Ollis et al., 1999). Recommended amounts of specific fatty acids for adults are the following: LA 4.4-20 g/day, LNA 1.35-2.2 g/day) and LC n-3 PUFA 0.16-1.6 g/day (Meyer et al., 2003). According to Ollis et al. (1999), only 15% of LNA is converted to VLC n-3 PUFA. Chicken meat is a valuable source of n-3 PUFA because of the possibility to change the profile of fatty acids (Kralik et al., 2003). The content of fatty acids and cholesterol level in chicken meat can be influenced by using the fats, which differ in their contents of fatty acids (Kralik et al., 1997). The content of EPA and DHA in chicken meat can be increased by addition of fish oil and fish flour to the diets (Chanmugam et al., 1992, Lopez-Ferrer et al., 1999). The content of linoleic and linolenic acids is increased by addition of soybean oil and rapeseed oil to the diets (Scaife et al., 1994).

Objectives

The aim of this research was to determine the effect of addition of PBE oil in different amounts to finishers and the content of n-3 PUFA, i.e. very long-chain fatty acid equivalent (VLCE) in white and dark meat.

Materials and methods

Chickens were divided into five groups. From the 1st to 21st day, they were fed with starter mixture (A), which contained 22.67% of crude proteins and 14.19 MJ/kg ME. From 22nd to 42nd day chickens were fed with finishers (B_1, B_2, B_3, B_4, and B_5), which were balanced at the level of 20.43% of crude proteins. The first control group was given B_1 mixture, while the 2nd, 3rd, 4th and 5th group were fed with B_2, B_3, B_4 and B_5 mixtures, which had the animal fat partially replaced by the Pronova Biocare Epax 3000 T6 preparation (PBE oil), in the amounts of 0.5%, 1%, 1.5% and 2%, respectively. This oil contains, besides other fatty acids, 15,36% eicosapentanoic acid (EPH) and 9.99% docosahexanoic acid (DHA). The content of fatty acids in the lipids of white and dark chicken meat was determined on 9 samples of each group by the Chrompack CP-9000 chromatograph with flame ionization detector. Each fatty acid was shown in % of the total fatty acids (Csapo et al., 1986). On the basis of the content of α-linolenic acid**,** eicosapentanoic and docosahexanoic acids in lipids, the content of stated fatty acids was calculated in white and dark meat. Veri long chain fatty acid equivalent was shown according to Komprda et al. (2003) as follows: VLCE = 0.15 LNA + (EPA + DHA).

Results and discussion

Table 1 shows the data, which refer to the content of fats and n-3 PUFA in white and dark chicken meat. Portions of fats in white meat fluctuated from 1.08 to 1.45%. Highly significant difference is found between 2nd and 3rd group, 2nd and 4th group, as well as between 3rd and 5th group. Chemical analysis of dark meat showed the portion of fats of 4.22-5.02%, but no statistically significant differences were found out between groups. Results that are similar to ours are stated also by Komprda et al. (1999), Škrtić (1999) and Crespo and Esteve-Garcia (2001). The contents of EPA and DHA in lipids of white meat are significantly higher in all experimental groups in comparison to the control groups. In comparison with the 1st group, the 5th group, which was fed with 2% of PBE preparation, contained 291.93% more EPA and 92.54% more DHA in the lipids of breast muscles. The results obtained in this research are similar to those of Hulan et al. (1988), but higher than those stated by Komprda et al. (1999a) and Zelenka et al. (2001). The feeding of chickens with

this preparation resulted in the increase of EPA and DHA in the thigh lipids. The highest content of unsaturated omega-3 fatty acids is found out in the lipids of dark meat in the 5th group, which was fed with mixture containing 2% of PBE preparation. Moreover, the content of EPA and DHA in the lipids of thigh muscles is increased from 0.48% and 1.45% (1st group) to 1.18% and 1,83% (2nd group); 1.30% and 2.83% (3rd group), 2.24% and 3.76% (4th group) and 2.76% and 4.91% (5th group). Statistical analysis showed highly significant differences ($P<0.01$) in the content of EPA and DHA between 1st and 2nd, 1st and 4th, then between 2nd and 5th, and 3rd and 4th, as well as between 3rd and 5th group. Table 2 presents the data of the n-3 PUFA content in g/100 g in white and dark meat. Graph 3 presents VLC n-3 PUFA equivalent in white and dark chicken meat. Komprda et. al. (2003) succeeded to increase the VLC n-3 PUFA equivalent in turkey meat by addition of linseed and fish oil to the diets. The addition of PBE preparation in the diets resulted in the increase of VLC n-3 PUFA equivalent from 48 mg/100 g and 93 mg/100 g to 59 and 143, 60 and 183, 73 and 258, and 119 and 390 mg/100 g, respectively, in white and dark chicken meat.
Comparison of the EPA and DHA contents in the lipids of white and dark chicken meat shows higher deposition of stated fatty acids in the lipids of white meat. Considering the fact that dark meat contains more fats than white meat, the contents of EPA and DHA in dark meat is thus considerably higher than in white chicken meat. Addition of the PBE preparation to diets resulted in the higher deposition of stated fatty acids in both white and dark meat (Table 2).

Conclusions

Based on the obtained results, it can be concluded that the addition of PBE preparation to the diets in the amounts of 0.0%, 0.5%, 1.0%, 1.5% and 2.0% resulted in the statistically significant increase of EPA and DHA in white and dark chicken meat. Very long-chain fatty acid equivalent (VLCE) was also increased in both meat kinds. Related to the increase of concentration of PBE oil in the diets, VLC equivalents were also increased from 48 to 119 in white meat, and from 93 to 90 mg/100 g in dark meat.

Background

Studies have shown that the fat embedded in the muscle or muscular tissue makes the meat juicy, tender, and tasty. These findings were reported by Parrish (1974) and Donald and Merkel (1993). Estimating quality of meat varies from country to country. Factors such as intramuscular fat content and maturity are important, since they directly affect the meat's tenderness, juiciness, and flavor. Parrish (1974) reported that intramuscular fat explained approximately 12-14% of tenderness. However, according to Gregory, Cundiff and Koch (1995), tenderness was reduced for highly marbled meat, while May, Dolezal, Gill, Ray and Buchanan (1992) reported that high WB-shear force reduced juiciness, flavor, and tenderness. The study also showed that tenderness had a correlation efficient of 0.19 and 0.73 for intramuscular fat content and juiciness, respectively. In addition, Miller, Carr, Ramsey, Crockett and Hoover (2001) reported that WB-shear force lower than 3.0 was tender, while that higher than 5.7 was tougher. Laila (1996) reported that correlation coefficients in relation to objective meat color and intramuscular fat content were 0.07 for L*, 0.06 for a*, and 0.12 for b* values.
However, Shackelford, Wheller, Meade, Reagan, Byrnes, and Koohmaraie (2001) reported that consumer preferences were significantly affected by doneness. As mentioned earlier, the intramuscular fat content was the prime factor affecting the meat quality in the U.S (Donald and Merker, 1993). Thus, according to Talamantes, Long, Smith, Jenkins, Ellis, and Cartwright (1986), beef production system for the effective fat deposit in muscles is important because carcass fat deposit is significantly correlated with intramuscular fat content. Considering sex as a variable, Hardt, Greene & Lunt (1995) observed that heifers had a higher intramuscular fat, with lower maturity and received a higher carcass quality grade.

Objectives

This study determined the meat quality of the Hanwoo (Korean native cattle) as a result of the diversity in the production system for sex and market weight. The physico-chemical traits and palatability of 773 *M. longisimus dorsi* muscles obtained from Hanwoo cattle were evaluated.

Materials and methods

Animals: A total of 773 cattle were sampled from 24 farms across the country and slaughtered in the National Livestock Research Institute (NLRI) slaughterhouse. Longissimus samples (2.5 kg) were taken from the 13th rib of each animal.
Analysis of objective and subjective meat quality:WB-shear force was determined by cooking steaks of 3-cm thickness of *m. longissimus dorsi* (LD) in a 70 ˚C water bath for 60 min. These were cooled in running water (ca. 18 ˚C) for 30 min so that core temperature reached below 30 ˚C. Eight cores were made, each measuring 1.27 cm in diameter. The shear force was measured by using a V-shaped shear blade at 400 mm/min speed (Wheeler et al., 2000). Cooking loss was calculated as percent of weight changes during cooking for WB-shear force measurement. Objective meat color was determined by using a Minolta Chromameter (CR301, Minolta, Japan) on a freshly cut surface of the WB-shear force block after a 30-min blooming at 1°C. Water-holding capacity was determined according to the filter paper method described by Ryoichi, Degychi, and Nagata (1993). Briefly, 0.5g of muscle tissue was placed on glass, and filter paper was pressed against the meat sample at 35-50 kg/cm^2 for 2 min. Water-holding capacity was calculated by using a planimeter. Sensory characteristics were determined by 10 semi-trained panelists who were randomly selected from a total of 15 recruits. They estimated the values of tenderness, flavor intensity, juiciness by using a six-point scale.
Statistical analysis:ANOVA, Duncan-test, and correlation coefficients were determined by using SAS package (1996). The following analyses of variations were performed to estimate the effects of sex and live weight on carcass quality. Yijk = μ + SEXi + WTCLASSj + (SEXxWTCLASS)ij + eijk, where Yijk =

carcass quality,μ = mean, SEXi = sex effect of ith carcass (i = 1, 2, 3), WTCLASSj = carcass weight effect of jth carcass (j = 1,2,3,4,5,6), (SEX x WTCLASS)ij = interaction between ith sex and jth carcass weight, eijk = error.

Results and discussion

Intramuscular fat content increased with increasing live weights for cows (3.07-4.00), bulls (1.00-1.96), and steers (2.75-4.22). Cows and steers contained higher intramuscular fat than bulls when live weight was lighter than 500 kg ($P < 0.05$). Maturity ranged from 1.00 to 2.02, with higher scores for heavier weights. Bulls matured faster than steers and cows ($P < 0.05$). The results showed a faster calcification for cows compared with that of other groups. A lighter meat color for cows and steers than that of bulls was thought to be related to the higher intramuscular fat content for these groups. Cows had a whiter fat color than that of other groups within the same weight group. Frequency of carcass quality grade "1" increased with a corresponding increase in live weights, and cows and steers had a higher frequency than that of bulls ($P < 0.05$). Sex significantly affected the intramuscular fat content, maturity, meat color, fat color, and texture ($P < 0.01$), while live weights (Table 3) had significant effects on intramuscular fat and maturity ($P < 0.01$). Carcass quality grade had a higher correlation with intramuscular fat content (r=0.87), meat color (r=0.32), and texture (r=-0.54); but had a relatively weaker correlation with fat color (r=0.07) and maturity (r=-0.04). These results were similar with those of the previous studies conducted by Griffin (1992) and Dikeman, Cundiff, Gregory, Kemp and Koch (1998). They all reported that high slaughter weights resulted in higher carcass quality grade. In addition, Mckenna et al. (2002) reported that higher slaughter weights resulted in higher intramuscular fat, but did not affect maturity. For meat color, that of bulls was darker than that of cows and steers. This result was consistent with that of Seideman, Cross, Oltjen and Schanbacher (1982). In terms of sex as a variable, Park et al. (2002) reported that the difference in sex for Hanwoo cattle significantly affected carcass quality factors, where intramuscular fat content was highly correlated with carcass quality grade (r=0.81). This finding is also consistent with that of the previous study.

Protein content decreased with increasing marbling scores from 22.4% to 16.6% ($P < 0.01$), while intramuscular fat content increased from 5.16 to 19.46% ($P < 0.01$). Similarly, moisture content decreased from 71.24% to 61.04% ($P < 0.01$) and ash content decreased from 0.95% to 0.67% ($P < 0.01$). Average protein content of Hanwoo meat (21.28%) was similar with that of the European breed (21.43%) as reported by Browning, Huffman, Egbert & Jungst, 1990 and that of the Japanese black cattle (20.4%) according to Konishi, Nade, Maeda & Uchiyama (1995). On the other hand, intramuscular fat content was lower than 11.9% in the Japanese black cattle (Konishi, Nade, Maeda & Uchiyama, 1995), and higher than 5.91% in the cross breeds (Miller, Ramsey, Claborn & Wu, 1995). In addition, the current result was consistent with that of the previous study (Jones, Savell & Cross, 1990) who reported that intramuscular fat content increased with increasing marbling score and carcass quality grade. Meanwhile, data on moisture obtained in this study (69.34%) was lower than 72.9-75% as reported by Van Koevering, Gill, Owens, Dolezal, and Strasia (1995) and Corah, Tatum, Morgan, Mortimer, and Smith (1995). For ash content, it is generally known that it is approximately 1% in beef muscle, and the ash content obtained from this study was similar with that obtained from the previous report (Miller, Cross, Baker, Byers & Recio, 1988) which showed that ash content was similar between breeds.

The results showed that higher fat contents significantly increased tenderness (from 3.35 to 4.46), flavor (from 4.22 to 4.76), and juiciness (from 3.99 to 4.70). These findings support the observation that intramuscular fat is the most significant variant that explains approximately 7-15% of meat tenderness (Parrish, 1974). These findings also agree with those of the previous report (Shackelford, Wheeler & Koohmarmie, 1995) which showed significant correlation between marbling score and meat tenderness. Likewise, the results agreed with those of Lorenzen et al.(2003) who reported that meat flavor and juiciness were improved by 0.3 and 0.4 between low select and top choice. Mckenna et al. (2004) similarly reported that increase in marbling score improved overall sensory characteristics.

The results showed that WB-shear force and cooking loss decreased as marbling score increased, with averages of 5.2 kg and 29.4% ($P < 0.01$), respectively. On the other hand, water-holding capacity significantly increased ($P < 0.01$) at an average of 47.39%. The result was similar to that in the Japanese black cattle (5.6 kg) as reported by Konishi, Nade, Maeda & Uchiyama (1995), and for and in the Angus and Hereford (5.06-5.38 kg) as reported by May, Dolezal, Gill, Ray & Buchanan (1992). Meanwhile, studies by Cross, Savell and Francis (1986) showed water-holding capacity results as higher than 39.0-43%. But the significant increase in water-holding capacity with increasing marbling score tended to be similar with that

of Kim and Lee's study (2003). Their study showed that the water-holding capacity increased from 51.3% to 55.6% from a carcass quality grade of 3 to 1. Van Koevering, Gill, Owens, Dolezal and Strasia (1995) reported 21.7-31.7% of cooking loss and Konishi, Nade, Maeda and Uchiyama (1995) reported 29.2% for American-Japanese black cattle, the current result was similar with the previous results.

Sex significantly ($P < 0.01$) affected the chemical composition and sensory characteristics. Sex also had significant ($P < 0.01$) effects on the objective color measurements (Table 6), and lightness had a low correlation with intramuscular fat content (r=0.17, Table 7). As far as slaughter weight is concerned, it significantly affected fat, moisture, and protein contents ($P < 0.01$), but this did not influence sensory characteristics. The significant differences in fat content between the sex groups and between slaughter weights indicated that these factors influenced fat deposition within the examined *longissimus* muscle. This result was consistent with that obtained by Miller, Cross, Baker, Byers and Recio (1988), where sex significantly affected the intramuscular fat content. The significant correlation between intramuscular fat content and juiciness (r=0.35), tenderness (r=0.23), and flavor (r=0.34); and between marbling score and juiciness (r=0.39), tenderness (r=0.26), and flavor (r=0.42) demonstrated that the amount of fat played a significant role in sensory characteristics. This result agreed with that of the previous studies (James, Mcbble & Jack, 1967; Shackelford, Wheeler & Koohmarmie, 1995) in that juiciness and tenderness received significantly higher scores from highly marbled muscles. Table 7 shows the effect of sex and slaughter weight on the objective meat quality traits. The result shows that sex had a significant effect on WB-shear force, but slaughter weight had no such effect. Sex also significantly affected water-holding capacity, and this result was similar with that of Waggoner, Dikeman, Brethour and Kemp (1990). WB-shear force significantly correlated with ($P < 0.01$) with juiciness (r=-0.29), tenderness (r=-0.34), flavor (r=-0.29), and intramuscular fat content (r=-0.32). The significant relationship between WB-shear force and intramuscular fat was similar with the result obtained by Gregory, Cundiff and Koch (1995). In addition, negligible effect of sex, slaughter weight, and intramuscular fat content on cooking loss was similar to that observed by Jones, Savell and Cross (1990). The high correlation between intramuscular fat content and moisture (r=-0.92) was similar to the previous result of Parrish (1974). On the other hand, the objective meat tenderness for carcass quality grades 2 and 3 was higher than 4.32 kg for Angus (Tatum, Smith & Carpenter, 1982) and 4.54 kg for Hereford (Patil, Goetsch, Lewis & Geird, 1993) for Angus. This suggests that the chiller aging treatment is required for the quality grade. Objective meat color of CIE L, a and b dimensions significantly ($P < 0.01$) increased as marbling scores increased from 1 to 7. Sex had significant ($P < 0.01$) effects on the objective color measurements (Table 6), and lightness had a low correlation with intramuscular fat content (r=0.17, Table 7). Subjective meat and fat color assessed by a 7-point scale indicated that higher intramuscular fat content reduced the subjective color scores of 4.54-4.80 for meat color and 2.58-3.04 for fat color. The result of objective color dimensions (i.e., CIE L, a and b) indicated that lightness and yellowness were similar with the previous results (Shackelford, Wheeler & Koohmarmie, 1995; Laila, 1996), but redness was stronger for Hanwoo beef.

Conclusions

As marbling degree increased, Warner-Bratzler shear force and cooking loss correspondingly decreased, while the water-holding capacity increased ($P < 0.01$). In the panel tests, the scores of tenderness, flavor, and juiciness increased ($P < 0.01$) with increasing marbling degrees. The shear force values had a negative correlation with juiciness, tenderness, and flavor. Sex of Hanwoo had significant effects on the carcass quality grade factors. The results of this study suggest a need for comparative studies on the range of marbling scores based on intramuscular fat content, and on objective and subjective meat quality for increasing sub-class of carcass grading which is included in the currently used four classes of carcass quality grading in Korea.

Background

Pork shoulders and hams are traditionally used as raw material for further processing of meat products and often are considered to be lower value than other cuts such as the pork loin. Recently, the pork industry has been investigating the potential for adding value to the pork carcass by identifying individual muscles or muscle groups within the shoulder and ham that are well-suited for new uses in processed products or for new product development. However, while the general properties of primal cuts as a whole are understood, the characteristics of individual muscles making up the primal cuts are not well known. Therefore, there is a need for research on meat quality characteristics of individual muscles from pork shoulders and hams. Further, it is important to know the effects of aging on the specific muscles in order to make the best use of individual muscles in processed products.

Objectives

The objectives of this experiment were to determine the changes in purge loss, water holding capacity, and tenderness during aging for ten selected muscles dissected from pig carcasses following harvest.

Materials and methods

Animals, treatments and sample preparation: Seven barrows or gilts (Hampshire sire × crossbred dam) were humanely harvested at the Iowa State University Meat laboratory. Carcasses were chilled in a forced-air cooler at -5 °C for 24h. Live weights, carcass weights, 45-minute pH and 45-muscle temperatures were recorded and are shown in Table 1. At 1 day postmortem, the *biceps femoris* (BF), *gluteus medius* (GM), *gracilis* (G), *infraspinatus* (I), *longissimus dorsi* (LD), *pectoralis profundi* (Fan, PP), *rectus femoris* (RF), *semitendinosus* (ST), *spinalis* (S), *triceps brachii* (TB) were dissected from both sides of each carcass. Muscles were cut into 2.54 cm thick portions, vacuum-packaged and aged at 4 °C for 7days.

Purge loss, water holding capacity (WHC) and WB-shear force: Purge loss was determined by weighing the muscle portions before vacuum-packaging and after 1, 3 or 7 days of aging to calculate percentage weight losses. WHC was determined using the method described by Honikel and Hamm (1994). WB-shear force measurements were performed using cooked muscle portions (internal temperature at 71 °C) by a texture analyser (TA-XT2i texture analyser, USA). Preparation of the samples for the tenderness measurement was done in accordance to AMSA Guidelines (American Meat Science Association, 1995). The conditions for the texture analyser was a pre-test speed of 3.0mm/s, test speed of 3.3mm/s, post-test speed of 10.0mm/s, distance of travel at 80.0 %, and trigger force of 0.15kg.

Statistical analysis: Data were analyzed using PROC GLM (SAS, 1998).

Results and discussion

Purge loss (%) was significantly increased ($P < 0.05$) in all muscles during aging (Table 2). The GM had the highest ($P < 0.05$) purge loss, while the TB was significantly lower ($P < 0.05$) than the other muscles. After 7 days of aging, the range for purge loss values from all muscles was 3.46-8.93%.

The WHC value for GM and LD muscles was significantly increased by aging, but the G and S were decreased ($P < 0.05$) as the aging period increased (Table 3). The S had the highest WHC ($P < 0.05$), while the BF was lower in WHC than the other muscle after 7 days of aging. The range of WHC values in all muscles was 87.36-93.49% after 7 days of aging.

It is generally accepted that the source of drip from pork is intracellular water which is lost from the muscle fibre post-mortem, driven by a pH and calcium-induced shrinkage of myofibrils during rigor development (Offer et al., 1989). Moeseke and Smet (1999) reported an increase in WHC of fresh meat during aging using a traditional drip measurement where samples were taken several days after slaughter for comparison with samples taken at 1 day post-mortem. However, in our study, WHC of the G and S muscles decreased, and the I, RF, ST and TB muscles showed a tendency to decrease during aging. Honikel and Hamm (1994) reported that conventional drip losses during storage of pork were in the range of 1-10%.

The WB-shear force for the TB was significantly decreased ($P < 0.05$) during aging, but the other muscles were not affected during aging. After 7 days of aging, the WB-shear force value for the S was the lowest ($P < 0.05$) among the muscles studied, but the BF was higher than the other muscles. The range for WB-shear force in the 10 muscles studied was 3.29-7.10 kg after 7 days of aging.

It has been reported that pork was completed of aging-related changes within 4-6 days post slaughter (Rees et al, 2002). Also, Wheeler et al. (2000) reported that tenderness ratings from trained sensory evaluation were highest for *semitendinosus* (7.2) and *triceps brachii* (7.1), followed by *longissimus lumborum* (6.4) and *semimembranosus* (5.7) and were lowest for *biceps femoris* (4.0). In the current study, WB-shear force values were greatest for the BF and lowest for the S. The TB showed significant tenderization during aging but the 9 other muscles were not significantly affected during aging.

The simple correlations between WB-shear force and water holding were 0.26 (purge loss) and –0.41 (water holding capacity) ($P < 0.0001$).

Conclusions

Purge loss of the TB was significantly less than for the other muscles in this study, while the GM had higher purge loss than the other muscles during aging. The WHC of GM and LD was significantly increased, but that of the G and S was decreased as the aging period increased. The S had the greatest WHC, while the BF had lower WHC than the other muscles after 7 days of aging. The purge loss and WHC values suggest that individual muscles will perform quite differently in processes utilizing differential amounts of added water and will affect expected yields depending on how individual muscles may be used Tenderness of the TB was significantly increased by aging, but the other muscles were not affected during the aging period. After 7 days of aging, the S remained the most tender, while the BF remained tougher than the other muscles studied. Thus, tenderness differences in pork muscles appear to largely retain the differences inherent to individual muscles and do not show a great deal of change as a result of aging.

EFFECTS OF HOUSING SYSTEMS ON CARCASS CHARACTERISTICS OF FINISHING PIGS

Kralik, G.[1], Romić Z.[2], Tolušić, Z.[1], Margeta V[1].

[1]Faculty of Agriculture, Josip Juraj Strossmayer University of Osijek, PO Box 719, 31000 Osijek, Croatia,
[2]«Žito» d.o.o. , P. Pejačevića 25, 31000 Osijek, Croatia

Background

Production of quality pig meat in conditions that positively affect welfare and health of growing pigs is lately becoming more important. Growing of pigs on straw bedding meets the requirements that are set to producers as far as the pigs' health and welfare is concerned. In that sense, the scientific investigations of such housing system are being intensified. The most obtained results show many advantages of such housing system however, there are also some disadvantages of deep litter housing system in relation to the conventional housing systems. When compared to the conventional housing system, the majority of scientists agree that there is a cost benefit of deep litter housing system (Gentry et al., 2002a, Morrison et al., 2003a), as well as benefits for animal welfare and environment protection (Lyons et al., 1995, De Yong et al., 1998, Beattie et al., 2000, Kelly et al., 2000, Klont et al., 2001, Guy et al., 2002, Morrison et al., 2003b). Investigations of productivity and slaughtering characteristics of pigs point out not only advantages of deep litter housing system (Beattie, 1996; Morgan et al., 1998; Beattie et al., 2000; Spolder et al., 2000; Turner et al., 2000; Klont et al., 2001; Maw et al., 2001; Lombooij et al., 2004), but also some negative aspects that are caused by this way of pig housing (Gentry et al., 2002b; Honeyman and Harmon, 2003; Morrison et al., 2003a, 2003b).

Objectives

Having in mind the opposite results of our previous researches, the aim of this research was to compare productive, slaughtering and economic characteristics of conventional and deep litter housing systems.

Materials and methods

The crossbreeds (GLxLW) x GL, divided into two groups, were used for this research. The first group of pigs was kept on deep litter, while the second group was kept in a conventional way, on cross-barred floor, without straw bed. Pigs in both groups were fed equally. In the first fattening phase (27-60 kg), the pigs were fed with mixture that contained 17.68% of crude proteins and 12.98 MJ/kg ME; in the second phase of fattening (60-110 kg) that mixture contained 14.71% of crude proteins and 13.10 MJ/kg. Throughout the fattening process, the food consumption was controlled, and the average daily weight gain, food conversion and costs of live weight gain were calculated. Throughout slaughtering, the meat portion (M%) in carcasses was obtained by the "two points" method (Rule Book, 1999, 2001), using the following formula:

$$M\% = 47.978 + 26.0429\frac{F}{M} + 4.5154\sqrt{M} - 2.50181\log_{10} F - 8.4212\sqrt{F}$$

F = the minimum thickness of visible fat (including rind) on the midline of the split carcases in millimeters, covering the lumbar muscle (*M. glutaeus medius*), M = the visible thickness of the lumbar muscle on the midline of the split carcases in millimeters, measured at the shortest connection between the front (cranial) end of the lumbar muscle and the upper (dorsal) edge of the vertebral canal.

According to the meat portions, the carcasses were divided into the (S)EUROP commercial classes. Costs of housing, feeding, health protection, as well as other costs that are in relation to specific conditions were taken into consideration in order to determine the economic factors.

Results and discussion

At the beginning of fattening process, live weight of growing pigs in both groups was almost the same (27.50 kg and 26.90 kg, respectively). Fattening of pigs on straw-bedded floor lasted for 117 days, and on cross-barred floor for 114 days. Pigs of both groups had equal average daily weight gains (0.67 kg and 0.66 kg, respectively), but the food consumption per kg of live weight gain was better in pigs that were kept on deep

litter than in pigs of the second group that were kept conventionally (3.15 kg and 3.31 kg, respectively). Food conversion was also better in the first group, kept on deep litter, than in the second group. Data obtained for mortality and waste of pigs did not show results that can differentiate between the two housing systems (Table 1). Throughout the fattening process, it was noticed that the pigs kept on deep litter spent more time moving around and were less aggressive than the pigs on cross-barred floor. Similar conclusions were stated by Lyons et al. (1995) and Morrison et al. (2003a). Positive effects of deep litter on the welfare and behavior of growing pigs was also pointed out by De Jong et al. (1998), Kelly et al. (2000), Turner et al. (2000), as well as Day et al. (2002).

Productive and slaughtering characteristics significantly affect the effectiveness and cost benefits of pig production. Beatie et al. (2000) state that pigs kept on deep litter in their finishing growth phase had better food consumption, less food usage per kg of live weight gain, better weight gain, and thicker back fat when compared to pigs that were kept in a conventional way. Lambooij et al. (2004) found out that the pigs kept on deep litter had significantly higher weight of carcasses and better water holding capacity. Honeyman and Harmon (2003) found out that, in comparison to the pigs kept on half-cross-barred floor, pigs kept on deep litter had higher average weight gain in the summer months, while in the winter months, they had equal average daily gain, but weaker conversion.

Data on the slaughtering traits of carcasses (Table 2) show that pigs kept on deep litter had higher weight of warm carcasses, thinner back fat and higher portion of muscular tissue in carcasses. Therefore, the classification of carcasses proved the advantages of deep litter housing system. The S and E commercial classes had the portion of 77.14% and 66.67%, respectively. Carcasses of the R class were not present in pigs kept on deep litter (Graph 1). The deep litter housing system resulted in better average meatiness of carcasses than the conventional system (58.25% and 57.07% of muscular tissue). Classification of carcasses into commercial classes was also in favor of the deep litter housing system. However, Klont et al. (2001) and Gentry et al. (2002a) did not find differences in meatiness between pigs of two different housing systems.

Analysis of economic aspects of housing systems (Table 3) shows that the deep litter housing system has better financial results. This is in relation to the lowering the costs per finishing pig, and gaining the better market price of the product as well as of the produced fertilizer. Similar conclusions were made by Gentry et al. (2002a) and Morrison et al. (2003a). Lowered costs per finishing pig and satisfactory quality of pork are the main preconditions of productivity and profitability of pig production.

Conclusions

Based on the obtained results, it can be concluded that pigs, which were kept on deep litter had better food consumption than pigs kept conventionally. Analysis of average daily gain values did not show differences related to housing systems of finishing pigs. Slaughtering characteristics show that pigs kept on deep litter had heavier warm carcasses, thinner back fat and greater portion of muscular tissue in carcasses. Moreover, classification of warm carcasses was in favor of deep litter housing system. Lowered costs and higher market price of such finishing pigs proved that deep litter housing system is also financially better than the conventional housing systems.

EFFECTS OF DIETARY *RHUS VERNICIFLUA* STOKES SUPPLEMENTATION ON MEAT QUALITY CHARACTERISTICS OF HANWOO (KOREAN CATTLE) STEERS DURING REFRIGERATED STORAGE

Lee, Sung Ki[1], Kim, Yong Sun[2], Song, Young Han[3] and Liang, Cheng Yun[1]

[1]Department of Food Science and Technology in Animal Resouces, [2]Institute of Animal Resources, [3]Division of Animal Resource Science, Kangwon National University, Chunchon, 200-701, South Korea.

Background

In recent years, there has been a global trend toward the use of natural substances present in fruits, vegetables, and herbs as antioxidants and functional foods (Farr, 1997). Greene (1969) was one of the first investigators to report on the potential color-preserving effect of antioxidants in meat. *Rhus verniciflua* Stokes (RVS) belongs to Anacardiaceae and has been used traditionally for medicinal purposes and for the protection of antiquities in Korea for a long time (Kim, 1996). Recently, it was shown that RVS has an antioixdant function. Antioxidant activity of *Rhus verniciflua* Stokes has been reported to correspond to well known enzymatic and non-enzymatic antioxidants in model linoleic emulsion experiments (Lim and Shim., 1997). The stem bark of *Rhus verniciflua* contains a high level of urushiols, which are polymerized formation of a lacquer film by the radical-chain reaction (Hirota et al., 1998). The exudate was previously found to have anti-AIDS, a strong antioxidant and immune-enhancing activities (Miller et al., 1996). However, urushiol was the main irritating component of exudate constituents of *Rhus verniciflua.* The heartwood of *Rhus verniciflua* dose not cause this type of allergenic action, which implies that it does not contain urushiols (Park et al., 2004). However, information on the application of *Rhus verniciflua* Stokes is still limited.

Objectives

The objective of this study was to determine the effects of different levels (0%, 2%, 4% and 6%/feed) of dietary *Rhus verniciflua* Stokes supplementation on meat color, water-holding capacity, volatile basal nitrogen, lipid oxidation and fatty acid composition in *M. longissimus* from Hanwoo (Korean cattle) steers during refrigerated storage at 3 ˚C.

Materials and methods

Animals, diets and treatments. Sample of *Rhus verniciflua* Stokes was collected from nature at Gapyeong, Gyeonggi province, Korea in 2003. The bark and heartwood of *Rhus verniciflua* Stokes were reduced to sawdust by means of an electrical saw. Hanwoo (Korean cattle) steers were divided into four groups. Control group (n=3) was fed a common basal diet (Control group) for 26 months. The other groups (n=5/group) were fed a supplemented concentrate diet with a *Rhus verniciflua* Stokes supplement of 2%, 4% and 6%/feed for 4 months before slaughter. The *Longissimus* muscle was removed about 48 hr after slaughter. Muscles were sliced (1.2 cm thickness), then overwrapped in polyethylene wrap film (oxygen transmission rate 35,273 $cc/m^2/24hr/tm$, thickness 0.01 mm). Samples were then held 7 days at 3˚C.

Analytical procedures. CIE L^* (lightness), a^* (redness), and b^* (yellowness) values for Illuminant C were measured by a color difference meter (CR-310, Minolta Co., Tokyo, Japan). Also, chroma (C^*) and hue-angle (h^o) values were calculated as $C^* = (a^{*2}+b^{*2})^{1/2}$, and $h^o = \tan^{-1}(b^*/a^*)$, respectively. The relative content of metmyoglobin at the meat surface was calculated by the method of Kryzwicki (1979) using reflectance at 473, 525, 572, and 730 nm. Reflectance readings were converted to absorbance[2-log(%reflectance)] and used in the equation (Demos et al., 1996). The pH value was determined by homogenizing 10 g sample with 100 ml distilled water for 1 min. A press technique reported by Grau and Hamm (1953) was used to determine water-holding capacity (WHC). Thiobarbituric acid reactive substances (TBARS) was measured according to the modified method of Sinnhuber & Yu (1977). VBN (volatile basic nitrogen) value was measured by Conway's method (Kohsaka, 1975). Total lipids for fatty acid analysis were extracted from muscle using the method of Folch et al (1957). Fatty acid methyl esters were prepared according to the procedure of Sukhija and Palmquist (1988). Data were analyzed as a 4 (diet condition) by 4 (storage day) factorial design using the General Linear Model procedure of SAS.

Results and discussion

As shown in Table 1, The CIE L^*, a^*, b^* and C^* values of 4% group were significantly ($p<0.05$) higher than those of the other groups over time. The CIE a^*, b^* and C^* values except L^* value were significantly ($p<0.05$) decreased during refrigerated storage in all of the groups. In particular, control and 6% groups were more accelerated compared to the other groups. The a^* value of day 7 was significantly ($p<0.05$) higher in 2% and 4% groups than in the other groups. The trend for C^* value was similar to that for a^* value. Hue angle increased ($p<0.05$) as storage time increased. And control group at day 7 had higher ($p<0.05$) hue angle than the other groups. As shown in Figure 1, the metmyoglobin (%) of day 0 was significantly ($p<0.05$) higher in 4% and 6% groups than in the other groups. It was significantly ($p<0.05$) increased during storage time in all of the groups, but 4% group had a lower rate of metmyoglobin accumulation during storage. As a whole, water-holding capacity (Fig. 2) was significantly ($p<0.05$) lower in control group than in the other groups. TBARS value (Fig. 3) which represent fat rancidity tended to increase as storage time increased in all of the groups. The TBARS value of day 0 was not significantly ($p>0.05$) different among 4 diet conditions, but the TBARS value after 5 days of storage was significantly ($p<0.05$) higher in control group than in other groups. The volatile basic nitrogen (Fig. 4) of 0 day was significantly ($p<0.05$) higher in control group than in the other groups. VBN increased gradually during storage, the VBN of day 7 was significantly ($p<0.05$) lower in 4% groups. As shown in Table 2, the proportions of C18:1, MUFA, UFA and MUFA/SFA ratio were significantly ($p<0.05$) higher in the meat from *Rhus verniciflua* Stokes-supplemented Hanwoo (Korean cattle) than in the control group. But, the proportions of SFA was significantly ($p<0.05$) highest in control group.

Conclusions

The meat from *Rhus verniciflua* Stokes-supplemented Hanwoo (Korean cattle) was effective in increasing color stability, water-holding capacity, unsaturated fatty acids and retarding lipid oxidation than was the control meat. In particular, dietary *Rhus verniciflua* Stokes supplementation with 4% of Hanwoo beef extended color display life compared to the other groups.

DYNAMICS OF MYOGLOBIN LAYER CHANGE DURING DISPLAY OF COLOR-STABLE AND COLOR-LABILE BEEF MUSCLES

R. Limsupavanich[1], D.H. Kropf[1], M.C. Hunt[1], E.A.E. Boyle[1], D.L. Boyle[2], and T.M. Loughin[3]

[1]Department of Animal Sciences & Industry; [2] Division of Biology; [3] Department of Statistics, Kansas State University, Manhattan, KS 66506, USA

Background

The ability of myoglobin (Mb) to oxygenate or "bloom" to a bright cherry red color of oxymyoglobin (OMb) and to retain its stability during retail display differs among different muscles (Hood, 1980; O'Keeffe and Hood, 1982; Renerre and Labas, 1987). Muscle cell respiration is temperature dependent (Urbin and Wilson, 1958; Bendall and Taylor, 1972) and was found to deteriorate with post mortem age (Bendall and Taylor, 1972; O'Keeffe and Hood, 1982). Lower temperatures enhance oxygen solubility in water, increase Mb oxygenation (Urbin and Wilson, 1958), and reduce enzyme activity (Urbin and Wilson, 1958; Bendall and Taylor, 1972). Bloom color on a muscle surface is influenced by oxygen consumption of muscle cells, oxygen partial pressure (pO_2) on the muscle surface, and the depth of Mb oxygenation (Brooks, 1929; O'Keeffe and Hood, 1982). Research has determined the depth of oxygen penetration into muscles directly by determining pO_2 (Morley, 1971; Feldhusen et al., 1995) or indirectly by observing pigment oxygenation (Brooks, 1929; O'Keeffe and Hood, 1982). We investigated both OMb and metmyoglobin (MMb) layer depths, and their relationship to surface color using novel open-topped clear Plexiglas® containers for continuous observation of pigment changes in muscle cubes and digital image analysis to quantitate the dynamics of pigment layer change.

Objectives

We investigated the combined effects of post mortem time (PT; 3, 10, or 14 d), storage temperature (ST; 0° or 4.4°C), and display temperature (DT; 0° or 3.3°C) on depths of oxymyoglobin (OMb) and MMb layers and instrumental color of beef *Longissimus lumborum* (LL) and *Psoas major* (PM) muscle cubes at 3 h and 1, 3, and 5 d of display.

Materials and methods

For each of 4 replications, sixteen paired muscles of LL and PM from the right side of USDA Select (n=48) and Choice (n=16) carcasses were obtained 48 h post slaughter from a commercial processing facility. Eight paired LL or PM were assigned randomly to 0ºC ST, while another eight pairs were assigned to 4.4ºC ST. At 3, 10, and 14 d PT, tissue from the anterior end of LL or posterior end of PM (same carcass for each ST) was cut into a cube and placed into an open-top, clear Plexiglas container (3.8-cm^3 for LL, 3.2-cm^3 for PM). Immediately after cutting, two adjacent sides of each muscle cube, with muscle fibers running perpendicular to the container base, were placed tightly in one corner of the Plexiglas container to maintain the deoxygenated form of Mb on muscle surfaces next to the Plexiglas. The extra portion of the muscle cube which extended above the top of the Plexiglas container was cut off at the open-top edge by cutting across the muscle fibers, to allow oxygen diffusion along the muscle fibers. The top muscle surface was covered immediately with PVC film (23,250 cc O_2/m^2/24 h at 23ºC and 0%RH) and exposed to ambient air. The LL or PM muscle cubes from each ST were placed in open-top display cases at 0º or 3.3ºC. The display luminance of 1614 lux was provided by the Ultralume™ 30 continuous fluorescent lighting (34 watts, 3000 K, Phillips, Sommerset, NJ, USA).

Due to time demands for muscle cube preparation, surface instrumental color measurement on top surface for each muscle cube was first done at 3 h bloom time. CIE L*, a*, b* (Illuminant A / 10 º observer; 1.27-cm diameter aperture) and reflectance spectral data (400-700 nm, 10-nm increments), were obtained using a HunterLab LabScan 6000 spectrophotometer (Hunter Associates Laboratory, Inc.; Reston, VA, USA). Values for %R 630 nm - %R 580 nm were calculated. The percentages of OMb and MMb on the muscle surfaces were estimated using K/S spectral data (AMSA, 1991). Surface instrumental color measurements and digital image photography of the pigment layers were recorded during 3 h, and 1, 3, and 5 d of display.

Following instrumental color measurement, digital image photography was performed on each muscle cube using a Sony Digital Mavica Still Camera model MVC-FD91 (Sony Corporation, Japan). Extreme care was taken to standardize digital photography. A scale in 1-mm increments, was included in each photograph for unit calibration for pigment layer measurement. Analysis of images was performed on an IBM ThinkPad T20 personal laptop computer model 2647-41U 700 MHz 128.0 MB RAM 12 GB storage capacity (IBM Corp., Armonk, NY, USA). Images were displayed on a high resolution (1024 x 768 pixels) TFT IBM ThinkPad LCD on S3 Inc. Savage/IX with true color (32- bit per pixel) screen setting. Digital images were processed using Adobe Photoshop 5.0 software (Adobe Systems Inc., San Jose, CA, USA). OMb and MMb layer depths were analyzed using the National Institutes of Health (NIH, Bethesda, MD, USA) *Scion Image* software (ScnImage release Beta 3b).

Color processing of images for the OMb layer depth measurement was performed by using the RGB mode TIFF image in Adobe Photoshop, converting it to CYMK color mode (Ringkob, 1997), and adjusting the color balance. The adjustments resulted in a bright orange yellow color of the OMb layer contrasting with a greenish brown color of the deoxymyoglobin layer. To separate the three Mb layers, the CYMK images were adjusted for color balance, hue, and saturation. Image processing and analysis for MMb layer depth measurement was performed on images recorded during 1, 3, and 5 d display. The image analysis for pigment layer depth determination was performed on ScnImage Software by acquiring the color processed RGB image. Stacks of an originally adjusted 24-bit color image were generated from a slice of the red channel (grayscale) with a "Stacks" drop down menu. The analysis of an image could be performed on this converted 24–bit color TIFF image. To calibrate the measurement unit, for each acquired image, a line selection tool was used to drag a 10-mm straight line on the scale presented underneath the muscle cube Plexiglas container. On the "Analyze" and "set scale" menu, the unit was set to mm. The measured distance in pixels was then calibrated with a known 10-mm scale. Five locations were measured for each pigment layer depth and averaged. The experiment was in a strip-split-split plot design. Analysis of Variance was performed utilizing the MIXED procedure of SAS (2000). Least-squares means for all variables and interactions were generated and separated using the DIFF option.

Results and discussion

As expected, muscle type and PT had the major effects on the depths of OMb and MMb layers and surface color. Their interactions also occurred in the data, especially on d 5 of display (Table 1). The effects of DT and ST on the OMb and MMb layers and surface color are presented in Table 2 and 3, respectively. Influences of main effects (muscle, PT, DT, and ST) and interactions will be discussed by each day of display.

At 3 h of bloom, the color-stable LL had a deeper ($P<.05$) OMb layer (3.45 mm) than the color-labile PM (2.02 mm). LL developed greater ($P<.05$) surface OMb, was ($P<.05$) lighter (higher L*), more ($P<.05$) yellow (higher b*), and had higher ($P<.05$) %R630 - %R580 values than PM, but it was not ($P>.05$) redder (a*). Feldhusen et al. (1995) reported no clear relationship between Mb oxygenation and a* value on muscle surface during 5 h of air exposure. PT affected ($P<.05$) surface MMb and bloom color attributes where muscles stored longer had a better bloom color. Surface OMb for 3, 10, and 14 d PT was similar (95.1, 95.1, and 96.4%, respectively). However, muscles 10 and 14 d PT had less ($P<.05$) surface MMb than 3 d PT and were brighter red and more yellow than 3 d PT. The greater surface MMb on muscles 3 d PT was likely due to lower pO_2 on muscle surface (Feldhusen et al., 1995), which likely resulted from higher oxygen consumption in muscles with less PT (O'Keeffe and Hood, 1982). Feldhusen et al. (1995) found that the oxygen penetration measured at 5 h after cutting increased with storage time. However, we found no effect ($P>.05$) of PT on the OMb layer at 3 h of bloom. Compared to 3.3ºC DT, muscles displayed at 0ºC were ($P<.05$) lighter, more yellow, and had higher %R630 - %R580 values, but were similar ($P>.05$) in OMb layer, surface OMb and MMb, and a* values (Table 2). There was no ($P>.05$) influence of ST (Table 3) on 3 h bloom color attributes.

At 1 d of display, the OMb layer of LL increased to 4.55 mm, while that of PM decreased to 1.73 mm. Feldhusen et al. (1995) reported a 4.5-mm deep OMb layer in *Longissimus dorsi* at 5 h of air exposure. They indicated a clear increase in oxygen penetration with time of air exposure during 5 h. The MMb layer of LL was ($P<.05$) thinner (1.18 mm) than PM (1.67 mm-MMb), which resulted in a brighter red and more yellow surface color (Table 1) in LL than PM. As expected, muscles 10 d PT had greater ($P<.05$) surface OMb, were redder and were more yellow than those at 3 d PT (Table 1), but 10 d did not ($P>.05$) differ from 14 d PT. We did not find an influence ($P>.05$) of PT on OMb and MMb layer depths. Colder DT (0°C) promoted a

deeper (P<.05) OMb layer formation (Table 1), likely due to better oxygen solubility in the intracellular water and less enzyme respiration (Urbin and Wilson, 1958). Surface color of muscles displayed at 0°C was better than those displayed at 3.3°C, however, the differences were not significant (P>.05).

At 3 d display, OMb layer (4.60 mm) in LL increased slightly from d 1, while that in PM continued to decrease (1.15 mm). In contrast, MMb layers of both muscles increased (2.24 mm for LL and 2.88 mm for PM). The OMb layer of LL was thicker (P<.05) and MMb layer was thinner (P<.05) than those in PM. As a result, LL had (P<.05) greater surface OMb, less surface MMb, was brighter red and more yellow than PM (Table 1). O'Keeffe and Hood (1982), however, found no differences in depth of OMb layer between these 2 muscles at 2 d PT. Muscles stored 14 d PT developed a thicker (P<.05) MMb layer than 3 d PT, but did not differ (P>.05) from 10 d PT. Storage at 0°C resulted in a thinner (2.34 mm, P<.05) MMb layer than at 4.4°C (2.78 mm, Table 3). Muscles stored and displayed at higher temperatures (4.4°C ST, 3.3°C DT) provided (P<.05) the least surface OMb and lowest value of %R630 - %R580 (data not shown).

After 5 d display, more interactions occurred between muscle and PT (Table 1). The a*, b*, %R630 - %R580, surface OMb and MMb, and OMb layer were influenced (P<.05) by muscle x PT. Among LL from 3 different PT, LL stored 14 d had (P<.05) the lowest values of a*, b*, %R630 - %R580, surface OMb, and OMb layer, but the most surface MMb. The OMb layer of 14 d PT LL, however, was similar (P>.05) to those of PM stored 3 or 10 d. PM from 3 different PT had similar (P>.05) a*, b*, and %R630 - %R580, which were (P<.05) lower than those in all the LL. Although not always significant, PM stored 14 d had the worse overall color, least surface OMb, most surface MMb, and thinnest OMb layer. More degradation of substrates and coenzymes may occur during longer PT of muscles, which likely causes less MMb to be reduced (O'Keeffe and Hood, 1982). Interestingly, no differences (P>.05) in MMb layer were observed. L* was affected by muscle main effect where LL was (P<.05) lighter than PM. ST at 0°C had (P<.05) greater a*, %R630 - %R580, and less surface MMb (Table 3).

Conclusions

This study suggests that longer PT (10 or 14 d) provided better color bloom, but as PT increased, color stability decreased as shown by faster OMb layer thinning and faster MMb layer thickening. The more color stable LL allowed a deeper O_2 penetration during bloom, a thicker OMb layer, and slower developing MMb layer during display. While MMb layer of the 2 muscle types reached similar thickness at 5 d display, the deeper OMb layer had a greater influence on surface color stability. The dynamics of myoglobin layer during bloom, which may be explained by their inherent biochemical traits of oxygen consumption and reducing capacity, were related to surface color bloom attributes and stability during display of the LL and PM muscles.

EFFECT OF BREED AND STRATEGIC FEEDING ON PORK TENDERNESS EVALUATED WITH INSTRUMENTAL AND SENSORY ANALYSES

Gunilla Lindahl[1], Chris Claudi-Magnussen[2], Anke Heyer[3] and Kerstin Lundström[3]

[1]Department of Food Science, Danish Institute of Agricultural Sciences, PO Box 50, DK-8830 Tjele, Denmark, [2]Danish Meat Research Institute, Maglegårdsvej 2, DK-4000 Roskilde, Denmark, [3]Department of Food Science, Swedish University of Agricultural Sciences, PO Box 7051, SE-750 07 Uppsala, Sweden

Background

Consumers have high expectations to outdoor produced pig meat, especially from organic outdoor pigs. However, these expectations are seldom achieved. Recent studies have shown that strategic feeding of pigs can change many pork quality characteristics in a consumer-wise positive direction. Accelerated growth rates occur in pigs with free access to feed following a period of restricted feeding (Oksbjerg *et al*., 2002), and feeding intensity is directly related to muscle growth rate and in turn to meat tenderness (Kristensen *et al*., 2002). Muscle growth rate is principally determined by the ratio between the rates of protein synthesis and protein degradation. A high rate of protein degradation at slaughter accelerates meat tenderness development post mortem. Pigs produced outdoors on a restrictive feeding regime and with free access to roughage, have reduced muscle growth rate and lower tenderness score (Danielsen *et al*., 2000). Contradictory results concerning the influence of the intramuscular fat content (IMF) on pork tenderness are reported (Göransson *et al*., 1992; Fernandez *et al*., 1999; van Oeckel *et al*., 1999).

Objectives

The aim of the present study was to evaluate the effect of various rearing systems including strategic feeding on pork tenderness using both instrumental and sensory analyses, as well as to evaluate the relationship between (IMF) and pork tenderness.

Materials and methods

During two years, 280 growing/finishing pigs were raised to approximately 107 kg live weight in four different production systems. Pigs were equally distributed within litter and breed to housing systems (outdoors/indoors), crossbreed (Duroc*LargeWhite/Landrace*LW) and gender (castrates/females). Outdoor pigs were fed *ad libitum*, with either an organic diet diluted with 20% alfalfa roughage throughout (org.dil; decreased energy density) or with first this diet and thereafter the undiluted organic diet (org.dil./org.; strategic feeding for compensatory growth). In two indoor treatments, pigs were fed restrictively with either an undiluted organic diet or a conventional diet. A random part of the material, 135 pigs (67 D*LW and 68 L*LW) was used in the present study.

Sensory profiling was performed on *M. longissimus dorsi* (LD) using a trained sensory panel of 9 assessors. The loins were sliced in 20 mm thick chops and fried on a frying plate at 155°C to a core temperature of 65°C. No salt or spices were used. Sensory attributes related to meat structure, ie., tenderness, hardness at first bite, stringiness and crumbliness, are reported in this paper. The intensity of each attribute was evaluated on an unstructured scale from 0 to 15 (0 for low intensity and 15 for high intensity).

300 g pieces of LD were cooked in a water bath at 70°C for 90 min for determination of Warner-Bratzler (WB) shear force. Maximal WB peak force (WBPF) and total WB-work (WBwork) were measured on 8 strips (10x10x50 mm), sheared across the fibre direction (speed: 55 mm/min, TA-HDI texture Analyser; Stable Micro Systems, Surrey, UK). The intramuscular fat content (IMF) was analysed from some samples (48 D*LW loins and 50 L*LW loins) by the SBR-method after hydrolysis with HCl using diethyl ether and petroleum ether for extraction.

Statistical analyses of meat quality traits were performed with the MIXED procedure in SAS (SAS Institute Inc., Cary, N.C., USA, version 8.2). The model included treatment, crossbreed (D*LW or L*LW) and gender (female or castrate) as fixed effects. Two-way interactions between the fixed factors were included in the

model, when significant ($p \leq 0.05$). Sire within crossbreed, as well as dam within crossbreed and sire, were treated as random. Each assessor, as well as the interaction between assessor and sensory session, was also included as random in the model of sensory traits. In the tables, data are expressed as least square means with pooled standard errors. The Unscrambler version 8.0 (Camo Process AS, Oslo, Norway) was used for partial least squares regression (PLS) using standardised variables and full cross validation. Means of the sensory scores from all the assessors were used in the PLS. Martens' uncertainty test was used for significance testing of variables in PLS.

Results and discussion

The rearing system, crossbreed and rearing year affected the sensory attributes of tenderness, hardness at first bite, stringiness and crumbliness (Table 1). Organic outdoor rearing resulted in more tender pork than conventional indoor rearing for both crossbreeds (year 2). Organic outdoor D*LW pork was also more tender than indoor organic D*LW pork (year 2). Pork from strategic organically fed outdoor L*LW pigs was more tender than pork from indoor organic L*LW pigs both years. Strategic outdoor organic feeding improved tenderness of L*LW pork (year 2), whereas no such effect was found in D*LW pork. Strategic outdoor feeding increased hardness at first bite and stringiness and decreased crumbliness in D*LW pork, whereas the opposite was seen in L*LW pork (year 2). Indoor rearing of the pigs produced pork with the highest hardness at first bite, especially with conventional feeding. The most stringy and least crumbly D*LW pork was produced by organic indoor rearing (year 2).

Contrary to sensory tenderness, no interaction between crossbreed and rearing was found on WB shear force. Rearing effect was only seen on WBPF (year 2). WBPF was highest in pork from indoor organic pigs and lowest in pork from strategic fed organic outdoor pigs. The improving effect of strategic outdoor feeding (compensatory growth) on pork sensory tenderness was not seen on WB shear force. However both tenderness and WB shear force were improved when compared to indoor organic restricted feeding. The effect of strategic feeding was not as pronounced in the present study as in the study of Kristensen *et al*., 2002. The reason might be that the pigs were not slaughtered at an optimal compensatory growth period in the present study.

There were significant relationships between most of the measured traits (Table 2). WBPF and WBwork were, as expected, highly correlated, and both were correlated to sensory tenderness at almost the same level within both crossbreeds. The correlations were generally higher for D*LW pork except for crumbliness with higher correlations for L*LW pork. The most marked breed difference was for the correlations with IMF. Significant correlations were found for all traits, except WBwork, within D*LW pork, whereas IMF only was significantly correlated to stringiness within L*LW pork. Van Oeckel *et al*. (1999) found correlations between WBPF and sensory tenderness of pork loin between -0.39 and -0.69 depending on different modifications of the WB-method, which is in agreement with the present study.

All sensory traits were to some degree correlated to WB shear force (Table 2) and thus it was interesting to evaluate the total influence of the investigated sensory traits on shear force. It has been discussed whether IMF has an impact on pork tenderness or not. Göransson *et al*. (1992) found some negative influence of IMF on tenderness in pork of Hampshire crossbreeds, whereas van Laak *et al*. (2001) found a linear relationship accounting for 47% of the variation in WB shear force in Duroc pork loin, but no relationship in Hampshire or Berkshire pork loins. Fernandez *et al*. (1999) found a tendency to improved tenderness with higher IMF in one experiment, but no effect in another experiment. Therefore IMF was included in the PLS in the present study. The rearing system did not affect IMF (Table 1), but IMF was higher in D*LW compared with L*LW loin (2.0% vs 1.4%, P=0.029). IMF varied between 1.1-3.8% in D*LW loin and between 0.7-3.1% in L*LW loin. PLS on WBPF showed significance for IMF only in D*LW loin, not in L*LW loin (Figures 1 and 2), which was in agreement with the single correlation coefficients (Table 2). Tenderness, hardness at first bite and stringiness were significant for loin of both crossbreeds, but crumbliness only for L*LW loin.

Conclusions

Outdoor strategic feeding for compensatory growth improved the sensory attributes of tenderness and hardness at first bite on L*LW pork loin, but this effect was not seen in D*LW pork loin. The outdoor rearing systems resulted in more tender pork, evaluated both with instrumental and sensory analyses,

compared with the indoor restricted rearing systems. IMF influenced WBPF in D*LW pork loin, but not in L*LW pork loin.

FACTORS AFFECTING BEEF LUMBAR VERTEBRAE DISCOLORATION

Mancini, R.A. and Hunt, M.C.
Animal Sciences and Industry, Weber Hall, Kansas State University, Manhattan, KS, 66506, USA

Background

Marrow discoloration is a factor that influences the appearance of bone-in meat products. This is particularly true in beef steaks containing lumbar vertebrae. However, to date, little research has focused on beef bone marrow discoloration, regardless of its affect on product display life.

Bone discoloration appears to be promoted by high-oxygen modified atmosphere packaging (MAP), which likely favors hemoglobin oxidation within exposed bone marrow (Lanari *et al.* 1995; Sorheim *et al.* 1999). In contrast, removing oxygen from modified atmosphere packages should encourage the deoxygenated form of hemoglobin; therefore, stabilizing vertebrae marrow color during storage and display. In addition, low levels of carbon monoxide in MAP should maintain a bright-red marrow color due to the formation of carboxyhemoglobin. Sorheim *et al.* (1999) speculated that carbon monoxide and oxygen exclusion might limit bone blackening. Although packaging technology has the potential to influence bone color, no published reports have evaluated the effects of package atmosphere on bone discoloration.

The oxidative state of hemoglobin released from red blood cells on the surface of cut bones likely determines marrow color (Lanari *et al.* 1995; Gill 1996). Thus, antioxidants that limit heme-protein oxidation within marrow should prove useful for preserving vertebrae surface color. Although ascorbic acid's ability to reduce methemoglobin in purified solutions has been reported, no published work has assessed the effects of ascorbic acid on bone marrow. The ability of ascorbic acid to delay myoglobin oxidation has made it a useful tool for minimizing surface discoloration in muscle (Lee *et al.* 1999; Shivas *et al.* 1984).

Objectives

Because bone discoloration is (1) an undesirable result of prolonged storage and (2) a process for which there is no established preventative measure (Warren *et al.* 1992; Gill 1996), our objectives were to:

1.) Investigate ultra low-oxygen and carbon monoxide modified atmosphere packaging (CO MAP) as a means of limiting lumbar vertebrae discoloration during storage.
2.) Investigate the ability of ascorbic acid, ascorbate-6-palmitate, and sodium erythorbate to minimize beef lumbar vertebrae discoloration during display.

Materials and methods

Experiment 1

Ten beef short loins (6 days postmortem) were cut perpendicular to the vertebral column into 2.54 cm-thick steaks. All lean, fat, and ribs were removed, yielding 2.54 cm-thick sections of only lumbar vertebrae. From each loin, 4 vertebrae were packaged separately in either ultra low-oxygen (80% N_2 and 20% CO_2) or carbon monoxide MAP (0.4% CO, 30% CO_2, and 69.6%N_2). One vertebra from each loin was packaged in high-oxygen (80%O_2 and 20% CO_2). Before packaging, initial instrumental color on the surface of each vertebrae section was evaluated (CIE L*a*b* and reflectance from 400 to 700nm; Illuminant A, 0.64 cm aperture, 10° observer). Packages were stored at 4°C.

From each loin, 1 vertebra per packaging treatment was evaluated after 1 day in storage. Because of the rapid discoloration resulting from high-oxygen MAP, vertebrae packaged in 80%O_2 were no longer evaluated. Instrumental color variables at 2, 4, and 6 weeks after packaging were then used to evaluate atmosphere-induced stability during storage (low-oxygen and 0.4% carbon monoxide packaging). The experimental design was a completely randomized block with repeated measures. Vertebral columns served as blocks (n = 10) to which packaging was assigned to vertebrae sections within each loin. Time of color evaluation was a

repeated measure assigned to units within a column. Data for all experiments was analyzed using the mixed procedure of SAS. Significance represents probabilities < 0.05.

Experiment 2:
Eight vertebral columns containing lumbar vertebrae were obtained at 6 days postmortem. Each was cut perpendicular to the length of the column into 1.91 cm-thick sections. From each column, two vertebral sections (n = 2 per treatment per column) with at least 2.54-cm² of freshly exposed lumbar marrow were randomly assigned to 1 of 7 treatments: Treatment 1 = No topical antioxidant; Treatment 2 = Distilled water; Treatment 3 = 1.5% Ascorbic acid; Treatment 4 = 2.5% Ascorbic acid; Treatment 5 = Ethanol; Treatment 6 = 1.5% Ascorbate-6-Palmitate; and Treatment 7 = 2.5% Ascorbate-6-Palmitate. Ascorbic acid and ascorbate-6-palmitate were made on a wt/wt basis using distilled water and ethanol, respectively. Vertebrae were topically treated with 1 ml of an assigned treatment, which thoroughly covered the entire fresh cut vertebrae.

To minimize package-to-package variation, 7 vertebrae sections from each column (1 per treatment) were packaged together in 80% O_2 and 20% CO_2. Packages were displayed at 1°C for 5 days in open-top display cases under continuous fluorescent light (1614 lux; 3000 K).

The color of marrow from each vertebrae section was evaluated initially and on days 1, 3, and 5 of display by 8 trained visual-color panelists using a scale of 1 = Bright reddish-pink to red (typical fresh cut bone), 2 = Dull pinkish-red, 3 = Slightly grayish-pink or grayish-red, 4 = Grayish-pink or grayish-red, 5 = Moderately gray, 6 = All gray or grayish-black, 7 = Black discoloration (0.5 point intervals). Instrumental color (CIE L*a*b*; Illuminant A, 0.64 cm aperture, 10° observer) was evaluated at 0, 1, and 5 days of display. Initial color (day 0) was evaluated prior to topical antioxidant treatment and packaging. The experimental design and analysis were similar to experiemnt 1.

Experiment 3
Ten bone-in short loins containing *longissimus* muscle and lumbar vertebrae (6 days postmortem) were fabricated into 1.9 cm-thick steaks. From each loin, 6 steaks with at least 2.54-cm² of freshly exposed lumbar marrow were assigned to one of the following treatments: Treatment 1 = Untreated control (0% Erythorbate); Treatment 2 = 0.05% Erythorbate; Treatment 3 = 0.1% Erythorbate; Treatment 4 = 0.5% Erythorbate; Treatment 5 = 1.0% Erythorbate; and Treatment 6 = 1.5% Erythorbate. All treatments were made on a wt/wt basis using distilled water. Experiment 2 indicated that there was little advantage to using 2.5% ascorbic acid; thus, 1.5% erythorbate was selected as the maximum concentration. Five milliliters of an assigned treatment was applied to the entire fresh cut surface of each steak, including the bone surface. To maximize distribution, treatments were spread over the entire steak surface using sterile cell spreaders.

Before treatment, the initial color (0 hours) on the fresh cut surface of lumbar vertebrae and *longissimus* muscles was measured instrumentally (Illuminant A, 1.27 cm aperture, 10° observer). Following treatment, steaks were packaged in 80% O_2 (20% CO_2) and displayed for 24 hours at 1ºC before instrumental color again was evaluated (24 hours post packaging) on both the *longissimus* muscle and the porous bone marrow of lumbar vertebrae for each steak. The experimental design and analysis were similar to experiment 1.

Results and discussion

Experiment 1
Initial vertebrae color prior to packaging was bright-red, typical of freshly-cut, oxygenated marrow (Table 1). High-oxygen packaging resulted in a rapid and significant loss of both redness ($\Delta a^* = 7.7$) and red color intensity (Δchroma = 6.8) within 24 hours after packaging. In addition, high-oxygen MAP decreased reflectance at 630 nm and increased reflectance between 540 and 580 nm, both of which indicate the conversion of oxy- to met- pigments. Thus, discoloration on the surface of lumbar vertebrae was likely due to methemoglobin. Our results support those with pork (Lanari *et al.* 1995), indicating that high-oxygen is detrimental to beef bone marrow color stability. Our reflectance data supports the role of hemoglobin's oxidative state (redox stability) in bone darkening (Lanari *et al.* 1995; Gill, 1996).

The benefits of 0.4% CO in MAP were immediately noted, and this packaging system increased surface redness within as little as 24 hours of storage (Table 1). In addition, vertebrae packaged in 0.4% CO MAP

remained bright-red for up to 6 weeks while those packaged in ultra low-oxygen MAP discolored after 2 weeks of storage. Sorheim *et al.* (1999) hypothesized that low levels of CO might limit bone discoloration. Our results support this, suggesting that formation of carboxyhemoglobin maintained a bright-red marrow color on the surface of lumbar vertebrae for up to 6 weeks in storage at 4°C. We agree that bone discoloration is increased by storage time (Warren *et al.* 1992; Gill 1996), but also recognize that beef vertebrae stored in high-oxygen MAP will darken within as little as 24 hours after packaging.

Experiment 2

Initial vertebrae color prior to treatment was bright-red. Untreated vertebrae and vertebrae treated with water or ethanol significantly discolored within 1 day after packaging in high-oxygen, resulting in no significant difference between negative and positive controls (Table 2). Applying ascorbic acid to vertebrae marrow significantly limited the rapid discoloration observed in control samples. Concentration of antioxidant had no significant affect on discoloration (1.5% was comparable to 2.5%). Overall, surface color during the 5-day display was preserved by topical antioxidant treatment in the following order: ascorbic acid > ascorbate-6-palmitate > controls; $P < 0.05$). During the 5-day display, ascorbic acid treated marrow had the least surface discoloration, the ascorbate-6-palmitate treatments were intermediate, and applying only water or ethanol had no benefits compared to untreated samples.

Experiment 3

Prior to display, all vertebrae were bright-red with no surface discoloration. Sodium erythorbate at 0.5, 1.0, or 1.5% prevented vertebrae discoloration within the first 24 hours of high-oxygen MAP display whereas untreated vertebrae and vertebrae treated with 0.05 or 0.1% erythorbate significantly discolored (Table 2). The *longissimus* from all treatments was bright-red with no signs of discoloration; therefore, erythorbate had no detrimental affects on muscle color (data not shown).

When bone-in beef steaks containing lumbar vertebrae were packaged in high-oxygen MAP, the marrow discolored rapidly while the *longissimus* muscle remained bright-red early in display. In experiments 2 and 3, both ascorbic acid and its isomer (erythorbate) proved useful for minimizing lumbar vertebrae discoloration. The reducing activity of ascorbic acid plays a role in muscle color stability via metmyoglobin reduction (Lee *et al.* 1999). We speculate that ascorbic acid maximized color stability on the surface of lumbar vertebrae by reducing methemoglobin. However, it is also possible that ascorbic acid limited methemoglobin accumulation by protecting hemoglobin from prooxidants derived from lipid oxidation.

Conclusions

We conclude that the detrimental effects of storage on beef lumbar vertebrae can be minimized through package atmosphere. Removal of oxygen from packages will limit vertebrae marrow discoloration during storage (2 weeks at 4 °C). To maximize the stability of hemoglobin on the surface of bone, combining 0.4% carbon monoxide with oxygen exclusion from modified atmosphere packages will maintain bright-red lumbar vertebrae for up to 6 weeks after packaging.

Although storage tends to promote discoloration, we conclude that high-oxygen MAP will induce rapid bone marrow discoloration. However, this rapid color deterioration on the surface of lumbar vertebrae can be prevented by ascorbic acid and sodium erythorbate. To maximize color stability through a 5-day display period at 1ºC, 2.5% ascorbic acid may be required. While ascorbate-6-palmitate minimizes vertebrae discoloration compared to untreated bone-in product, it does not perform as well as its water-soluble counterparts, ascorbic acid and sodium erythorbate.

DIET AND AGEING EFFECT ON INSTRUMENTAL AND SENSORY CHARACTERISTICS OF MEAT FROM PODOLIAN YOUNG BULLS

Marino, R., Caroprese, M., Santillo, A., Pelosi, S., Pacelli, C. and Braghieri, A.

1Dipartimento PRIME, Università di Foggia, Italy
2Dipartimento di Scienze delle Produzioni Animali, Università degli Studi della Basilicata, Italy
3CNR-ISMAR, Lesina, Italy

Background

Meat quality largely depends on organoleptic properties such as colour, texture, flavour and juiciness which are related to production (breed, age, sex, diet) and technological (refrigereration or ageing time) factors.
Some studies (Bidner et al. 1985; Fortin et al. 1985; O'Sullivan et al. 2003) found no effect of different forage to concentrate ratio supplementations on meat quality. Ageing produces changes in meat characteristics (Zamora et al., 1996, Ruiz de Huidobro et al. 2003), influencing the final perception of the product. Tenderness has been considered the most important meat quality characteristic for consumers (Risvick 1994). It is well known that throughout ageing muscles undergo a series of physical and biochemical changes which are responsible of their conversion to meat. Particularly these modifications concern the Z-disk weakening and the myofibrilis degradation which are highly related to meat tenderness (Koohmaraie, 1994). Both instrumental and sensorial trials have been commonly used for assessing it.

Objectives

The present study aims to assess the effect of different ageing periods and diet supplementation on physicochemical and sensory properties of meat from Podolian young bulls. Such information is at present deficient in literature and has the potential to improve meat quality, primarily tenderness, and so to satisfy consumer desires.

Materials and methods

Experimental design

The experimental animals were twenty organically farmed Podolian young bulls, reared at pasture and divided into two groups of 10 each according to hay to concentrate ratio. In the high concentrate (HC) group the forage to concentrate ratio was 60 to 40 while in the low concentrate (LC) group was 70 to 30. The dry matter chemical composition of supplementation was determined by standard procedures (AOAC, 1990). On average, oats hay used as forage contained 6-7% crude protein, 27-34 % crude fibre, 62-63% NDF, and 0.5 MFU/kg, while the d.m. chemical composition of durum wheat flour shorts as concentrate was 17% crude protein, 7% crude fibre, 27% NDF and 0.95 MFU/kg. Animals were slaughtered at 16-18 months of age. Mean slaughter weight was 378±14.8 kg. The carcasses were assessed for conformation and fatness according to the SEUROP-system (UE n.1208/1981 and UE n.1026/1991). Dressed carcasses were weighed and split into two sides within 1 h *post mortem*, chilled for 48 h at 1-3°C. Dressing percentage (DP) was calculated as carcass weight to slaughter weight ratio x 100. After 48 h post mortem, each side was divided in hind and fore quarters and each quarter was dissected into different anatomical regions. The pH was measured at 1 and 24 h *post mortem* on *Longissimus dorsi* (LD), using a portable pH-meter (Hanna, HI 9025) and a combined glass electrode. The LD muscle was removed from the left and right carcass side and aged in vacuum-packaging at 4°C until 15 and 21 days *post mortem* respectively.

Meat quality

Colour parameters (lightness-L*, redness-a* and yellowness-b*) were measured according to the CIE system (CIE, 1986) using a Minolta Chromameter CR 200. Chroma (C) and hue-angle (H) were calculated according to Liu et al. (1996).
Two 1 cm wide cores were removed from each muscle parallel to the muscle fibre and placed as raw samples in the Warner-Bratzler Shear attachment, which was attached to the model 1140 Instron texture machine. The sensory analysis (flavour and tenderness) was performed by a trained eight-member panel on steaks grilled to an internal temperatue of 75°C. The values were normalised standardising each assessor by his standard deviation according to Cifuni et al., (2004).

Data were subjected to an analysis of variance, using the GLM procedure of the SAS statistical software (1999). Individual animal variation within different supplementation and muscle was used as the error term. When significant effects were found the Student t-test was used to locate significant differences between means.

Results and discussion

Podolian young bulls produced carcass of 198±9.55 kg with an average carcass yield of 52.4±0.78%. Carcass conformation of both groups was classified as good, R according to the SEUROP system, while fattening condition received a score of 2+ and 2- for the HC and the LC groups, respectively.There was a significant decrease in pH during the 24 hours post mortem. Values vary from 6.5±0.07 at 1 hours post mortem to 5.5±0.06 at 24 hours. Meat with high ultimate pH values (dark-cutting or Dark, Firm, Dry-DFD) is a persistent quality defect that shortens shelf life, especially for vacuum-packaged meat and affects meat colour, texture and water holding properties (Gill & Newton, 1981). No DFD carcasses were identified in this study and, in general, the rate of pH fall was similar for all animals.
Table 1 shows colour parameters evolution in *Longissimus dorsi* of Podolian meat as affected by ageing and different supplementation. Colour parameters were unaffected by different supplementation. Lightness (L*) was not affected by ageing while red index and chroma (color saturation) decreased as ageing time increased and yellow index and hue angle (proportions of redness and yellowness) were found higher ($P < 0.001$) at 21 days post mortem. Meat colour changed during ageing period. The colour of the muscle surface is determined mainly by both the amount and the redox state of myoglobin (Fox, 1987). In the present trial, we found that red index decreased during ageing, in agreement with the results obtained by Feldhusen et al. (1995) that found no obvious connections between oxygenation and measurements of red index. These authors claimed that higher percentages of oxymyoglobin did not lead to an increase in a* in the muscle surface of the meat that has been ripening for time periods longer than 5 days.
In Figure 1 tenderness parameters of meat from Podolian young bulls are reported. Warner-Bratzler shear force (WBS) was affected by ageing and different supplementation. After 21 days meat from HC group was significantly more tender ($P < 0.001$) than after 15 days. Meat from the HC group showed, after 15 days, higher WBS values than LC ($P < 0.01$). Extending ageing period produced an improving in tenderness, intended as sensory attribute, in both group. Tenderness was scored significantly higher ($P< 0.05$) in the LC group than HC after 15 days of ageing.

Both instrumental and sensorial analyses gave the same results: 1) the meat from LC group was more tender than that from the HC group after 15 days of ageing; 2) during the ageing period the meat became more tender even if only in the HC group the increase in tenderness was significant. Comparison between sensory and objective measures of meat tenderness in previous researches gave very variable results. Some authors have found a good correlation (e.g. Touraille, 1982) whereas others found very poor coefficients (e.g. Shackelford et al. 1995). We found a positive relation between WBS and sensorial tenderness using raw meat. Indeed, shear force on raw meat reflects the background of collagen toughness, collagen being the main component of muscle connective tissue and the major determinant of the texture of meat, whereas shear force on cooked meat may be considered a measure of myofibrillar toughness (De Smet et al. 1998). Our WBS values are in agreement with values found by Torrescano et al.(2003) in raw samples of 14 bovine muscles. Forage finishing of beef has produced mixed results on tenderness and palatability attributes. Our findings showed that major forage fed animals produced a more tender meat than major concentrate fed animals after 15 days of ageing along with French et al.(2001), who found that supplementing grass with low levels of concentrates produced the most tender and acceptable meat two days post mortem, and in disagreement with Mitchell et al. (1991), who reported a negative effect of forage finishing on meat tenderness. After 21 days the different forage to concentrate ratio didn't affect meat tenderness.

Figure 2 shows flavour evolution of Podolian meat as affected by ageing and different supplementation.

The flavour was unaffected by different supplementation and ageing time. In both experimental group the ageing time improved flavour and HC and LC groups showed very similar values at 15 and 21 days of ageing. Flavour intensity increased with ageing time. This result is due to post-mortem processes such as proteolysis and lipolysis which result in the development of flavour precours. We found no effect of different forage to concentrate ratio supplementation of meat flavour. Muir et al. (1998) claimed that the differences in flavour and acceptability due to feed accounted for differences in carcass fatness.

Conclusions

The results of this study showed that a longer ageing time improved the tenderness of meat as determined through an instrumental and sensorial approach. A higher forage to concentrate ratio can improve tenderness but a longer ageing eliminates all diet effects on eating quality of beef. A longer ageing time didn't affect the colour parameters regarded by consumers as appreciating features.
We can conclude that ageing time is one of the main technological factors affecting beef quality and that the choice of a proper ageing time is critical for optimising the organoleptic properties of meat.

EFFECT OF CLASSING THE BULL CARCASSES WITHIN QUALITATIVE CLASSES (EUROP) ON CHEMICAL AND PHYSICAL-TECHNOLOGICAL PROPERTIES OF MEAT

Mojto, J., Zaujec, K., Lahučký, R., Novotná, K. and Pavlič, M.
Research Institute of Animal Production, SK – 949 92 Nitra, Hlohovská 2, Slovak Republic

Background

Classification of the slaughtered bodies of cattle according to the EUROP system gives the processor and farmer good survey on the quality in fattening cattle. It makes it easier for the meat processor to plan the production and meat distribution more effectively, and the farmer can take rational breeding measures that increase the portion of muscular substance in the carcass of cattle, and at the same time enable better economic valorization of the animal at purchase and realization. The task of a meat processor should be to supply the network of shops not only with valuable parts of the carcass but also with meat of high nutritional and sensorial quality. Is it possible to predict at least partially the quality of muscular substance by the assessment of the quality class of the carcass (meatiness and fattiness)? Which are then the relations between the carcass quality and quantitative parameters of meat? A number of authors have tried to answer this question (Temisan and Augustini, 1987; Shemeis *et al*., 1994; Fiems *et al*., 2000; Saňudo *et al*., 2000; Maher *et al*., 2001; Kim and Lee, 2003). Results of the mentioned authors are quite variable and they show that the classes of fattiness have better expression ability to predict the quality of meat (Bach *et al*., 1986).

Objectives

To evaluate the relationship between the quality class of the carcass of bulls assessed after the EUROP system and the meat quality (*m. longissimus thoracis*).

Materials and methods

We used total 340 adult slaughter bulls of different breeds (Slovak Spotted, Slovak Pinzgau, Holstein, Belgian Blue, Braunvieh, Limousine and Blond d'Aquitaine) in the experiment. Their average weight before slaughter was 515 kg. After slaughtering the carcass sides were examined and classified by a classifier after the official EU scheme (EC 1208/1981) and classed within the classes of meatiness (E, U, R, O P) and classes of fattiness (1, 2, 3, 4, 5). A muscle sample was taken from *m. longissimus thoracis* from the right side of carcass 24 hrs. post mortem. The sample was stored in a refrigerator at the temperature between +1^{o}C and 3^{o}C for further qualitative analyses. Content of total water, protein and intramuscular fat was determined in the apparatus Infratec 1265 48 hrs. post mortem. Furthermore the pH value (firm Radelkis), meat colour (Spekol) and water holding capacity (Hašek and Palanská, 1976) were measured. In the remaining sample the weight loss by cooking and shear force in the cooked meat (Warner-Bratzler) were determined on the 7th day after the slaughter. Values $\overline{x} \pm s$ of the studied qualitative parameters of meat were calculated and the differences between the quality classes of the carcasses (t-test) were tested by means of the STATGRAPHIC programme.

Results and discussion

In table 1 there are the average values of qualitative parameters of meat according to the qualitative classes of the carcasses considering the degree of meatiness (E, U, R, O, P). The results show that there are no significant differences among the classes of quality, except for small exceptions. The values are variable, there are no visible marked trends towards increasing or decreasing the values of qualitative parameters with the improvement or deterioration of carcass quality. The evaluation of shear force in cooked meat is worth mentioning; the most tender meat was in the least meaty carcass sides. The value of shear force in E class was 4.93 and in P class 3.44 kg ($P<0.05$). We noticed increasing content of intramuscular fat with deterioration of the meatiness in the slaughtered body (E = 1.99 and P = 2.49 g . 100 g^{-1}). Maher *et al*. (2001) found no constant influence of the effect of classification on the values of qualitative parameters in *m. longissimus dorsi* and *m. semimembranosus* in bullocks and heifers, using the most frequent classes

according to the statistics in Ireland ($R4^+$, $R4^-$, O^{4+} and O^{4-}). If we compare the meat quality taking into consideration the classes of fattiness in the slaughtered body (1, 2, 3, 4, 5) we obtain results given in tab. 2. The content of intramuscular fat increased linearly with increasing fattiness of the carcass (class 1 = 1.19; class 5 = 2.52 g .100 g^{-1}). The differences between classes were statistically significant $P<0.05$). On the contrary, water holding capacity decreased (class 1 = 35.69; class 5 = 32.45 g . 100 g^{-1}). Results with other parameters of meat quality are quite variable. Bach *et al*. (1986) observed in bulls and Shemeis *et al*. (1994) in cows that with increasing fattiness of the carcass also the content of intramuscular fat increased, the values of shear force decreased, and the smell and flavour of meat were evaluated more favourably. Fiems *et al*. (2000) calculated the correlation coefficient between the degree of fattiness in carcass and content of intramuscular fat r = 0.704, values of shear force r = -0.244 and colour of meat r = -0.159 in bulls of Belgian Blue breed. The correlations, we calculated, were weak (0.104; -0.170 and –0.132). We also found out that the degree of marbling in meat correlated strongly with the content of intramuscular fat (r = -0.781).

Conclusions

Our results confirmed hitherto knowledge that the estimation of beef quality assessment is more precise if we use the classes of fattiness in the slaughtered body. We found most linear changes with the intramuscular fat using the meat classes as well as the classes of fattiness. Practical utilization of the results considering separately the classes of meatiness or classes of fattiness is questionable as the resulting quality class is in the EUROP system always the combination of the class of meatiness and the class of fattiness.

CHEMICAL AND PHYSICAL CHARACTERISTICS OF FRESH SUBCUTANEOUS FAT FROM ALENTEJANO PIG BREED

Neves, J.; Freitas, A; Eusébio, I.; Martins, J.M., Nunes, J.
Universidade de Évora, Dep. Zootecnia, Aptd. 94, 7002-554, Évora, Portugal. E-mail: jneves@evora.pt

Background

The Alentejano pig differs from the modern highly selected breeds regarding growth rate and body composition. Comparatively with others, this pig shows a slow rate of growth and a high lipogenesis activity at the early stages of development. The lipids are deposited mainly in subcutaneous, renal and pelvic regions. The percentages of fatty cuts can attain more than 50% of the carcass weight and the backfat thickness at the last rib level can grow to 60 mm at 120 kg live weight (LW) (Almeida et al., 1993; Neves et al., 2001). This kind of carcass is considered ideal for the manufacture of dry cured products, and was for decades the main source of meat in the diet of the people living in Alentejo region. Nowadays, the production fulfills a double function: it provides meat for the manufacture of cured products and for fresh consumption. The manufacture industry (cured hams, forelegs and sausages) requires pigs reared in traditional extensive systems, slaughtered at 140-160 kg BW and with 18-24 months of age (De Pedro and Olmo, 2000). The emerging market of the fresh meat requires animals with 90-100 kg LW, obtained at 10-12 months of age. The adipose tissue plays an important role on the characteristics of cured or cooked products and fresh meat. The animal growth implies chemical, biochemical and physical changes in the adipose tissue, mainly due to an increase on the lipids content. These changes affect the gross chemical composition or the fatty acid composition, which could determine its global quality (firmness or softness, color or oxidation sensibility) (Lebret and Mourot, 1998).

Objectives

The aim of this work was to investigate the evolution of the chemical composition of fatty tissues and its effect on chemical and physical traits.

Materials and methods

Thirty Alentejano pigs were weaned at 28 days and castrated at 60 days old. After weaning, they were transferred to open-air individual pens with a protecting roof and fed a commercial diet (15 % CP; 3100 kcal DE) at 85 % of *ad libitum*. This diet had 3 % crude fat, distributed by the following major fatty acids: C16:0 (17,7 %), C18:1 (28,9 %) and C18:2 (31,2 %). The animals were weekly weighted and after a 24 h fasting period, 5 pigs were initially slaughtered at 40 kg LW. The remaining animals were fasted and slaughtered (5 animals) at 70, 80, 90, 100 and 110 kg LW. After slaughter, the left side of each carcass was submitted to a 24 h chilling, followed by commercial cuts and sample collection of backfat at last rib level. Adipose subcutaneous backfat at the 12^{th}-13^{th} rib level and ham were also sampled. All the samples were vacuum packaged and stored (-20 ºC) until analysis. Analyses included moisture (Portuguese norm - 1614), total protein (Portuguese Norm - 1612) and lipids (calculated as 100 - [protein + water]). Color CIE L* a* b* (Minolta CR-200) and pH (Portuguese Norm - 3441) were also determined. Lipids for fatty acid determination were extracted at 50 ºC, and prepared to obtain the methyl esters to be analyzed by GC/FID. An ANOVA was carried out and the means comparison was made by SNK test. The correlations between the variables studied were determined by the Pearson coefficient. SPSS statistical software was used.

Results and discussion

Table 1 presents the results of gross chemical composition and some physical traits. The slaughter weight affected significantly the gross chemical composition and the subcutaneous color values. As the slaughter weight increased, the water and protein amount decreased and the lipids concentration increased, mainly between 40 and 70 kg LW. From 70 kg to 110 kg LW, we observed the same significant differences between the two slaughter groups, but the differences among the tree major chemical compounds were less pronounced. The evolution of the gross chemical composition was paralleled by the increase of backfat depth and the increase of this adipose depot on the Alentejano pig carcass. This evolution of the chemical

composition seems to agree with the three phases of development of the adipose tissue: hyperplasia between 7 and 20 kg, hyperplasia and hypertrophy between 20 and 70 kg, and finally an exclusive hypertrophy after 70 kg LW (Anderson and Kauffman, 1973). The higher increase between 40 and 70 kg LW could be explained by a predominant hypertrophy of the adipocytes, accompanied by a decrease of the amount in protein and water in the tissue, whether the amount of lipids increased (Camara *et al*., 1994).
Between 40 and 70 kg LW the backfat became less colored and mainly less red. The a* (red) value decreased (7,4 to 3,7), the b* (yellow) increased (1,39 to 4,2), the hue angle increased (from 10,45 º to 49,00 º) and the cromatocity decreased (7,6 to 5,6). These results could be explained by a dilution effect of the connective network and capillary infiltration, as a result of the lipids synthesis and deposition. The pH values showed large variations among the six groups studied, and no trend was identified. The results from the correlation matrix showed a high correlation between lipids and pH (0,88; P>0,05). As known, the lipids have a neutral pH, and an increase of their concentration implies an increase of the pH value. The deposition of lipids in adipose tissue (adipocytes) seemed to produce a great change in color backfat evidentiated by the high correlation between lipids and the chromatic coordinates a* and b* (-0,85 and 0,82; P>0,05); and in hue angle (0,94; P>0,05) and croma (-0,59).

Table 2 presents the results of fatty acid composition. The slaughter weight affected greatly the amount of the major fatty acids between 40 and 70 kg LW, showing a slight difference between 70 and 100 kg LW. At 40 kg LW, subcutaneous tissue presented less C16:0, C18:0 and total saturated, and C18:1 and total monounsaturated fatty acids, but more C18:2 and total polyunsaturated fatty acids. After 70 kg LW the slaughter weight affected the amount of C16:1, C18:1, C18:2, total monounsaturated and total polyunsaturated fatty acids. This heavier group registered a significantly great amount of C16:1, C18:1 and total monounsaturated fatty acids, and a lower content of C18:2 and total polyunsaturated fatty acids. However, quantitatively, the differences between the upper and the lower values were rather small. In general, the adiposity increase during the growth process induced a reduction of the unsaturation degree of the fat depots (Nürnberg, 1995). This could be explained by the greater participation of the metabolic pathway synthesis *de novo,* mainly saturated. In our experiment, we didn't observe a reduction in the unsaturation degree, but a change in the proportions of poly and monounsaturated fractions was detected (increase of monounsaturated and decrease of polyunsaturated fractions). Since the diet used in our trial had only a 3% crude fat, the increase of the saturated fatty acids through a *de novo* synthesis is suggested. In another study with Alentejano pigs slaughtered at 95 kg LW, Neves (1998) found less amounts of C16:0 (23,50%) and C18:1 (44,45%) and a greater amount of C18:2 (12,06%) than the ones obtained in this study. However, although the diet used had a similar fatty acid composition, it was richer in crude fat (6%) which could have stimulated the exogenous synthesis (Mourot *et al*., 1994) and a great deposition of C18:2.

Conclusions

- The Alentejano pig revealed a great adipogenic capacity at early developmental stages. Lipid concentration in subcutaneous fat showed a high increase between 40 and 70 kg LW and only a slight increase between 70 and 100 kg LW.

- The high adipogenic activity in the backfat at early development stages was accompanied by a large change in the fatty acid profile, with the increase of total saturated and monounsaturated fatty acids, and a decrease of total polyunsaturated fatty acids. After 70 kg LW, the differences found in fatty acid composition didn't seem to be important enough to change the global quality of the Alentejano pig subcutaneous fat.

- The evolution of gross chemical composition had a great effect on the backfat color attributes.

PHYSICAL CHARACTERISTICS OF THE LONGISSIMUS TRAIT MUSCLE OF THE ITALIAN AND POLISH HORSE MEAT

Nicastro F., Di Matteo S., Pagone A., Zezza L., Gallo R.

Department of Animal Production, Via G. Amendola, 165/A cap. 70126, University of Bari, Italy

Background

Of the commonest horse-breeding in Italy the Italian Trotter ranks the first (11.260) heads of cattle). It is used as a sports-horse followed by rustic breeds which are currently utilised in country's resorts or for meat production such as the "Avelignese" (9.782), the "Cavallo Agricolo Italiano da Tiro Pesante Rapido" (heavy-cart horse) (6.377), the "Maremmano" (3.540), the "Murgese" ("2.722), the "Bardigiano" (2.200), the 'Sanfratellano" (1.469) and the "Tolfetano" (1.377) (FAO, 2002).

The Italian horse-meat sector is one of the most important all over the world. In 2002 the Italian production accounted for 77.34% of the world wide one and 35.92% of the European one (Fao 2002). In 2002 horse-breeding in Italy counted 285.000, and such a number kept unchanged with respect to the previous year. Also the number of slaughtered animals (278,283) was the same as the previous year (Istat, 2001) (National Poll Institute).

In 2001, according to the last ISTAT information (data) processed by "Assocarni" little less than 300,000 horses were slaughtered in Italy, with an increase by 19,9 related to 2000 of these 69,3% in privately owned slaughter houses. In detail, 278,283 horses and 2,228 including asses, mules and hynnies. To this end it is noteworthy to mention that horse-slaughtering since 1999 at the time of the bovine BSE onset has a positive trend Martuzzi et al., 2002) with significant influence on import-export, and increase in quality of imported meat.

The average yearly per capita meat consumption in Italy is about 13 kg which is 1.6% of total meat quantity eaten in one year (82 kg per capita) (Istat, 2001). Italy, then, ranks the first in Europe for horse-meat consumption which in the other E.U. Countries accounts for 0.4 kg per capita (Martin-Rosset, 2001). Horse-meat consumption greatly varies within the national territory, most horse-slaughter in Italy occurs in Apulia (33.4%), Lombardy (13.7%), Piedmont (10.5%), Veneto (8.5 %) and Latium (5.8%) (Istat, 2001). Home production, despite the limited consumption, cannot meet the market demand, hence the need of importing heads of cattle and meat from abroad mainly Eastern Europe Countries (Martuzzi et al.,2001); for, in 2001 23,156 tons of horse meat were imported with an increase by 25.5% compared to 2000 (Fao, 2002).

Objectives

The aim of this research is to study some quality indicators of carcasses and of horse meat belonging to two different genetic type on the Italian market.

Materials and methods

Twelve female crossbred foals, seven TPR x Abruzzese genetic type and five TPR x Polish genetic type were slaughtered at the age between 24 and 26 months.

After slaughtering all carcasses were weighed and measured pH value. This last was taken from shoulder, leg and Longissimus dorsi (Ld) muscles by means of pH meter (Hanna Instruments HI 9023) equipped with an immersion glass electrode. Then, a sample of the Ld muscle from the 8th and 9th rib was taken to the lab and stored at 4°C. This sample was measured pH values at 24,48, 96 and 168 h, and of colour at 0.75, 48 and 196 h from slaughter. Colour was measured by Microscan XE colour meter through Hunter L* a* b* tridimensional system. Also hue (arctg b/a) and chroma or colour saturation values were measured (= (a2+b2)1/2). Shortly after slaughter samples were taken and put in plastic bags and immediately frozen at –80°C. All samples were defrosted at the same time to carry out the shear force tests before and after cooking and to evaluate cooking loss. For the shear force each meat sample was tested to the core 3 times before and after cooking, and their shear force value was determined by means of WBS test (Warner Blatzer Shear Force) through Instron 9000 texurometer.

In order to evaluate losses due to cooking, samples were weighed before and after cooking, in a convector oven at an inside temperature of the sample of 60° C over 30 minutes, measured by a diving (sinking) probe thermometer. Cooking loss was considered as a percent of the initial weight. The data analyzed for variance werw evaluated by using Student's 't' test (SAS, 1996).

Results and discussion

Table 1 shows post mortem pH values of Italian and Polish mares meat. pH measurements 45 minutes after slaughter were considerably higher in Polish mares for both the fore-quarter and rear one muscles ($P < 0.01$). The meat pH of the Italian mares is higher ($P< 0.05$) than the Polish mares one only 48 hours after slaughter.
Ld colour values measured at different post mortem times are shown in table 2. Shortly after slaughter meat colorimetric parameters of the Polish mare were remarkably different from those of the Italian mares. Conversely, at 48 hours both a* and b* values appeared higher in the foreign meat ($P<0.05$). Moreover, always at 48 hours, the Polish mares meat showed a lesser hue ($P <0.05$) and a higher saturation ($P <0.05$), appearing more intensely coloured. After one week storage (168 h) the situation is alike, since Polish mares showed higher redness index and chroma ($P <0.05$), thus indicating a more vivid colour. Investigations by Robelin et al (1984) on other breeds confirm our results related to the effect of sex and genotype on the horse meat colour.
The consistency of meats (table 3) belonging to the two genotype under investigation is nearly the same both for raw and cooked. Ld shear force data show that force needed for cutting raw meat of mares was similar. An instrumental force significantly ($P<0.05$) higher was necessary to cut cooked meat samples of polish mares. Literature reads that the genotype as well as other factors (Boccardi et al., 1979;Robelin et al, 1984; McCormick, 1999) affect meat tenderness relating to three classes of muscular proteins: the connective tissue, (collagen, elastin, reticulin, mucopolysaccharide of the basal substance) the myofibris (actin, myosin and tropomyosin) and the sarcoplasm (sarcoplasmic proteins, sarcoplasmic reticulum) (Lawrie 1983).
Shrink or drop in weight results following to cooking loss evidence a water retention capacity being nearly the same between the Italian and Polish mares. Final pH, obtained after post-mortem glicolysis, directly affects denaturation and proteolysis degree of sarcoplasmic proteins. These phenomena, in turn, influence meat tenderness, water retention capacity and colour (Lawrie, 1985). A high pH indicates a lesser proteic denaturation and a lesser proteolysis during ripening (Raduco-Thomas, 1989) and explain the major capacity of proteins in retaining water (Cook, 1926; Empey, 1933).

Conclusions

The results of this research leads to the following considerations :

- pH was not influenced by the genotype effect ;
- when slaughtered meats of the two genetic types under study showed a nearly similar colour. During storage lapse Polish mares meat intensified its colour more than the Italian mares one.
- The Italian and Polish meat tenderness was the same both cooked and raw. Similarly this behaviour was also noted for cooking loss.

EFFECTS OF *POST MORTEM* DEBONING TIME ON PHYSICAL, CHEMICAL, MORPHOLOGICAL AND ORGANOLEPTIC PROPERTIES OF CHICKEN BREAST MEAT DURING *POST MORTEM* AGING

Okumura, T.[1], Morimatsu, F.[1], Yamada, R.[1] and Nishimura, T.[2]

[1]R& D Center, Nippon Meat Packers, Inc., 3-3 Midorigahara Tsukuba 300-2646, Japan
[2] Graduate School of Biosphere Science, Hiroshima University, Kagamitama1-4-4 Higashi-hiroshima, 739-8528, Japan

Background

It is often said that chicken beast meat is not favourite for lack of its juiciness and tenderness in Japan, although chicken is most cheap in meat. The improvement of chicken beast meat qualities is now being required. It is well known that rigor mortis happens immediately after slaughter and the muscles in an animal become tough. It was reported that rigor mortis reached to the maximum at 2 hours after slaughter, which leads to make chicken muscle the toughest (Negishi and Yoshikawa, 1994). This phenomenon not only hardens meat but also reduces juiciness of meat, resulting in decline in meat quality even if meat is stored for *post mortem* aging at low temperature.
In Japan, the production of broiler meat is expanded. The deboning process in a factory in Japan is immediately conducted after slaughter in order to save time for production of broiler meat from a living body, because freshness of chicken meat is required from a market. In general, boiler breast meat in Japan is evaluated non-juiciness. This problem is caused by rigor mortis after slaughter. In order to prevent such a decline in meat quality, it is important to make influence of rigor mortis as small as possible. It is reported to pass a time zone of rigor mortis in the state on the bone as one of the methods of making influence of rigor mortis small (McKee *et al.*, 1997). However, it has not clarified how deboning time after slaughter influences rigor mortis and meat quality after *post mortem* aging.

Objectives

The objective of this work was to clarify the effects of *post mortem* deboning time on physical, chemical, morphological and organoleptic properties of chicken breast meat after *post mortem* aging in order to the improvement of juiciness and tenderness.

Materials and methods

Preparation of chicken breast: In analysis and sensory evaluation, chicken breast meat obtained from male broiler (White Rock×White Cornish) deboned at 1, 2, 4, 6 or 24 h (hours) *post mortem* was aseptically put into polyvinylidene chloride bags, vacuum-sealed, and stored at 0 ˚C for 4 days. In morphological observation, one obtained from female broiler deboned at 1, 8 or 16 h *post mortem*. Each sample deboned at 1 h *post mortem* was observed after aging until 8 or 16 h at 0 ˚C.

Sensory evaluation: Samples for sensory evaluation were skinned and grilled at 140˚C until internal temperature became 70 ˚C. Tenderness, juiciness and palatability were evaluated by well-trained panels using Kramer ranking tests (1963).

Cooling loss and cooking loss: Amounts of drips separated from samples after storing at 4 ˚C for 4 days were measured and the cooling loss was expressed with the rate of drip to sample weight. Their samples were skinned and vacuum-sealed. Amounts of drips separated from samples during heating at 70 ˚C for 70 minutes in a water bath were measured and the cooking loss was expressed with the rate of drip to sample weight before heating.

Shear force values: Pectoral muscles separated from chicken breast used for measurement of cooking loss were cut into 4×1×1 cm. Their shear force values were determined by Tensipresser™ (TTP-50BX, Taketomo) with a cylindrical plunger of 5.5 mm in diameter (Ozutsumi *et al.*, 1988).

Morphological observation: Pectoral muscles of chicken breast deboned at 1, 8 or 16 h *post mortem* were immediately fixed with 0.5 % paraformaldehyde in K-phosphate buffer (pH 7.3) by standard method. The samples for observation with optical microscope (DX-50, Olympus) were stained with hematoxylin and eosin. The pre-fixed samples were fixed with 2% osmium tetroxide and dehydrate by standard method. They were embedded in epoxi resin and the blocks were cut with ultracut ultramicrotome. Their sections were stained with uranyl acetate and lead citrate for observation with transmission electron microscope (1200EX, Joel). The distance between Z lines of each sample was measured as arbitrary average value of ten points.

Myofibrillar fragmentation index (MFI): Myofibrils prepared from chicken breast meat were suspended, observed at 1,000 magnification under a phase-contrast microscope, and photographed. MFI (%) was measured as the ratio of myofibrillar fragments composed of 1-4 sarcomeres.

Results and discussion

Sensory evaluation: Table 1 shows the sensory properties after post-deboning aging for 4 days at 0℃. Chicken breast deboned at 4 h *post mortem* was the most tender and juicy among those deboned at 1, 2, 4, 6 h *post mortem*. Chicken breast deboned at 6 h *post mortem* was more palatable than that deboned at 4 h *post mortem*. It was shown that chicken breast deboned at 4-6 h *post mortem* were the most tender, juicy and palatable those after post-deboning aging.

Cooling loss and cooking loss: Figure 1 shows cooling loss and cooking loss after post-deboning aging. Cooling loss of chicken breast deboned at 1 or 2 h *post mortem* was higher than those of ones deboned at 4, 6 and 24 h *post mortem*. On the other hand, the cooking loss of chicken breast deboned at 1 h *post mortem* was also lager than those of meats deboned at 4, 6 and 24 h *post mortem*.

Shear force values: Shear force value of chicken breast meat after post-deboning aging was shown in Figure 2. Shear force value of breast meat deboned at 1 h *post mortem* was lager than those of meats deboned at 2, 4, 6 and 24 h *post mortem*, and shear force value of breast meat deboned at 2 h *post mortem* was also lager than those of meats deboned at 6 and 24 h *post mortem*. These results were consistent with those of the sensory evaluation for juiciness and tenderness.

Morphological observation: Optical micrographs of pectoral muscle deboned at 1, 8 and 16 h *post mortem* were shown in Fig. 3. Some crooked portions were observed in the myofibrils of pectoral muscle deboned at 1 h *post mortem*, while they were not observed in breast muscle deboned at 8, 16 h. The observation by transmission electron microscope showed that the distance between Z lines in myofibrils of chicken pectoral muscle deboned at 8 or 16 h *post mortem* was longer than that of muscles deboned at 1 h *post mortem* (Table 2). It was suggested that the latter myofibrils were observed to be wounded partially, because the rigor mortis was accelerated after deboning.

Myofibrillar fragmentation index (MFI): Figure 4 shows MFI after post-deboning aging. The MFI of chicken breast meat deboned at 1 or 2 h *post mortem* was smaller than those of meat deboned at 4, 6 and 24 h. It was also shown that weakening of Z lines of chicken pectoral muscle deboned after 4 h *post mortem* was significantly increased, and its tenderization was also accelerated.

Conclusions

From these results of this work, it was concluded that deboning of chicken breast after 4 h *post mortem* improved meat qualities such as tenderness, juiciness, cooling loss, cooking loss and shear force value.

Background

Prediction of the sensory quality of beef from on-line carcass measurements would be of great value for the beef industry. During the last years different optical probes have been developed for the on-line evaluation of meat. Fluorescence and reflectance measurements have been used to detect connective and adipose tissue in beef (Swatland & Findlay, 1997; Swatland, 2000) and spectrophotometric measurements have been correlated with important attributes of meat quality, such as water-holding capacity or intramuscular fat (Swatland, 1995). The electrical impedance spectroscopy (EIS) has been applied with success as a predictor of the intramuscular fat content in beef and pork (Madsen et al., 1999; Marchello et al., 1999), and can be used to select green hams on the basis of the pH and fatness (Oliver et al., 2001) and even to predict sensory quality attributes of dry cured hams (Guerrero et al., 2004).

Objectives

The objective of this study was to evaluate an EIS (Electrical Impedance Spectroscopy) on-line probe, based on electrical impedance measurements, as predictor of the sensory quality of beef.

Materials and methods

This study was carried out on a set of 30 carcasses of yearling bulls (500 kg live weight) of two local breeds from northern Spain: Asturiana de los Valles (AV) and Asturiana de la Montaña (AM). These carcasses were selected from 5 different biological types derived from different combinations of breed (AV and AM), physiological state (bull and steer) and presence of muscular hypertrophy (*mh*/*mh*, *mh*/+, +/+), in order to obtain a sample set that included a wide range of carcass and meat traits.

At 24 h *post-mortem* carcasses were quartered between the 5th and 6th ribs and several measurements were performed on the *Longissimus* muscle of the left carcass: pH (pH24) was recorded on the loin of the 5th rib and electrical measurements were performed with an EIS on-line probe, supplied by the company NTE (Riu et al., 2001), inserted perpendicularly to muscle between the 4th and 5th lumbar vertebrae (*Longissimus lumborum*, LL) and between the 10th and 11th ribs (*Longissimus thoracis*, LT). The probe has two needles (length 50 mm) separated by 8 mm. Each needle is composed of 2 electrodes having the device a total of 4 electrodes. A temperature sensor was included in the probe to record the inner temperature of the sample. This device measures two parameters: R_∞ and R_0, that record the resistence at the higher (112 kHz) and the lower (5 kHz) frequencies, respectively, expressed in ohms (Ω). A third parameter, called K-value, is calculated, corresponding to the ratio R_∞ over R_0.

The loin comprised between the 6th and the 11th ribs was extracted and transported to the laboratory. The 6th rib joint was kept on a poliexpan tray covered with plastic permeable to O_2 at 4 ºC during 7 days, for subsequent determination of moisture (ISO 1442), intramuscular fat (IMF, ISO 1443) and water holding capacity measured as expressible juice of raw meat (EJ) according to a modification of the method of Grau and Hamm described by Sierra (1973). The rest of the loin was sliced, vacuum packed and kept at 4ºC for 7 days ageing, being later frozen at -18 ºC. The instrumental toughness (kg/cm^2) was evaluated on cooked meat in an Instron 1011 equipment with a Warner-Bratzler shearing device. Sensory analysis was performed by an eight member trained panel on steaks cooked to an internal temperature of 70º C. On a 100 mm scale, panellist assessed a profile composed of hardiness, juiciness and chewiness.

Analysis of variance was performed to study the effect of biological type on the physico-chemical, electrical and sensory traits. Differences between means were calculated with the LSD test. Multiple linear regressions were assessed between variables by the stepwise method. Principal component analysis was made to describe the relationships between meat quality and electrical parameters and discriminant analysis was applied to

study the ability of electrical measurements to classify the meat samples according to the water holding capacity (WHC), measured as expressible juice (EJ): high (H, EJ>21%) or low (L, EJ<21%). All the statistical analyses were performed using the SPSS programme 11.5.1 (2002).

Results and discussion

There was a significant effect of biological type on EJ ($p<0.001$) and IMF ($p<0.05$) of meat (Table 1). Meat of AV bulls with muscular hypertrophy (*mh*/*mh* or *mh*/+) showed higher juice losses and lower intramuscular fat than any other meat type, and there was a general tendency of EJ to increase as the intramuscular fat content of meat decreased.

Biological type affected also significantly to R_∞ ($p<0.05$) and K ($p<0.001$) when measured on the LT (10^{th}-11^{th} ribs). Values of R_0 were higher as the IMF of meat increased and K values decreased as the juice losses increased. There were not significant differences between meat types on toughness or hardiness, but there was a tendency of meat with lower fat content and higher juice losses (AV bulls) of showing lower juiciness and higher chewiness than meat of AV steers or AM bulls.

The principal component analysis (Fig. 1) showed that the electrical variable K (ratio R_∞:R_0) was positively related with juice losses (EJ) and moisture, as it is a parameter proportional to the ratio of extracellular water to total water in meat (Lozano et al. 1995). However, R_∞ and R_0 were positively related with the IMF content of meat, because the resistance of the muscle at high frequencies depends directly on the geometry of the conductive medium under measurement, hence it reflects the amount and/or size of fat cells. Furthermore, because fat is an insulator, the greater the fat content the higher the impedance reading. The first principal component explained 33% of the total variance and contrasted meat of high juice losses (EJ), high K value and high chewiness, hardiness and toughness with meat of high IMF content and juiciness.

Multiple regression analysis of electrical variables confirmed that R_0-LT and R_0-LL were negatively related with EJ and contributed significantly to predict this variable ($r= -0.66$, r.s.d.= 2.39, $p<0.001$). These results agree with those presented by Swatland (1982), Whitman et al. (1996) and Gobantes et al. (2000) who showed that low frequency electrical conductivity (R_0) is related to water holding capacity of meat. When including in the stepwise regression analysis physico-chemical and electrical variables, the best prediction of EJ was obtained from the IMF, R_0-LT and R_∞-LT, that explained 67% of the variance ($r=0.82$, r.s.d.= 1.82, $p<0.001$). This confirms that the intramuscular fat content of meat has a great influence on the water holding capacity, as described by Oliván et al. (2003), who compared meat quality of different breeds (AV and AM) and/or genotypes (*mh*/*mh*, *mh*/+, +/+) and found that the higher the intramuscular fat content the lower are juice losses of raw meat. Therefore, electrical variables that estimate the amount of fat cells in the tissue (R_0-LT and R_∞-LT) may be used as predictors of the expressible juice losses of meat.

The electrical variable that contributed significantly to predict the IMF content of meat was R_0-LL ($r= 0.39$, r.s.d.= 0.96, $p<0.05$). However, when including all quality traits in the stepwise regression analysis, none of the electrical variables was selected but moisture and juiciness were significantly related with IMF as they explained together 81% of the variance of data ($r=0.90$, r.s.d.= 0.46, $p<0.001$).

Discriminant analysis was used in order to test the ability of on-line measurements (pH and electrical variables) to classify meat samples according to the amount of expressible juice (EJ): high (EJ>21%) or low (EJ<21%) (Table 2). When using pH24 and the electrical variables measured on the LL (4^{th}-5^{th} lumbar vertebrae), 60.0% of samples were well classified. However, pH24 and electrical measurements performed on the LT (10^{th}-11^{th} ribs) allowed to classify 73.3% of the meat samples correctly in high (H) or low (L) juice losses. When the chemical composition of meat (moisture + IMF) was also included, the proportion of well classified samples increased to 90.0 %, being 100% in the group of high EJ (H). This is not the first time that electrical impedance measurements allow the classification of meat by quality traits. Guerrero et al. (2004) showed that EIS measures detected correctly 69% of green hams with problems of pastiness, due to its relationship with PSE meat.

Conclusions

The results of the present study indicate that the electrical measurements performed with the EIS on-line probe on the carcass of yearling bulls at 24 h *post-mortem* are useful predictors of the sensory and technological quality of meat at 7 days *post-mortem* and could be used for on-line beef quality grading.

Background

Pork quality refers to meat technological aspects such as colour, water-holding capacity, cooking losses or texture, as well as to sensorial properties. The genetic background of the pigs (Oliver et al., 1994; Gil et al., 2003) and the ante-mortem treatment constitute sources of variation in pork quality (Van der Wal, Engel & Hulsegge, 1997). Pale, soft and exudative meat (PSE meat) may appear as a result of both factors (Gispert et al., 2000) and affects the colour and quality of cooked ham. The pale colour of PSE meat is explained by the protein denaturation (Bendall & Wismer-Pedersen, 1962). PSE is a technological defect found on average in 6% of the hams in Spain, but this percentage can be higher depending on genetics and pre-slaughter treatment in the abattoir (Gispert et al., 2000). As a consequence, the hams become exudative and some muscles can be very pale or show bicolour with a decrease in the quality of the final product. Moreover, other factors such as the diet can influence meat colour as well. In this sense, Ramirez et al. (2002) found that supplementation with Fe in the pigs'diet s modified the lightness of the meat positively, producing a reddish pork meat. On the other hand, colour stability in cooked ham is affected by light and by oxigen content and probably by some components of the brine such as sodium ascorbate (Farkas et al., 1990).

Objectives

The aim of this study was to ascertain the effect on the colour and colour stability of the final product from exudative hams by the addition of porcine pigments to the brine used in the processing of cooked hams.

Materials and methods

Selection of the raw hams: Thirty-three hams were selected at 15 h *postmortem* (pm) in a local processing plant on the basis of pH and electrical conductivity (EC) in the *Semimembranosus* muscle (if pH< 5.6 or CE > 6 μS, PSE meat) in order to have three groups of 11 hams each: group 1 (control, with normal meat quality hams), group 2 (control, with exudative hams) and group 3 (APRORED -pork pigments- with exudative hams). The weight of the hams was 10,62 ± 0,74 kg.

Pork pigment: APRORED is a 100% water soluble food preparation based on pork pigments (stabilized hemoglobine) used as an ingredient in the meat processing industry (APC Europe).

Cooked hams process: The hams were weighed before and after muscles were boned-out. Subcutaneous and intermuscular fat, connective tissue, bone and rind were removed. Two hundred and ten grams of brine per kg of meat were injected into the pork legs. The brine - containing 0.35 % phosphate, 0.05 % ascorbate, 0.80 % dextrose, 0.05 % carragenate, 1.7 % NaCl, 0.01 % nitrite, and with 0.04 % of APRORED in the case of group 3 - was injected into the pork legs to increase their weight by 21 %. After injection, raw hams were placed in the vacuum tumbler and a vacuum was drawn to 200 mbar. The tumbling schedule was set for the hams to rotate a total of 2100 revolutions at 4 ºC (3 periods of 60-90 min of continuous tumbling). The hams were packed into aluminium moulds and then placed in an oven and cooked to an internal temperature of 65 ºC using a cabinet temperature of 70 ºC. The total cooking time was approximately 8 h.

Colour measurements: Colour measurements were carried out with a Minolta Chroma Meter CR-200 using the white tile provided by the manufacturer as the internal standard and set to illuminant C. Triplicate measures were taken on *Biceps femoris* (BF) and *Semimembranosus* (SM) muscles. The measurements were expressed as CIE L*a*b* (CIE, 1976). After this, a study of the stability of the colour was done on slices 15 mm thick on the SM and BF muscles of cooked hams. Measurements at time 0 were taken immediately after cutting the slices, and then at times 15, 30 and 120 minutes. The pigment content was determined in the fresh and cooked hams using the method of Hornsey (1956) based on the determination of total pigments by means of extraction with acetone as the principal solvent (Hornsey, 1956).

Sensorial evaluation of the ham colour: The red colour of cooked ham was assessed by two-experienced panellists according to a 10 point scale for red colour (1 =very pale; 10 = very dark).
Statistical analysis: Data were analysed using the General Linear Model procedure of the Statistical Analysis System (SAS., 1988).

Results and discussion

Table 1 shows the Least Squares Means and Standard Errors of the meat quality variables for the three groups of hams selected on the basis of pH and EC at 15 h p.m. in the SM muscle.
Meat quality: pHu was significantly lower in groups 2 and 3 than in group 1 (5.55, 5.54 and 5.67 respectively) as expected. With respect to EC, group 1 showed lower values (4.35) than groups 2 and 3 (15,81 and 13,84). Although significant differences were found between groups 2 and 3, they were considered not important from the meat quality point of view: both groups showed a very high mean value of EC indicating exudative meat (Oliver et al., 1991).
Colour: The variable related to colour (L*) measured in the SM of the fresh hams was significantly different in group 2 in relation to groups 1 and 3. No significant differences have been observed in L* value in the BF muscle although there was a tendency to have pale meat in group 2. With respect to pigment content (acid haematin) no significant differences in fresh or cooked hams were found. However, the cooked hams of group 2 presented lower concentration of acid haematin (28.97) than the other groups (34.06 and 33.19). This result could indicate a positive effect of APRORED in the colour of the final cooked ham obtained from exudative hams. This effect could also be observed in the visual assessment of the cooked hams: there was an increase in visual redness (VS) in both muscles in group 3 (Table 1), which in BF was statistically significant. The correlation between L* value and Visual assessment in SM and BF muscles was -0,60.
Colour stability: The L* value after slicing was higher in group 2 for both muscles at all times (Fig. 1), but the difference was not significant. The a* value was significantly higher for group 3 than for groups 1 and 2 at all times, due to the Aprored addition. Regarding b* value, no significant differences were found in SM and BF muscles at any time.

Conclusions

The study of the colour in cooked hams from normal and exudative meat indicated that the group of hams treated with APRORED had L*and a* values and visual redness assessment more similar to normal hams than to exudative hams, probably as a consequence of the effect of pigment addition on the colour of cooked ham. However, a second trial is in course to confirm these preliminary results.

Background

Handling of animals during transport, lairage and slaughter is one of the most important causes of stress in pigs and that, together with genotype, most influence the final carcass and meat quality. A supplementation of magnesium (Mg) in the diet of pigs may reduce the response of the animals to stressful stimuli by reducing the levels of cortisol and cathecolamines in plasma (Kietzman & Jablonski, 1985). An increase of tryptophan (Trp) concentration in the diet enhances the synthesis of brain serotonin and may have sedative effects (Leathwood, 1987). Some authors report an improvement of pork meat quality as a result of the supplementation of Mg (Schaefer et al., 1993; D'Souza et al., 1998, 1999, 2000; Apple et al., 2000; Hamilton et al., 2003; Swigert et al., 2004) or Trp (Adeola & Ball, 1992; Henry et al, 1996). However, other studies contradict these findings or obtain inconsistent results (Caine et al., 2000; O'Quinn et al., 2000; Apple et al., 2002; Hamilton et al., 2002). The effects of the supplement of Mg on meat quality seem to be related to the stress-susceptibility of the pigs, that is to their halothane genotype (Apple et al., 2000; Caine et al., 2000). On the other hand, Souza et al. (2000) found that under a negative antemortem handling treatment, a dietary Mg supplementation improves significantly pork quality and reduces the incidence of PSE carcasses. Accordingly, Geesink et al. (2004) report that a short-term supplementation of the diet with magnesium acetate or with a combination of this salt with Trp and vitamins does not improve pork quality when pigs are not stressed beyond levels associated with routine slaughter procedures.

Objectives

The aim of this study was to evaluate the effect of the supplementation of the diet with Mg and Trp on the response to stressful factors and on meat quality of pigs. Animals homozygous with respect to the halothane gene (positive, nn, and negative, NN) were used to achieve this objective.

Materials and methods

Animals, diets and pre-slaughter treatment: Seventy-one entire male pigs (36 NN and 35 nn) from Pietrain, Landrace and Large White lines, with an average live weight of 108.51± 8.32 kg, were used in this study. All animals were housed individually in pens with a space allowance of 4 m^2, permitting visual and olfactory contact between each other. They were fed the same diet until 5 days before slaughtering, when three diet groups were established for each genotype: diet 1 group, same diet supplemented with 1.2 g elemental magnesium (Mg) and 8 g L-tryptophan (Trp) per kg; diet 2 group, same diet supplemented with 8 g Trp per kg, and control group, with no supplement. Two batches of 35 and 36 animals were slaughtered in 2 different days. The animals of each batch were mixed in 6 different groups according to diet and genotype and transported from the farm to the experimental abbatoir for one hour on rougher secondary roads. Lairage time for the first pigs slaughtered was about 30 min and for the last ones was of 7 h. They were all stunned with 90 % CO_2 and slaughtered. In each batch, the animals from the 6 groups were slaughtered alternatively. Hot carcass weight was measured at 45 min. *postmortem* (pm), and used to calculate the killing-out (%).
Skin lesions: After sticking, and when the carcasses were hoisted on the bleeding rail, fresh scratches on the skin were inspected and subjectively scored according to their location (head/neck, flanks/back and hindquarter) and occurrence (0= No occurrence, 1=1 occurrence, 2=2 to 5 occurrence, and 3=more than 5).
Meat quality measurements: The left side of the carcass was used to perform meat quality measurements on the *Longissimus thoracis* (LT) and *Semimembranosus* (SM) muscles. Muscle pH at 45 min (pH45) and at 24 h (pHu) pm were measured using a portable pH meter equipped with a Xerolyt electrode. Electrical conductivity at 24 h pm (ECu) was measured at the last rib level using a Pork Quality Meater. The muscle water holding capacity (WHC) was determined in the LT muscle as drip losses following the reference method supported by OECD (Honikel, 1997).

Colour measurements: Colour measurements were carried out with a Minolta Chroma Meter CR-200 using the white tile provided by the manufacturer as the internal standard and set to illuminant C. Triplicate measurements were taken on LT muscle. The measurements were expressed as CIE L*a*b* (CIE, 1976).
Statistical analysis: The GLM procedure of SAS software (SAS, 1999) was used. Genotype and diet were considered as fixed effects (the interaction was not significant in any of the variables studied) and when the slaughter day effect was significant ($P<0.20$) it was included in the model as a blocking variable.

Results and discussion

Five animals died before being slaughtered (during transport or while unloading the lorry), all of them from halothane positive pigs (nn): three corresponded to the control and the other two to the diet 1 group (Mg + Trp). The sedative effect of the diet with Trp (diet 2) seemed to facilitate the coping of the animals to stressful factors, such as new environments. The presence and severity of skin lesions indicative of aggressive behaviour are presented in Table 1. Skin lesions in the head/neck, flanks/back and hindquarters were significantly higher in the group of animals fed diet 1 compared with the animals of the control group. This was in agreement with the results of Caine et al. (2000), who found a higher frequency of pre-transport aggression in pigs fed on a supplement of 40 mg Mg (in the magnesium aspartate hydrochloride form)/kg of live weight during the 7 days prior to slaughter, with respect to the controls. No differences were found in the occurrence of skin lesions between diet 1 and diet 2, except in the flanks. That increase in skin lesions of the animals of diet 1 and 2 would suggest an increase of activity due to fighting and a depletion of the glycogen resource before slaughter. That was reflected in the ultimate pH and other meat quality variables. Table 2 shows the effect of the diet on several meat quality variables: pH_u SM tended to be higher ($P=0.080$) in the animals fed diet 1 and diet 2 than in the control. The incidence of DFD carcasses (dark, firm and dry), established as $pH_uSM \geq 6.0$, was 12.5% in the diet 1 group and 16.7% in the diet 2 group, and 0% in the control. The ECuLT tended to be slightly lower ($P=0.088$) when animals were fed diet 2. The most important differences among groups were found for the L* (lightness) and the drip loss variables. L* values were lower ($P<0.05$), indicating darker muscle colour, in the LT of pigs fed the supplemented diets than in the LT of controls, whereas drip losses were lower ($P<0.05$) in the LT of animals fed with diets 1 and 2 than the control. Thus, the supplementation with Mg+Trp or with Trp improved the muscle colour and the WHC. These results are in accordance with the ones reported by Hamilton et al. (2002), with a supplement of 3.2 g Mg per day and 2 days of treatment, and by D'Souza et al. (1998) who studied the effect of a supplement of 3.2 g Mg per day using magnesium aspartate for 5 days. Hamilton et al. (2002, 2003) and Frederick et al. (2004) evaluate the effect of different times of feeding the Mg supplement prior to slaughter and report that the shortest time studied (1-2 days) may be effective in improving pork colour and muscle WHC. From the present preliminary results and in the conditions of this experiment, it would seem that the darker colour and the decrease in drip losses of the muscle were a consequence of the inclusion of a supplement of (Mg+Trp) and Trp in the diet.

Conclusions

The mixture of Mg and Trp increased the frequency of skin lesions due to fighting during transport and lairage. The aggressive behaviour due to mixing contribute to an increase in pH_u in the meat from the animals fed diet 1 and diet 2 and, as a consequence, some meat quality characteristics (colour and water holding capacity) improved. However, to ascertain if these supplements are adequate to be used in animal production in order to improve meat quality, other factors such as food intake and daily growth should be considered.

Background

It has been shown that intramuscular fat improves eating quality upon 15% in its extractable level (Thompson, 2001), and explains approximately 10-15% of variations in palatability (Dikeman, 1987). However, underlying mechanisms by which the fat improve palatability have been controversial. Miller et al. (1994) postulated that intramuscular fat acts as lubricant in chewing action, and reduces the relative number of muscle fibers within a certain amount of meat. On the other hand, Rymill et al. (1997) demonstrated that intramuscular fat indirectly improved eating quality through its effect on the prevention of over-cooking (e.g., burning), and raised a fundamental question whether the fat content is a direct cause of improved palatability in highly marbled meat. Similarly, Thompson (2001) believed that intramuscular fat increases consumer satisfaction by stimulating salivary gland, which consequently brings into being high juiciness in mouth feeling.

Our previous survey indicated that Korean consumer preferred highly marbled meat (Cho et al., 1999), and that was associated with more favorable palatability (Park et al., 2000). The latter study, using 229 Hanwoo *m. longissimus* with a large range of intramuscular fat content, demonstrated that meat containing high intramuscular fat received significantly higher sensory scores in tenderness, juiciness and flavor intensity. For the reason, Korean beef industry has made a long-term effort to improve the degree of marbling. On the other hand, highly marbled foreign product has been imported; while a total of imported beef took approximately 66% share in Korean beef market in 2003 (Korean Ministry of Agriculture and Forest, 2003).

Objectives

To evaluate objective and subjective meat quality traits for highly marbled imported beef *longissimus* muscle in comparison with Hanwoo beef.

Materials and methods

Sampling and treatment: A total of eight imported and seven Hanwoo *longissimus* muscles (visually from the 6th thoracic vertebrae to the last lumbar vertebrae) were purchased from HaNaRo Nong-Hyup Mart in Seoul. Breed, feeding regime and day of ageing were identified on the basis of labels on the whole cut box, as well as data from importing company. The imported products comprised four Wagyu (grain feeding for 450 days and aged for 31 days) and four Angus (grain feeding for 150 days and aged for 71 days). Seven Hanwoo samples were composed of four carcass quality grade (QG) 1 and three QG 3. As the domestic meat samples were collected following day of slaughter, the samples were aged at 1°C for 14 days.

Quality determination: WB-shear force was measured on cooked steaks (2.54 cm thick) in a pre-heated water bath for 60 min until the core temperature reached 70º and then cooled in running water (ca. 18ºC) for 30 min to reach a core temperature below 30ºC. Eight cores of 1.27-cm diameter were made for each sample, and peak force was determined using a V-shaped shear blade with a cross-head speed of 400 mm/min (Wheeler et al., 2000). Cooking loss was calculated as percent of weight changes during cooking for WB-shear force measurement. Non-trained eight panelists evaluated sensory characteristics of tenderness, juiciness and flavor intensity on a six-point scale. The panelists were asked to score from one (1) for extremely dislike to six for extremely like. Thin slice samples (ca. 4mm in thickness, and 50 x 70 mm in size) were cooked by placing on the tin plate (ca. 245-255°C) with turning at the first pooling of liquid on the surface of the strip, or at the start of shrinkage. The cooked strip was immediately served to each panelist for evaluation. Intramuscular fat content was determined by a microwave-solvent extraction method described by AOAC (2000). Fatty acid composition was determined by the Folch solvent extraction method (Folch et al., 1957), according to the method described by Chae et al. (2002). Least square means were estimated using

a general liner model (SAS, 1997), and difference in objective and subjective meat quality traits between the four groups of meat were evaluated by a pair-different test at 0.05 %.

Results and discussion

By definition, sensory characteristics of cooked meat is an overall mouth feel perceived by interactions between multi–parameters including deformation and breakdown during a consecutive action of chewing, and stimulation of salivary gland (Jowitt, 1974). This can be explained by the so-called 'hole effect', by which the sensory panelists tended to perceive higher juiciness and flavor intensity with tender meat and, *vice versa* (Shorthose and Harris, 1991). For the reason, the effect of individual sensory trait such as tenderness, juiciness and flavor on consumer acceptability cannot be considered separately. In other words, toughness of fiber component, intramuscular fat content and water-holding capacity simultaneously influence overall eating quality and consumer satisfaction.

Given the facts, the current result cannot be a direct indication of meat quality associated with either breed or origin of products because ageing time considerably varied from 14 to 71 days (Table 1), but that mirrors its quality *per se* on the market. The current analysis showed that the imported Wagyu after 450 days of grain feeding had a 22 % of intramuscular fat content in *longissimus* muscle (Table 1). Based on our unpublished data, that was a considerably higher percentage than that for average Hanwoo QG 1^{+}. On the other hand, the grain-fed Angus for 150 days had a significantly ($P<0.05$) lower intramuscular fat than Hanwoo QG 1, but greatly ($P<0.05$) higher than Hanwoo QG 3. This implies that the production strategy for highly marbled Hanwoo can be no longer sole solution for Korean beef industry. At the first glance, there was no difference in WB-shear force and sensory characteristics between Hanwoo QG 1 and 3, and between Wagyu and Angus. However, the imported products showed a significantly ($P<0.05$) lower WB-shear force than Hanwoo. This was likely attributed to the considerably longer ageing period, and was rather anticipatable. It is general consensus that difference in meat quality is largely equalized by approximately 14 days of chiller ageing (Hwang et al., 2003), and the changes take place at a relatively slower rate with extended ageing time (Lee and Lee, 1998). On the other hand, the instrument measurement was not reflected on sensory characteristics whereby sensory tenderness and juiciness did not differ between the domestic and foreign products.

Sole difference between Hanwoo and imported meats was observed in flavor intensity in that Hanwoo received significantly ($P<0.05$) desirable scores. It has been shown that chiller ageing at 1°C significantly increased 'off-odour' after approximately 35-60 days, depending on initial quality (Lee and Lee, 1998). However, it was unsure that the result was associated with differences in breed (Raes et al., 2003), feeding regime (Wood et al., 2003), ageing period (Lee and Lee, 1998), or interactions. Nevertheless, the result was an indication of superior eating quality of Hanwoo to the imported beef. An early study (Kim et al., 1999) showed that Hanwoo *longissimus* muscle was more acceptable than imported one when the Hanwoo meat contained significantly higher intramuscular fat. In addition to the study, the current result demonstrated that imported meat was less acceptable for Korean consumers, in spite of higher marbling than Hanwoo.

As Hanwoo QG 1 showed a significantly ($P<0.05$) less cooking loss than Hanwoo QG 3, more favorable sensory traits were somehow expected. However, difference was undetectable. Park et al. (2000) indicated that high intramuscular fat improved tenderness, juiciness and flavor when that was evaluated the following day after slaughter. The current result, on the other hand, indicated that the carcass quality grade had no detectable effect on sensory characteristics as well as objective texture measurement, when meats were aged for 14 days at 1°C.

Apart from nutritional aspect, composition of fatty acids is a decisive component in meat quality due largely to their variations in melting points and oxidation capacity which has significant effects on palatability and flavor development during cooking (Wood et al., 2003). Numerous studies (e.g., Raes et al., 2003; Laborde et al., 2001) have demonstrated that fatty acid composition affected sensory characteristics. Table 2 presents differences in the fatty acids between the meat quality groups, and their relations to tenderness, flavor and juiciness. Significant difference in individual fatty acid between the groups varied. The result was rather expected as fatty acid compositions were significantly affected by breed, carcass quality, and chiller ageing, and these were in a similar trend with previous studies (Laborde et al., 2001; Insausti et al., 2004; Wood et al., 2003). The current manuscript was not intended to discuss details about these effects on fatty acid composition. However, it was particular noticeable that the level of total n-3 PUFA was significantly ($P<0.05$) lower in Hanwoo QG 1, while C18:0 were significantly ($P<0.05$) lower in both the QGs 1 and 3 than these for the rest meats. Even though sensory tenderness and juiciness did not differ between imported

and Hanwoo beef, C20:4n-6 had a significant relationship with juiciness, while C18:1n-9, C20:3n-6 and C20:4n-6 were significantly ($P<0.05$) correlated with tenderness. In addition, flavor intensity was significantly correlated to C18:0 ($P<0.05$) and C19:1n-7 ($P<0.0$). The result indicated that fatty acids were associated with eating quality through their effects on various sensory characteristics.

Conclusions

Chilled beef with a high degree of marbling has been imported, and currently takes a large share in beef market. This was somehow perturbing to Korean beef industry because highly marbled Hanwoo meat has been considered as a sturdy characteristic versus imported beef. The current study demonstrated that Korean consumers found more favorable flavor intensity in Hanwoo beef in spite of lower marbling score and higher WB-shear force. However, it was unsure whether the result was related to difference in breed, feeding regime and/or ageing time. The result coincided with difference in fatty acids such as C18:0.

Background

In 1992, economic losses associated with low pork quality were estimated to be only 3% of the unrealized revenue lost from nonconformities in carcass quality. Today, low pork quality accounts for nearly 24% of the unrealized revenue lost from nonconformities in carcass quality, with most of those losses associated with pale, soft, and exudative (PSE) pork, and muscles containing low water-holding properties (Stetzer and McKeith, 2003). The 2003 estimate of PSE incidence was 15.5% (Stetzer and McKeith, 2003) compared to 10.2% reported for 1992 by Cannon *et al.* (1996).

It is often difficult to define the extent of PSE within a muscle; in many cases, muscles will exhibit varying degrees of PSE tissue. For example, the medial portion of a ham muscle may be entirely PSE, whereas the lateral portion of that same ham muscle may appear normal. The weight of hams increased 19% compared to 1992 (Stetzer and McKeith, 2003), making the aforementioned scenario more likely to occur because as the mass of a ham increases, it becomes more difficult to chill rapidly.

The ham processing industry uses a majority of the ham muscles produced by the packing sector, however, little research has been conducted to look at the production inefficiencies, such as decreased processing yields, increased rework, and decreased consumer demand from inferior products, that result from using raw materials that contain muscles with poor color and water-holding properties.

Objectives

The purpose of the study was to determine the impact of different quality raw materials on the processing characteristics of hams.

Materials and methods

Pork leg (fresh ham), insides (IMPS #402F; NAMP, 1997; USDA, 1997), containing both *M. semimembranosus* and *M. gracilis*, were characterized as having a low, intermediate or high incidence of pale, soft, and exudative (PSE) muscle tissue according to NPB (1999) guidelines and were sorted accordingly. Objective color measures (CIE L*-, a*-, and b*-values) and pH values were collected at the time of sorting using a Hunter MiniScan XE (HunterLab Associates, Inc., Reston, VA) and a handheld pH meter (pHStar, SFK Technologies, Inc, Cedar Rapids, IA). Objective measures of color and pH (n = 100 per group) were collected in two locations on the medial side of selected muscles. Groups also were characterized for the percentage of PSE in the muscle tissue by removing and collecting weights on PSE portions in 45 kg samples from each group. Muscles in the “Low PSE” group contained < 5% PSE tissue, whereas muscles in the “Intermediate PSE” group ranged between 20% to 30% PSE, and muscles from the “High PSE” group ranged between 40% to 60% PSE. Approximately 3,000 kg of raw materials were collected for each group and an additional 3,000 kg of commodity muscles were collected to serve as a control. All raw materials were shipped by refrigerated carrier to a commercial ham processing facility.

Upon arrival, raw materials were unloaded and purge was collected and weighed before it was reintroduced into the process. Muscles were injected with a curing solution, macerated, tumbled, formed, and cooked using normal procedures within the commercial processing facility to produce a 10.2 × 15.2 cm ham, water added product. After cooking, ham logs were chilled and stored for approximately 3 weeks before slicing. Ham logs were crust-frozen, sliced, and packaged in 454 g packages. Hams slices were evaluated for defects

after slicing, which were classified as normal rework (i.e., small tears, end pieces, or other minor imperfections) or PSE rework (i.e., severe product defects associated with low functionality muscle). Ham slices were evaluated for color uniformity during packaging. Slices containing nominal variations in color were classified as normal or no defect, those containing slight contrasts in color uniformity or small pale spots were classified as having minor defects, and those exhibiting substantial contrasts in color uniformity, large pale spots or small pockets were considered to have major defects. Packages (n = 100 per group) also were evaluated for objective color measures (CIE L*-, a*-, and b*-values) using a Hunter MiniScan XE (HunterLab Associates, Inc., Reston, VA).

Packaged, finished ham products from each group were selected randomly and shipped to Texas A&M University. Upon arrival, ham packages were placed in a 2°C cooler for storage. Packages of ham (n = 17 per group) were selected after 15-, 30-, 45-, 60- or 75-days of storage, objective color measures (CIE L*-, a*-, and b*-values) were collected as previously described, and the weight of purge was measured from each package. On day 45, ham slices also were evaluated for consumer sensory evaluations. Consumer evaluations were conducted at the sensory testing facility at Texas A&M University and participants were recruited from the faculty, students, and staff. Participants were asked to rate samples from each ham group for flavor intensity, overall like of flavor, visual appeal, and color. Participants were placed in individual panelist booths and given samples one at a time in random order. Ballots consisted of an 8-point scale for each trait evaluated (1 = extremely dislike; 8 = extremely like). In addition, purchase intent was determined by asking participants to select three packages of ham from an assortment of 12 packages. All groups of hams were represented equally and their arrangement was randomized. Packages that participants selected and the order that they selected packages was recorded.

Data were analyzed using SAS (SAS Institute, Cary, NC). Descriptive statistics and frequency distributions were generated using the PROC Means and PROC Freq procedures, respectively. Analysis of variance was performed using the PROC GLM procedure with product quality group tested as the main effect. When main effects were determined to be significant ($P < 0.05$), least squares means were generated and separated using a pairwise t-test (pdiff option).

Results and discussion

Sorting was effective in stratifying quality groups as the group containing the lowest amount of PSE had the highest mean pH value (6.14) and the group containing the most PSE muscle had the lowest mean pH value (5.62). Furthermore, pH differences between groups were incremental, with approximately 0.2 units separating each group. Kauffman *et al.* (1978) found that hams classified as “PSE” had a pH of 5.5, whereas “normal” hams had a pH of 5.9 and dark, firm, and dry hams had a pH of 6.3 (all as measured in *M. gluteus medius*).

Differences in objective color measures between raw material quality groups were as expected. The “Low PSE” group had the lowest L*-values and b*-values and the highest a*-values, whereas the “High PSE” group had the highest L*-values and b*-values and the lowest a*-values. Color and pH values for the control group were situated between the values recorded for the “Low PSE” group and the “Intermediate PSE” group. We estimated that the incidence of PSE was less than 5% and 20 to 30% in the “Low PSE” and “Intermediate PSE” groups, respectively. Because color and pH data indicate that raw materials in the control group fit between those groups, we expect that the control group contained 10 to 15% PSE muscle, which is similar to incidence rates reported by Stetzer and McKeith (2003), Cannon *et al.* (1995) and Kauffman *et al.* (1992).

Stratification of L*- and a*- values for boneless hams from different quality groups was identical to stratification of L*- and a*-values observed in raw materials. Hams manufactured from the control group had the lowest b*-values, which was unexpected because raw material data indicated that the “Low PSE” group had the lowest b*-values. This finding is probably not important because numerical differences in b*-values were extremely small.

Hams manufactured from the “Low PSE” group had the lowest purge loss, followed by hams from the control group. No difference in purge loss was observed between hams manufactured from the

"Intermediate PSE" group and the "High PSE" group. O'Neill *et al.* (2003) reported that drip loss in cooked hams manufactured from PSE pork was four times greater than hams manufactured from normal pork. Differences observed in this study were not as severe as those described by O'Neill *et al.* (2003), however, this may be because drip and purge loss were measured using different methods. The discrepancy in purge loss differences between hams manufactured from the different quality groups may partially be explained by the extent of purge loss in the raw materials before processing. Control and "Low PSE" raw materials possessed the ability to hold water more effectively as they had 0.7% and 0.6% purge loss, respectively, in storage before processing. In contrast, raw materials from the "Intermediate PSE" group had 1.0% purge loss and raw materials from the "High PSE" group had 2.6% purge loss indicating much lower water-holding capacity. This is not unexpected as Offer (1991) previously described lower water-holding capacities in muscle containing greater denaturation. After processing, it was not expected that hams manufactured from the "Intermediate PSE" and "High PSE" groups would have similar purge loss percentages. We expected the "High PSE" group would have the greatest purge loss because greater quantities of PSE muscle should have less functional protein and lower water-holding capacities.

Boneless hams were sliced, sorted into 454 g samples, and vacuum-packaged. Before packaging, ham groups were assessed for quality defects that would be considered "normal rework" (i.e., ends and pieces, small pockets, etc.) or "PSE-outs" (i.e., severe holes caused by a lack of functional protein). Boneless hams manufactured from the "Low PSE" group had the lowest incidence of quality defects and lowest total yield loss. Incidence rates for "PSE-outs" and total yield loss were three times greater in control product than were observed in hams manufactured from the "Low PSE" group. Incidence rates for "PSE-outs" in the "Intermediate PSE" and 'High PSE" groups were 5 to 6 times greater than those observed in the "Low PSE" group. Moreover, total yield losses observed in the "Intermediate PSE" and "High PSE" groups were four to five times greater than the yield losses observed in the "Low PSE" group. O'Neill et al (2003) reported the importance of water retention and cohesiveness in slicing. As greater percentages of PSE in the raw materials were incorporated into the ham formulations, water retention and cohesiveness would be reduced because of the incorporation of less functional protein. Surprisingly, incidence rates for "normal rework," and "PSE-outs," and thus total yield losses were greatest in hams manufactured from the "Intermediate PSE" group. We expected incremental increases in slicing defects as the percentage of PSE pork included in the hams increased; clearly this was not the case. Raw materials in the "Intermediate PSE" group may have been the most heterogeneous and therefore presented the greatest challenge of merging "functional protein" with "non-functional" protein (i.e., PSE muscle).

After packaging, finished hams (after "normal rework" and "PSE-outs" were sorted out) were assessed for minor and major appearance defects. Generally, percentage of defects increased incrementally with increasing levels of PSE product in the raw materials. Hams manufactured from the "Low-PSE" group had the highest percentage of packages with no defects and virtually no packages with major defects. In contrast, only half of all packages containing ham manufactured from the "High PSE" group had no defects, whereas 43.1% contained a minor defect.

Demographic data provided by consumers indicated that nearly 64% of participants were between the ages of 20 and 39 and approximately 45% were male and 55% were female. Consumers indicated no preference for "flavor" or "overall like" of ham from any of the quality groups. Consumers gave the lowest color ratings for ham manufactured from the "High PSE" group, but gave similar color ratings for hams manufactured from the other quality groups. Ratings for visual appeal were similar to ratings for color as consumers gave the lowest ratings for ham from the "High PSE" group, but did not differentiate ham manufactured from the other quality groups. Purchase intent for packages of ham manufactured from the different quality groups showed even greater consumer discrimination against hams manufactured from different quality groups than color or visual appeal responses. Overall selection showed that nearly 60% of consumer selections were packages of ham manufactured from the "Low PSE" quality group with 64% of consumers making one of those packages their first selection. Packages of ham manufactured from the "Intermediate PSE" quality group had the second most frequent selection, whereas packages of ham manufactured from the control group and the "High PSE" quality group were selected the least frequently. We expected selection frequencies for packages of ham from the control group and "Intermediate PSE" group to have similar selection responses, however, clearly this was not the case. It is unclear why consumers discriminated

against ham packages from the control group. Consumer data showed that color and visual appeal responses for ham from control, "Low PSE," and "High PSE" products were similar.

It is interesting to note that when consumers were asked to make independent ratings of hams, they gave responses that indicated very little difference in the color and visual properties of the hams manufactured from the various quality groups. Nonetheless, when consumers were in a situation that they could directly compare packages of ham (i.e., similar to a retail environment), there was distinct discrimination against hams manufactured with greater amounts of PSE in the raw materials. Whether or not consumers would be willing to spend more for hams manufactured with low quantities of PSE will require further research.

Conclusions

Sorting pork raw materials according to quality parameters impacts the processing yields and consumer appeal of products manufactured from those raw materials. For boneless ham manufacturing, processing yields and defects were minimized when muscles containing high levels of PSE tissue were eliminated. Further research is needed to determine the optimal ratio of allowable PSE product in formulation that enables processors to maximize consumer appeal with the economic realities of sorting out PSE pork.

BENCHMARKING VALUE IN THE PORK SUPPLY CHAIN: PROCESSING CHARACTERISTICS AND CONSUMER EVALUATIONS OF PORK BELLIES OF DIFFERENT THICKNESSES WHEN MANUFACTURED INTO BACON

Person, R.C.[1], Baird, B.E.[1], Mueller, S.L.[1], McKenna, D.R.[1], Griffin, D.B.[1], McKeith, F.K.[2], Scanga, J.A.[3], Belk, K.E.[3], and Savell, J.W.[1]

Background

Bacon consumption and use has seen extensive growth throughout the 1990's. This trend has had an important effect on the pork industry by increasing demand and value of fresh pork bellies. The 1992 Pork Chain Quality Audit (Cannon *et al.*, 1992) reported that 10% of bellies were too thin for bacon production and an additional 2% were too soft/oily to be used in bacon manufacturing. Quality defects identified by packers, such as belly thickness, often manifest substantial losses in profitability at the processor level due to reduced processing yields and a greater percentage of inferior products when sliced.

Improvements in swine genetics, nutrition, and management decisions have produced pork carcasses with 19% heavier hams and 21% heavier loins than carcasses from 10 years ago, whereas belly weights have remained constant (Stetzer and McKeith, 2003). Mandigo (2002) reported that bellies from current market swine contain approximately 29% less fat compared to bellies from swine 40 years ago. These changes have resulted in decreases in the thickness of bellies. This is a cause of concern because thicker bellies have been found to have higher processing yields than thinner bellies (Jabaay *et al.*, 1976). Nonetheless, West *et al.* (1973) and Jabaay *et al.* (1976) have shown that consumers prefer leaner bacon, which is often derived from thinner bellies that contain less fat.

Objectives

To understand the relationship between belly thickness, processing yields and consumer preferences so that bacon processors may develop raw material specifications that maintain processing efficiency without compromising customer satisfaction.

Materials and methods

Fresh pork bellies (IMPS #408; NAMP, 1997; USDA, 1997) were selected from 500 kg lots consisting of bellies ranging in weight from 5.4 to 7.3 kg at a commercial bacon manufacturing company. Bellies (n = 96 per group) were sorted subjectively into "thin" (approximately 2.0 cm), "average" (approximately 2.5 cm), and "thick" (approximately 3.0 cm) belly thickness classifications by three evaluators. Sorting procedures were validated by measuring the thickness of all bellies using digital calipers at three locations (blade end, center, and ham end) along the dorsal and ventral edges. Bellies were skinned, and skin weights were recorded to calculate skinning yield. After skinning, bellies were injected to 110% of raw weight with a curing solution specific for that commercial facility and chilled at 2°C for 24 hrs. Following storage, bellies were smoked, chilled, and pressed into uniform rectangles according to standard industry procedures. Weights were recorded during all phases of production and used to calculate processing yields.

Bellies were sliced into uniform strips (approximately 3 mm and weighing 28 g) using standard industry equipment. During slicing, bacon slices were classified according to their characteristics for secondary lean and slice thickness. The most valuable slices, "#1 slices," were those that met requirements for secondary lean characteristics (*M. cutaneous trunci* greater than 50% of the width of the slice) and appropriate slice profile thickness (no measurement less than 1.9 cm in profile thickness at any point). The less valuable slices, "#2 slices," were those that had insufficient secondary lean characteristics (*M. cutaneous trunci* less than 50% of the width of the slice) or inappropriate slice thickness (a measurement less than 1.9 cm in profile thickness at any point). Those slices not meeting "#1 slice" or "#2 slice" characteristics and slices

from the cranial or caudal ends of bellies were classified as "ends and pieces." Weights of each component were recorded and slicing yields were calculated. During slicing, approximately 500 g of bacon slices were collected from the center portion of every third belly (n = 32 per group). Bacon slices were vacuum-packaged and shipped to the University of Illinois for further testing.

Consumer evaluations of bacon were conducted at the University of Illinois. Bacon slices were placed on racks and cooked in convection ovens set at 232°C for 12 min. To ensure even cooking throughout slices, racks were rotated after 6 min. Bacon slices were removed from racks, blotted with paper towels to remove excess grease, and placed on paper plates as individual slices. Participants were recruited from residents of the Champaign-Urbana, Illinois area and asked to complete a basic demographic worksheet. Consumers (n = 120) were placed in individual sensory evaluation booths and asked to evaluate bacon slices, served in a random order, for flavor, fattiness, saltiness, crispiness, leanness, and pinkness. In addition, consumers were asked to evaluate the visual appearance of uncooked bacon slices. Bacon slices were laid out individually under cool white fluorescent light against a white background and placed in separate evaluation cubicles to prevent visual comparison between slices. Slices were selected randomly from packages representing each thickness group, and slices were replaced periodically throughout the evaluation timeframe. Also, purchase intent was recorded for both taste and appearance. Sensory and visual evaluations were scored on 5-point scales. For flavor, fattiness, saltiness, crispiness, leanness, and pinkness, scales were 1 = much too little, 2 = somewhat too little, 3 = just right; 4 = somewhat too much, 5 = much too much. For taste and visual appearance, scales were 1 = extremely unacceptable, 2 = moderately unacceptable, 3 = neither, 4 = moderately acceptable, 5 = extremely acceptable. For purchase intent for taste and appearance, scales were 1 = definitely, 2 = probably, 3 = might, 4 = probably not, 5 = definitely not.

Proximate composition was determined using raw, and cooked (n = 5 slices per group) bacon slices. Samples were ground and moisture content determined using AOAC (1995) approved methodology, and fat content of samples was determined by a chloroform-methanol method.

Data were analyzed using SAS (SAS Institute, Cary, NC). Descriptive statistics and frequency distributions were generated using the PROC Means and PROC Freq procedures, respectively. Frequency distributions for consumer sensory responses were tested for significance ($P < 0.05$) using chi-square analysis. Analysis of variance was performed using the PROC GLM procedure with belly thickness group tested as the main effect. When main effects were determined to be significant ($P < 0.05$), least squares means were generated and separated using a pairwise t-test (pdiff option).

Results and discussion

Objective measures of belly thickness were recorded to validate subjective selection procedures. Mean thickness between groups were different with approximately 4 mm separating "thin" from "average" bellies, and 5 mm separating "average" from "thick" bellies. "Thin" bellies had slightly higher skinning losses than "average" or "thick" bellies, but this is likely a function of green weight as the weight of skins collected from each thickness group was nearly identical. Likewise, bellies from the "thin" thickness group had the highest cooking shrink, which also was probably related to lighter belly weights because all bellies were subjected to the same smoking and cooking cycle. Brewer *et al.* (1995) reported a strong correlation (r = 0.70) between belly thickness and raw belly weight. Currently, most bacon processors purchase bellies by weight categories. This possibly accounts for a portion of the variation in belly thickness, but there still is substantial variation within weight ranges that may be best controlled by sorting bellies based upon thickness measures in lieu of or in concert with weight. By sorting bellies on thickness, processors may be able to regulate cooking shrink if all bellies in a cook cycle are of a similar thickness. Within the weight ranges included in this study (approximately 5 to 7 kg), which accounts for approximately 42% of available bellies (Stetzer and McKeith, 2003), we were able to find the variation in raw materials. "Thick" bellies had the highest final yield, which was approximately 2.3 percentage points higher than the yields for bellies from the "thin" and "average" groups. No differences in final yields were observed between bellies from the "thin" and "average" groups.

Bellies from the "thin" group had the lowest slicing yields as evidenced by the lowest percentage of #1 slices (i.e., more valuable product), and the highest percentage of #2 slices (i.e., less valuable product), and "ends

and pieces." Thickness groups had an equal percentage of slices classified as #2 product because of inadequate secondary lean (7.2% for "thin," 7.5% for "average," and 7.1% for "thick"). This is not surprising because we would expect the *M. cutaneous trunci* to remain relatively proportional to the width of the belly. Thus, "thin" bellies had a higher yield of #2 slices because those slices were too thin in profile to be classified as #1 slices (1.5% for "thin," 0.3% for "average," and 0.2% for "thick").

Demographic information provided by consumers showed that 80% of participants were 24 years old or older, 43% had an income of $35,000 or higher, and 60% were female. Consumer evaluations of bacon flavor showed that consumers gave similar responses for "thin" and "average" thickness bellies, whereas respondents indicated that slices of bacon from "thick" bellies lacked bacon flavor. Nearly 60% of consumers indicated that the saltiness of bacon slices from "thick" bellies was appropriate, whereas 38% and 43% of consumers indicated that slices of bacon from "thin" and "average" thickness bellies were too salty. Belly thickness may have an effect on flavor attributes with thicker bellies diluting flavors more than "average" or "thin" bellies. In contrast, Brewer *et al.* (1995) found no differences in bacon flavor or saltiness as belly thickness increased. A consumer panel was used in this study, whereas a trained sensory panel was used by Brewer *et al.* (1995). This may explain why a discrepancy in findings exists. Generally, consumers gave similar responses for fattiness evaluations for each thickness group, which may be expected because bacon is approximately 50% fat.

"Thin" bellies had a greater frequency of responses indicating less crispiness compared to bacon slices from "average" and "thick" bellies. It appears bacon from "thin" bellies may require greater cooking times to achieve the crispiness level consumers desire. Compositional data showed that bacon slices from "thin" bellies contained approximately 7% higher moisture than bacon slices from "average" or "thick" bellies, which may have provided extended evaporative cooling during cooking, and prevented slices from becoming as crispy as slices from "average " and "thick" bellies. This could have ramifications on precooked bacon slices because processors may need to adjust cooking parameters for slices from "thin" bellies to meet the crispiness expectations of consumers.

Generally, responses for overall taste were similar for all belly thickness groups. "Thin" and "thick" bellies had a slightly greater frequency of responses indicating unacceptable taste than slices from "average" bellies. This may be related to fatty acid composition of "thin" bellies, which are usually softer and/or oilier, may have a higher percentage of unsaturated fatty acids, whereas "thick" bellies, which are usually firmer, may contain a greater percentage of saturated fatty acids. In agreement with overall taste data, consumers showed slightly increased likelihood of purchasing bacon from "average" thickness bellies based on taste compared to "thin" or "thick" bellies, with 65.6% of consumers indicating they would "definitely" or "probably" purchase bacon from "average" thickness bellies compared to 50.5% and 48.3% for bacon slices from "thin" or "thick" bellies, respectively. Likewise, greater than 25% of consumers indicated they would be unlikely (i.e., "probably not" or "definitely not") to purchase bacon manufactured from "thin" or "thick" bellies, respectively, because of taste compared to 17.3% for "average" bellies.

Most consumers (73.7%) gave responses indicating that the lean to fat ratio for bacon slices from "thick" bellies was too low (i.e., too much fat in relationship to the amount of lean), whereas greater than 50% of participants indicated that the lean to fat ratio in bacon slices from "thin" and "average" bellies was "just right". Similarly, Brewer *et al.* (1995) observed that as belly thickness increased, sensory assessments of lean-to-fat ratio decreased.

Approximately 70% of consumers indicated that the pinkness of lean in bacon slices from "thin" and "average" bellies was "just right," whereas 56.6% of consumers indicated that the pinkness of bacon slices from "thick" bellies was less than ideal (i.e., "much too little" and "somewhat too little"). It is unclear if the fatness of bacon slices from "thick" bellies "diluted" the pinkness of color in those slices or if it is more difficult to distribute a curing solution in those bellies, resulting in less pinkness.

Consumer responses for visual acceptability indicated that raw bacon slices from "average" (72.4%) and "thin" (78.7%) bellies were acceptable (i.e., "moderately acceptable" or "extremely acceptable"). In contrast, a majority of consumers (56.3%) found slices of bacon from "thick" bellies visually unacceptable. Purchase intent based on visual appearance closely mimicked consumer responses for visual appearance.

For bacon slices from "thin" and "average" bellies, 62.3% and 59.4%, respectively, of consumers indicated that they were likely to purchase those products. In contrast, 62.4% of consumers indicated that they were unlikely to purchase bacon manufactured from "thick" bellies. Our findings agree with the results of Jabaay *et al.* (1976) and West *et al.* (1973) who reported that consumers preferred the appearance of leaner bacon.

Compositional differences were observed in bacon slices from different thickness groups. Raw bacon manufactured from "thin" bellies had the highest moisture content (47.9%) and less fat (36.2%) than raw bacon from "average" (40.5% moisture; 46.4% fat) and "thick" (40.4% moisture; 46.3% fat) bellies. Brewer et al. (1995) reported that as bellies became thicker, moisture content decreased and fat content increased. Compositional differences between thickness groups were similar for cooked bacon. Cooked bacon from "thin" bellies contained less fat (34.7%) than cooked bacon from "average" (42.5%) and "thick" (43.5%) bellies. It is surprising that the composition of bacon from "average" and "thick" bellies was so similar because consumers identified bacon from "thick" bellies as having the lowest lean-to-fat ratio and discriminated against it because of its excessive fatness.

Conclusions

Belly thickness influenced the processing yields and consumer reactions to the acceptability of bacon. "Thick" bellies offer processors the greatest processing yields, however, it is likely that consumers will discriminate against the resulting products because of excessive fatness. Consumers viewed bacon from "average" and "thin" bellies very favorably, however, working with "thin" bellies may reduce industry profitability because of lower processing yields. Swine producers and geneticists should focus on producing swine with bellies of "average" thickness.

EFFECT OF VACUUM PACKAGE STORAGE ON PORK PURGE AND COLOR

Sebbana, S.[1], Pommier, S.A.[1], Murray, A.C.[2], Gibson, L.[2], Sosnicki, A.[1] and Klont, R.[1]

[1] PIC North America a Sygen Company, Franklin, KY, USA
[2] Agriculture and Agri-Food Canada, Lacombe, AB, Canada

Background

Vacuum packaging is used to extend the shelf life of fresh pork and is known to preserve the microbiological integrity of the product for up to 12 weeks (Jeremiah et al, 1995). Purge is a consequence of chilled storage and is seen as a defect when the Japanese customer opens the vacuum package. Factors such as pre-slaughter management, stunning procedures, chilling rates and holding temperatures will affect drip and color. Genetics play an important role in this regard and this data set will investigate the effect that breed has on the meat quality of vacuum packaged loins.

Objectives

The objective of this study was to investigate the effect of background genetics on meat quality of vacuum packaged loins as assessed by measuring purge and color of the meat.

Materials and methods

Pig breeds used in this trial originated from the PIC genetic nucleus in Kipling Saskatchewan, Canada and included the following basic genotypes: Landrace (Land), Large White (LW), Duroc, White Duroc (Wdur), Berkshire (Berk), Hampshire (Hamp), Synthetic line (Syn), Berkshire x Hampshire Cross (BH), hal-negative Pietrain ($Piet^-$), hal-positive Pietrain ($Piet^+$). A section of the longissimus muscle from the right side between the 5th and 10th ribs was cut into four equal size portions and vacuum packaged. Packages were then randomly allocated to one of four storage intervals (0, 4, 6 and 8 weeks) and stored at 2ºC (± 0.5ºC) for the designated storage interval. Following storage, the packages were weighed and opened. The meat samples were removed, blotted dry and weighed. The packages were air dried and weighed. Purge was calculated by difference. Samples were then placed on Styrofoam trays, over-wrapped with an oxygen permeable film (Vitafilm Choice Wrap), and allowed to bloom for 1 hour prior to being evaluated by a 5-member trained and experienced sensory panel for muscle color (5 point descriptive scale), surface discoloration (7 point descriptive scale), and retail appearance (7 point hedonic scale). The packages were then opened and the samples were evaluated for off-odors (5 point descriptive scale) and odor desirability (5 point hedonic scale) (Jeremiah and Gibson 1995). CIE L*, a* and b* were measured in triplicate on each muscle section at each storage interval using a Minolta CR-300 reflectance meter (illuminant - C, observer angle - 2º). Statistical analysis was performed using the GLM procedure of SAS (2001).

Results and discussion

Percent purge loss measurements by genotype over storage time are presented in Figure 1. In general, there is known to be a positive relationship between percent purge and the length of storage (Apple et al. 2001; Apple et al. 2002; Kim et al. 1998,). Statistically there is a significant interaction between genotype and week in storage. Overall, the Berk shows the lowest level of purge while the $Piet^+$ has the highest percent purge values. The high percent of purge of the $Piet^+$ was expected due the presence of the halothane gene (Apple et al., 2002). The low purge level of the Berk is expected since it usually displays low rates of muscle lactic acid production that would result in a minimum amount of protein denaturation and better WHC (NPPC, 1995). In terms of time dependent effects on purge, the Dur, Syn and BH are the only lines that show a significant increase between week 4 and week 6. All the other genotypes show no significant increase in purge after after week 4. This observation indicates that accumulated purge has reached a maximum at week 4 and that in order to measure rates of accumulation in packages, purge may well be better evaluated within the first 4 weeks of packaging.

L* measurements are presented in Figure 2. In general, as the storage time increases the meat tends to have a paler appearance. This trend is generally and clearly displayed in the results where, at packaging time (Time

0), L values for all genotypes were below 50, and then rose sharply to above 51 by Week 4 ($P<0.05$). The magnitude of increase after 4 weeks in storage was then minor for all genotypes. Overall, Piet$^+$ was the palest and Syn along with Land and LW were on the other end of the spectrum, showing the darkest loins. In general, these evaluations confirm the trend towards lighter meat color for all genotypes (Apple et al. 2001; Apple et al. 2002). Along with this increase in L* (paleness), both a* and b* increased with storage time for all genotypes (results not shown). The increases in a* and b* translate to increases in chroma and hue angle, which implies an increase in color intensity and a shift toward the yellow but within the red part of the spectrum.

The changes in purge and color during vacuum packaged storage for up to 8 weeks were accompanied by changes in a number of sensory traits (results not shown). Discoloration increased by up to 10% and retail acceptability decrease from "desirable" to "neither desirable nor undesirable". Piet+ and piet- lines were poorer at all storage times and approached "undesirable" at 8 weeks. By 8 weeks storage all genotypes had a moderate off odor which resulted in a decrease in odor acceptability (from "acceptable" to "slightly unacceptable").

A detailed characterization of the quality (pH, drip loss, etc) of the longissimus muscles of these genotypic lines can be found in the paper of Pommier et al. (2004).

Conclusions

Genotype had a large effect on both the amount of purge in the vacuum package and on the meat color. The effects of length of storage in vacuum packages on percent pork purge loss and color are consistent with basic literature (Kim et al, 1998). In addition, the results indicate that majority of purge in the package accumulates during the first 4 weeks post packaging. Increasing storage time increased the amount of muscle discoloration, paleness, chroma, hue angle and prevalence of off odors, and after 8 weeks of storage, muscle samples decreased in retail desirability and odor acceptability as observed previously (Jeremiah et al, 1992). Any attempt to determine differences between genotypes in the rate of fluid accumulation should focus on the initial 4-week period because in most cases maximum purge is attained at that time.

REARING OF PARTLY OUTDOOR PIGS IN ESTONIA AND THE QUALITY OF THE PORK

Rei, M.[1], Tammik, M.[1], Vilks,V.[2], Raudsepp, A.[2]

[1]Estonian Agricultural University, Dept. of Food Science, Sector of Meat Technology, Kreutzwaldi 58, Tartu 51014 - Estonia

[2] Linnamäe Peekon Ltd Pig Farm, Oru vald 91001 - Estonia

Background

Meat quality depends on many factors – rearing, feeding, pre-slaughter handling, transportation, slaughtering, stress etc. Meat quality defects such as PSE-meat can be caused by poor transport and unsuitable pre-slaughter conditions.

This paper discusses studies made to investigate two different feeding and rearing systems and the pork quality in different stress conditions (low stress and high stress). Research is completed as part of the 5th Framework project "Susporkqual" and financed through EC contract No QLK 5-CT-2000-00162. Countries involved in the research were: Denmark, Poland, France, Sweden, Ireland, England and Estonia.

Objectives

The aim of the project for Partner 9 and 9A (Estonia) was to study: a) the interactive effects of genotype and rearing methods on stress reactivity at slaughter and on meat quality choosing country specific breeds and rearing methods, b) the effect of rearing methods on reactivity to transport; c) to find out if it is possible to produce pork more effectively by using partly out-door rearing and different feeds.

Materials and methods

The main difference between pigsties was, that the conventional pigsty had only an inside area (15,22 m²), whilst the partly outdoor pigsty had two areas: an inside area and an outside area. Compared to conventional pigsty (0,7m² per animal) stocking density was higher in partly outdoor pigsty (1,1 m² per animal).

Piglets were from sows of Estonian Landrace breed and boars from crossbreed Landrace and Large White. All piglets were female. We selected stress-negative sows and boars on the bases of a DNA – test. Two different compositions of feed were used for indoor and outdoor pigs: a) import with soya (diet a); b) domestic (diet b) with pea + rape corn. Diets a1, b2 were given to pigs with a live weight of 30 to 60 kg and diets a3, b4 to pigs with a live weight of 60 to slaughtering. The diets were based on the general principles of pigs feed content in Estonia /5/.

Live weights (~ 30, 60 kg and pre - slaughter) of pigs, feed conversation rate (FCR) and weight gain were determined during rearing period.

Slaughtering of 80 pigs was proceeded in two different conditions: half of the pigs (n = 40) were slaughtered in Linnamäe Peekon (LP) at low transportation stress conditions (distance from farm to slaughterhouse ~ 500 m) and the other half (n = 40) in Saaremaa Meat Plant (SMP) after having left behind a distance of 200 km by lorry and ferry – high transportation stress conditions. So we had eight different groups in slaughtering: e.g. pigs from pen 1 (n = 20) were divided into two: 10 pigs were slaughtered in LP and another 10 – in SMP (Scheme).

Methods

I. Carcass weight. Two measurements of carcass weight were made: 1.warm carcass weight; 2. cold carcass weight:

II. Back fat measurements. Linear measurements of the back fat thickness were made the day after slaughter (24 hours) at four locations.

- One measurement was made on the shoulder area (at the cut between the third and forth vertebra in sternum) over the middle of M. trapeziu.s (backfat 1).
- One measurement was made on the loin area (at the cut behind the last rib) over the middle of M. Longissimus dorsi(LD).(backfat 2)

- Two measurements were made on the ham cut: one measuring over the middle of M. gluteus medius (backfat 3) and one measuring over the two fat layers at the thickest point at the cartilage of the hip bone. (backfat 4).

III. pH. All the pH-measurements were made in LD at the last rib with a combined electrode. The electrode was calibrated at 35 °C for the measurements in hot carcass (pH45 min) and at low temperatures for measurements in cold carcass (pH24h with ARGUS X /Sentron pH – meter.
IV. Temperature. All the temperature measurements were made with ARGUS X/Sentron pH – meter. In LD at the last rib: measurement 45 minutes after sticking – temp 45 min and 20 – 24 hours after slaughtering temp 24h.
IV. Chemical composition of meat. Chemical composition of meat: protein, fat, ash and moisture content were determinated in the 4 cm sample from LD at the last rib towards the ham. Intercalibrated methods were used. Analyses was made in the Tartu Department of the Estonian Food and Veterinary Laboratory.
V. Lean meat content in SMP was determined with Ultra – FOM 100 and in Linnamäe Peekon by the ZP – method.

Results and discussion

Compared to conventional rearing partly outdoor rearing resulted in 19,45% bigger average feed intake; 9,9 % higher FCR; faster growth, described by the growth rate, higher dressing % and faster alacrity of pre slaughter live weight. All back fat measurements (except nr 4, conventional) were higher in partly outdoor reared pigs (Table 1).
The present work involves studies made to investigate how pork quality is conditioned by different stress conditions (low stress and high stress) in connection with two different feeding and rearing systems. To avoid the appearing of PSE-meat during the journey from farm to slaughterhouse, the transportation distance should be as short as possible. Great attention has to be paid to the transportation vehicle and pre-slaughter handling. During transportation the quality of the vehicle, ventilation, stocking densities and the travel distance are important factors influencing the stress-level of the pigs /1,3,4,/. Poor on farm handling increases the susceptibility to pre-slaughter stress /2/.
The carcass quality is affected by several factors, of which pre-slaughter handling in general seems to be one of the most important. Carcass quality (especially skin damages) depends on the type of rearing. The skin of partly outdoor pigs was damaged by mosquitos. Transport and pre-slaughter handling also affected carcass quality. The pigs slaughtered in Linnamäe Peekon had less skin damage. The pigs` intravitalis activity did not affect carcass quality (except mosquito'-bites). When comparing the skin damage by slaughter condition, it becomes obvious that the middle part of the carcass was less damaged in LP, but the front part and the fore shank were less damaged in SMP. Carcasses had less scratches and bone fractures in LP. The technological process in small slaughterhouses brings about a lower amount of defects. Big slaughterhouses like Saaremaa MP have a high mechanization level. In such slaughterhouses the carcass quality depends greatly on the machinery. Experimental results indicate better carcass quality of pigs slaughtered in LP.

Conclusions

In partly out-door conditions the pigs grow faster and the amount of used feed per pig and per kg of pork is higher.
Dressing % is higher in pigs produced in partly out-door conditions and is also depending on slaughter conditions. Higher dressing % was indicated in pigs slaughtered in Linnamäe Peekon (low stress, no long transportation).
The results of the research show that transport was the most stressful procedure for pigs.
It is important to load the pigs (especially the outdoor ones) very slowly and calmly.
Rearing, feed and place of slaughter had a significant influence on the carcass temperature.
Rearing methods had great influence on the back fat thickness.
Rearing animal welfare aspects, pigs and pork characteristics, partly out-door rearing is recommended in some piggeries in Estonia.

EFFECT OF FREE AND RUMINALLY-PROTECTED FISH OILS ON FATTY ACID COMPOSITION, SENSORY AND OXIDATIVE CHARACTERISTICS OF BEEF LOIN MUSCLE

Richardson, R.I.[1], Hallett, K.G.[1], Ball, R.[1], Robinson, A.M.[1], Nute, G.R.[1], Enser, M.[1], Wood, J.D.[1] and Scollan, N.D.[2]

Background

It is recommended that the concentrations of long chain polyunsaturated fatty acids (PUFA) such as eicosapentaenoic acid (C20:5*n-3*, EPA) and docosahexaenoic acid (C22:6*n-3*, DHA), for which oily fish are an excellent source, should be increased in the human diet (Simopoulos, 1998). Rumen biohydrogenation in cattle limits the amount of long chain PUFA which can be transferred into ruminant muscle, but this process also results in the production of *trans*-C18:1 and conjugated linoleic acid (CLA; particularly the trans-10, cis-12 CLA) intermediates in the rumen. It is recognised that the main sources of CLA, which may confer a health advantage to humans, are meat and milk from ruminants (Chin et al., 1992). The amount of CLA in muscles of animals given increased amounts of unprotected n-3 fatty acids was increased two- to three-fold whilst *trans*-C18:1 increased four- to seven-fold (Enser et al., 1999) with free fish oil being more effective at inhibiting rumen reductases than linseed oil.

We have previously demonstrated that feeding concentrates containing free fish oil, in comparison to megalac (a saturated fat source), increased the content of long chain n-3 PUFA in beef muscle and lowered the n-6:n-3 ratio (Scollan et al., 2001). However, the P:S ratio was unchanged, reflecting the high degree of ruminal biohydrogenation. This might be overcome by protecting the fish oils against ruminal biohydrogenation, yet some free fish oil should be available in order to encourage CLA production. The increase in long chain PUFA in beef meat had significant negative effects on colour shelf life and organoleptic properties in previous work (Vatansever et al., 2000), hence it is important to feed supra-nutritional concentrations of the antioxidant, Vitamin E, and to monitor lipid and colour oxidation and sensory aspects of the meat produced.

It is hypothesised that the use of protected fish oil, in conjunction with some unprotected fish oil, in the diet of ruminants represents a useful method for simultaneously targeting the three major objectives of producing healthy beef meat, which are (1) increase the P:S ratio, (2) reduce the n-6:n-3 ratio and (3) increase CLA content.

Objectives

The current study was designed to manipulate the long chain PUFA and CLA content of beef fat and muscle by feeding free and ruminally-protected fish oil. The effect of the level of feeding of the protected fish oil on beef muscle fatty acid composition and its effects upon sensory characteristics and colour and lipid oxidative stability during simulated retail display were also determined.

Materials and Methods

Thirty two Charolais steers with an initial mean liveweight of 619kg (s.e 7.9) were allocated on age and live weight to one of four dietary treatments, each consisting of eight animals. The 4 diets consisted of *ad libitum* grass silage plus one of four concentrates in which the lipid source was either Megalac (high in saturated palmitic acid; 16:0 from palm oil) and 100g free fish oil (FFO; rich in EPA and DHA) or megalac/FFO supplemented with a ruminally protected fish oil supplement (PFO) which was fed separately. Diet 1 megalac/FFO (control); Diet 2, megalac/FFO and 50g/d PFO (PFO1), Diet 3 megalac/FFO and 100g/d PFO (PFO2) and Diet 4 megalac/FFO and 200g/d PFO(PFO3). The PFO supplement comprised soyabean and fish oil (tuna rich in DHA), and was prepared and protected from ruminal biohydrogenation by encapsulating the lipids in a matrix of rumen inert protein (Scott et al., 1971). The PFO was considered as part of the

overall concentrate allocation per day in maintaining an overall forage:concentrate ratio of 60:40 on a DM basis. The diets were formulated so that the total dietary oil intake was approximately 5.5% (45% of which was the test oil) of total diet. Vitamin E was added to the concentrates at a level of 350IU/kg.
Animals were slaughtered conventionally and carcasses chilled overnight. At 48h post-mortem, samples of m. *longissimus thoracis* at the 11th rib were removed and blast frozen and stored at –80ºC for subsequent fatty acid analysis. Lipid was extracted using chloroform/methanol and the neutral and polar lipids separated by silicic acid column chromatography. Fatty acid methyl esters were prepared by alkaline hydrolysis followed by methylation with diazomethane and analysed on a CP Sil 88, 100m x 0.25mm ID column (Chrompack, UK). An additional 180mm section of m. *longissimus lumborum* was conditioned at 1°C for 12 days in vacuum pack. A 100mm section was then frozen at -20°C for sensory analysis. After overnight thawing at 1°C, 20mm thick steaks were cut and grilled to 74°C internal temperature. The meat was assessed by a 10 person trained taste panel using 100mm unstructured line scales. Four steaks 20mm thick were cut from the remaining sample, packed in modified atmosphere trays (O_2:CO_2, 75:25) and subjected to simulated retail display (700lux lighting for 16h a day, 4ºC±1ºC). Colour (L*a*b*) was measured on the surface of two steaks at three points, daily with a Minolta Chromameter. The remaining steaks were taken at 10d of display and analysed for thiobarbituric acid reacting substances (TBARS) by the methods of Tarladgis et al. (1960) as a measure of lipid oxidation.

Results and discussion

There were no effects of diet on total DM intake, forage or concentrate intake, liveweight gain during the feeding period, carcass weight, conformation or fatness (results not shown). There were also no significant differences in total, neutral or phospholipid contents in muscle between diets (Table 2).
The 22:6*n*-3 content of muscle total lipid increased by 3.5 fold from the control to the highest level of supplementation (Table 1), all of which came from the phospholipid fraction. The content of 20:5*n*-3 also increased whilst 22:5*n*-3 decreased. CLA did not change and *cis*-18:1*n*-9 and 16:1 decreased. There were no changes in the main long chain PUFA in the neutral lipid fraction, which is very low in these fatty acids. CLA did not increase with increasing PFO, but the concentration in total lipid was similar to that found in our previous studies when free fish oil was present in the diet (Enser et al., 1999).
Total saturated fatty acids fell non-significantly by a small amount, in the PFO diets, and the total PUFA increased only slightly in the total lipid, which gave no change in the P:S ratio whether calculated by incorporating the long chain PUFA or not (Table 2). The n-6:n-3 ratio, as expected, did not change when calculated as 18:2*n*-6:18:3*n*-3, but when calculated as total n-6 PUFA to total n-3 PUFA showed a small but significant decrease with increasing PFO (Table 2). There was little change in total PUFA, the increasing EPA and DHA displacing mainly monounsaturated fatty acids, but at nearly 200mg/100g of muscle, a 100g serving would make a substantial contribution to daily requirements.
Despite the fairly small changes in PUFA content of the muscle, there were large significant effects on lipid stability. TBARS rose significantly between the control and the highest concentration of PFO in the diet. The long chain PUFA have more unsaturated double bonds and are correspondingly more susceptible to oxidation than those fatty acids with only one or two double bonds. It should also be noted that there was sufficient incorporation of EPA and DHA from the control diet, which contained free fish oil, to give a higher value for TBARS than is normally seen with this control diet (Vatansever et al., 2000). From day 7 of display it is clear that the control diet gave slightly more colour stable meat than those with PFO, but that the 7d display required by UK supermarkets is achieved by most samples (Figure 1). The highest level of PFO produced meat that was more tender than the control (Table 3), but which developed significantly higher abnormal flavours. Despite this there was no significant effect on overall acceptability.

Conclusions

Feeding protected fish oils increased the nutritionally important long chain *n*-3 PUFA in muscle. Since these PUFA are predominantly deposited in phospholipids, which are diluted by the more saturated fatty acids in neutral lipids results in only small effects on the usual indices of healthy nutrition such as n-6:n-3 and P:S ratios. The incorporation of some free fish oil produced an expected concentration of CLA, which did not increase with increasing PFO, despite its imperfect protection. Long chain PUFA are sufficiently, oxidatively unstable that even small increases in their concentration made the total lipid more unstable and had a small effect on colour stability, as seen previously (Vatansever et al., 2000). Despite producing more

apparent off-flavours there was some evidence that the highest level of PFO incorporation produced more tender meat and overall hedonic acceptability was unchanged.

Background

The colour of fresh meat is an extremely important quality issue influencing the consumer´s purchase decision. That characteristic is influenced by the pigment content (Lindahl *et al*., 2001), the chemical state of the pigment and the microstructure of muscle tissue determined by the rate and extense of the pH fall. The relative influence of each of these factors depends on the muscle considered (Guignot *et al*., 1992).

Barrosã calves are produced according to a traditional extensive production system in a region well known for its mountains and uplands where the winter is the main period of feed scarceness. Since they have not suffered as much genetic pressure as other breeds, the biochemical characteristics of their muscles could be different. No work was done therein to characterize the meat of Barrosã breed from the production point of view.

Objectives

The main objective of this study was to investigate the relationship between fibre metabolic/contractile profile and some other traits veal characteristics evaluated on *Longissimus dorsi*, *Supra spinatus* and *Biceps femoris* muscles.

Materials and methods

Around 1 hour after slaughter, samples from *Longissimus dorsi* (Ld), *Supra Spinatus* (Ss) and *Biceps femoris (Bf)* of twenty Barrosã calf carcasses of both sexes, with ages ranging from 6 to 10 months were taken and frozen in liquid nitrogen for histochemical analysis as described by Roseiro *et al.* (2003). Sixty carcasses were selected for pH, colour and haem pigment analyses. Samples of the three muscles were taken and frozen at -18ºC until assessment of haem pigments (Hornsey, 1956). Results were expressed as µg haematin/g wet tissue, using a standard curve of haematin instead of the factor used by Hornsey (1956). The pH was measured at 24h after slaughter using a glass electrode (Mettler Toledo LoT406-M6-DXK-S7/25). The colour parameters (Lab) were measured 24h *post-mortem* on the carcass surface using a Minolta CR300 in the CIE L* a* b* space.

Vitamin E was determined according to European Standard-EN 12822 with minor modifications. 20g of sample trimmed of visible fat and connective tissue was weighed into a dark flask added of 1g of pyrogallic acid and 200 mL of saponification solution. This solution was prepared fresh each day and comprised 50 mL of 60% potassium hydroxide solution and 150 mL of ethanol absolute. The mixture was heated at reflux for 40 min at 100º C and then cooled and extracted 3 times with petroleum ether. After the evaporation of the solvent under vacuum, the residue was redissolved in 5 ml of hexane HPLC grade and filtrated through a membrane Acrodisc 25 mm GHP, GF 0.20 µm (Gelman Sciences, Inc.). α-Tocopherol was measured by HPLC (Spectra-Physics, model Spectra 100) using a Spherisorb S 5W silica, 5µm, 4.0x125 mm cartridge (Waters PSS 845549) at 292 nm. Hexane/1,4-dioxane (99:1) was used as mobile phase at a flow rate of 0.8 mL min^{-1}. Recovery of α-tocopherol from meat was determined by the addition of an internal standard to samples before saponification. Detector signals were quantified using peak areas and a calibration curve. The α-tocopherol content was expressed as mg/100 g of muscle

Data were analysed using one-way and two-way analysis of variance (ANOVA) and significant differences were determined using Tukey´s HSD post hoc test (Statistica 6.0-StatSoft Inc., 2001) Differences were considered different at $p<0.05$.

Results and discussion

Muscle traits

Least square means of fibre type composition, colour parameters, pH_{24}, α-tocoherol and haem pigment concentration obtained from *Longissimus dorsi*, *Biceps femoris* and *Supra spinatus* muscles are presented in Table 1. Significant differences were found among muscles for all traits studied except for b* value and βR fibres percentage. Ss muscle presented higher mean α-tocopherol ($P<0.05$) and haem pigment ($P<0.001$) than Ld and Bf muscles, which did not differed. Regarding pH_{24}, Ss and Ld muscles showed significantly higher mean values than Bf muscle. There were no significant differences between Ld and Bf muscles in regarding to fibre metabolic and contractile profiles, except for αW fibres. Bf muscle showed the highest frequency of αW fibres, but not presented the highest glycolytic profile which belong to Ld. Ss muscle presented a metabolic profile significantly less glycolytic than Ld, but did not differ from Bf.
Guignot *et al* (1992) reported a contractile profile in Friesen-Holstein calves, similar results to those observed in this study, for the same muscle.

The number of fibres in bovine muscles is almost determined at birth. However, the relative fibre type composition is affected to a number of genetic and environmental factors such as age, sex, breed and exercise performance. The main fibre type change occurs in the first few months of life. Based on different breeds, which varied in age between 0 and 12 months, Wegner *et al*. (2000) stated that such fibre type conversion occurred as early as 6 months old and was characterized by an increase and decrease frequency of type IIb and type IIa fibres, respectively, and no alterations in the type I incidence.
All Barrosã calves used in our study were more than 6 months old and the age effect on muscle fibre profile was not evaluated. Nevertheless, there was a remarkable effect of the weight at slaughter on contractile ($P<0.001$) metabolism (Table 2). Attending to the low correlation between the animal age and weight at slaughter, that influence could be attributed to differences in diet and animal handling. Listrat *et al* (1999) referred that muscle fibre characteristics could be related to the energy level of the diet and to daily dry matter intake. However, the diet effect on muscle fibre type profile of calves are not easily explained since during the most important period for fibre type changes, they are basically fed with mother's milk. The impact of diet on muscle fibre profile of calves reared in an extensive system needs more attention.

The influence of sex on meat traits was generally less expressive inducing significant changes only on βR and αW fibres and pH_{24}. Dreyer *et al.* (1977) reported that muscles of bulls contained more red fibres than those of steers. Johnston *et al.* (1981) found a significant higher percentage of αW fibres in Ld muscle of heifers than in steers. In our studied population, male muscles showed significantly ($P<0.001$) higher and lower percentages of βR and αW fibres, respectively, than females (data not shown).

Table 2 – Effect of weight, sex and slaughter season on muscle characteristics.

	F VALUE

In same row, means with different letters are significantly different. * P<0.05; ** P< 0.0; ***P<0.001; ns-not significant. ND-not determined; L*,a*,b*- colour parameters

Relations between pigment content, muscle traits and production factors

Correlations between the haem pigment concentration and the other Barrosã meat parameters are depicted on Table 3, and were not significant.

The highest haem pigment content was found, as expected, in the most oxidative muscle corroborating the trend observed by Meynier & Gandemer (1991). This parameter was affected by the animal weight at slaughter (P<0.001) and the slaughter season (P<0.05) but not by sex. Irrespective of the carcass weight, the highest pigment value was measured in older animals (data not shown).

Table 3 – Correlations between muscular traits.

	1	**2**	**3**	**4**	**5**
1 α-tocopherol	1,00				
2 Haem pigment	-0,23 ns	1,00			
3 pH_{24}	-0,27 ns	0,10 ns	1,00		
4 L*	0,24 ns	-0,27 ns	-0,36*	1,00	
5 a*	-0,07 ns	0,29 ns	-0,29*	0,12 ns	1,00
6 b*	0,23 ns	-0,11 ns	-0,52***	0,44**	0,51***

* P<0.05; ** P< 0.01; ***P<0.00; ns-not significant. L*,a*,b*- colour parameters.

The effect of slaughter season on haem pigment content as well as on pH_{24} is not easily comprehensible, but it could possibly be related to animal handling, diet composition and feed availability. Although animals are slaughtered throughout the year, spring and autumn can be described as stronger production seasons. The grass availability and its composition are not regular all over the year and this fact could have implications in growth traits and influence the carcass and meat quality. The pigment concentration referred in our study for Ld muscle was similar to those reported by Gil *et al.* (2001), in older animals of Retinta breed.

Relations between colour, pH, muscle traits and production factors

Due to its difficult access, colour parameters were not measured on Ss muscle. Comparing the other two muscles, L* and a* values were significantly higher in Bf than in Ld muscle (P<0.001). The absence of a significant correlation with the pigment content confirms the results obtained by Hunt & Hedrick (1977) and Tam *et al*. (1998) and disagreed with the findings of Lindahl *et al.* (2001). Although McDougall (1982) claimed that the pigment content was the main factor affecting muscle colour, that relationship depended on the muscle location (Guignot *et al*., 1992).

A study of Priolo *et al.* (2001) have shown that meat from animals finished on pasture is darker than those finished on concentrate, with the formers presenting a L value about 5% lower. In accordance to Page *et al.* (2001) a significant correlation between muscle pH_{24} and colour values was also observed. This correlation can be explained in that colour in muscle tissue is based on the reflectance of light off free water and on

oxygenation of the myoglobin At a higher muscle pH, proteins are bound strongly with water, allowing less free water to escape to interstitial space around cells and the muscle fibres to swell. Therefore, meat with higher pH will be darker in colour because there is less free water to reflect light. These authors also stated that a higher pH_{24} produced less red and yellow beef. Our results agreed with Page's experiment. The Ld muscle showed a significant higher mean pH_{24}value ($P<0.001$) and lower L* and a* values ($P<0.001$) than Bf muscle.

Background

Meat consumption in Japan is considerable at present, with beef imports particularly high from the USA and Australia. Certain brands are quite popular and have become standards of choice. But this merely reflects personal preferences and attitudes, without basis in objective data. The Japanese domestic beef (black cattle) is of course best known to the people in Japan. The breeding periods and types of feed differ for this domestic brand. But little research has been conducted of the meat quality of imported beef.

Objectives

Consequently, the present study was conducted to address this matter using Aussie beef frequently to be found in stores in Japan. Based on the results, comparison is made with American brand (US) beef considered as equivalent in quality to or even better than the former.

Materials and methods

Beef sample: Strip loin samples of Aussie and US beef (N=4) were chilled and aged for 30 days for sensory and physicochemical analysis. All samples of either brand were graded as Choice or better. The Australian species, Angus cross, is primarily fed barley while the American Angus cross is given feed whose major constituent is corn.

Sensory evaluation: Evaluation in all cases was made using beef (thigh side) sliced at 8 mm in thickness. Raw meat and meat grilled for 2 min, (1 min for each side) at 180˚C by an electric plate were evaluated by a team of experts from Nippon Meat Packers using the two-point comparison method.

Color of meat and fat: Lab-values were obtained for lean and fat of the 8 mm slices using a color difference meter (Minolta CR-200). Lean color was assessed after 2 days store-front storage under fluorescent lighting for meat packed with plastic O_2-permeable film at 4˚C.

Myoglobin content: Beef samples were cut up into pieces for homogenization and myoglobin (Mb) content as well as the met-Mb (MetMb) ratio in minced meat were determined by the extraction method (Sakata and Nagata, 1992; Trout, 2003).

TBA value: Distillation was carried out for determination of malonaldehyde (MA, Yamauchi and Ando, 1973) in the above minced meat sample. TBA value was expressed as MA mg/1000g meat.

Water and fat contents: Using minced meat, water and fat contents were determined by the freeze-dried and Soxhlet extraction methods, respectively.

Water holding capacity: Five cm thick beef cuts were vacuum-packed and cooked at 70˚C for 90 min. Cooked meat yield (%) of meat following water loss due to cooking was designated as water holding capacity. Using a press-machine, beef (10×10×5 mm) was pressed at 15kgw/cm^2 for 40 sec. The amount of water released and pressed meat area were determined based on the water holding capacity of raw meat.

Hardness assessment: Beef hardness of the 8 mm slices was assessed by the multi-bite method using a Tensipressor (Taketomo TTP-50BXII).

Melting point and area % of muscular fat: Muscular fat extracted by the Soxhlet method was used to determine fat melting point using apparatus specifically designed for this purpose.

Ratio of fat size in lean muscle: The 8 mm meat slices were photographed and monochrome figures were incorporated into computer provided with an image analysis system (Pias LA525). Using this system, fat marbling and lean portions were divided into black or white sample groups and on the basis of the size ratio, fat size (% of whole meat area) and number were determined.

Composition of fatty and amino acids in lean muscle: Fatty acid composition was clarified by gas - chromatography (Hewlett-Packard 6890) using muscle specimens. Amino acid analysis on minced beef was carried out for clarification of free and peptide-forms using an amino acid analyzer (JEOL JLC-500/V) and carnosine were determined at the same time.

Results and discussion

Sensory evaluation: Table 1 shows the results for sensory evaluation of the 2 beef brands. Aussie raw beef exhibited a darker red and the fat was white, in obvious contrast to the US beef. The grilled samples were assessed as better aroma, more tasty and more tender. But these qualities differed according to the sample. US beef was generally considered more tender.

Color of meat and fat: Table 2 shows changes in color with storage. On 0 day (1 hr after slicing), the L value was greater in US beef, with a and b values essentially the same. This would account for its brighter red color. On day 2, L had decreased and a value was greater. Changes in Aussie beef were fewer during this period. US beef thus has greater tendency to undergo discoloration. Table 3 indicates fat color for the 2 brands and L to be higher and a lower in Aussie beef. It thus follows that Aussie beef has greater white fat content.

Myoglobin content: Mb content and MetMb% during storage are shown in Table 4. Mb content was greater in Aussie beef. At 2 days storage, Mb content of both brands had decreased, suggesting the possibility of drip from meat surface during storage. MetMb increased with the period of display, more so in US than Aussie beef.

TBA value and carnosine content: Tables 5 and 6 show respectively values for TBA and carnosine. TBA value was higher in US beef on day 0 and 2 while Aussie beef contained greater carnosine.

Water content , cooking yield and water holding capacity: Table 7 shows water content for lean meat and Table 8, water holding capacity (WHC), The values were basically the same for the two brands in cooked meat yield (Table 8-1), released water (-2) and area of pressed meat (-3).

Hardness assessment: Table 9 shows the value of this parameter as determined using a Tensipressor. The US beef was generally significantly more tender.

Fat content in lean muscle and melting point: Table 10 shows fat content in lean muscle and its melting point. The values were essentially the same for the 2 brands. Aussie beef had greater fat content (Table 11), this being consistent with greater degree of fat marbling as seen on the computer image display. US beef exhibited significantly lower fat melting point.

Fat and amino acid composition: Myristoleic acid (C14:1) and arachidic acid (C20:1) were higher in US beef and stearic acid (C18:0) was significantly abundant in Aussie beef. Ratios of unsaturated fatty acids were significantly lower in Aussie beef, this possibly causing higher fat melting point. Glutamic acid was higher, through not significantly, in Aussie beef (data not shown).

The results for sensory evaluation and color measurement of raw beef indicated Aussie beef fat to be lighter in color and meat color darker red compared to US beef. This reflects the chromatic character of Aussie beef, which is superior in quality owing to its fatness character. US beef appears to incur more discoloration owing to fluorescent lighting in the display case, while that of the former is stable maintained. The MetMb ratio was higher in US beef subsequent to display, causing the meat to become brownish. TBA was lower in Aussie beef with consequently less rancidity. This feature and discoloration are due to oxidation which has been shown to occur less in Aussie beef. Aussie beef capacity for preservation is thus greater. The presence of relatively more carnosine, an antioxidant, may be one reason for this. The sensory evaluation of grilled beef, aroma, taste and tenderness showed essentially the same results for the two brands. The evaluation team gave the same scores for eating quality. US beef was considered a little more tender than the Aussie brand. No relationships could be detected among tenderness, water holding capacity and fat marbling. US beef in this study showed looser muscle fibers and this possibly may explain its somewhat greater tenderness.

Conclusions

Based on the results of this study, the following conclusions were drawn: Subcutaneous fat in Australian meat cattle was at one time noted to be almost entirely yellow with little marbling. This was due to the cattle feeding mainly on grass. But grain feed with special formula for fattening has resulted in improved meat quality and greater meat exports to Japan. Aussie beef is shown by the present study to be superior in quality owing to its greater water holding capacity. The Japanese are grateful for this high quality beef. Aussie beef imports will continue to increase until BSE inspections in the USA is fully implemented with satisfactory results.

THE EFFECT OF REFRIGERATION CONDITIONS ON THE QUALITY OF LAMB MEAT

J. Santos-Silva[a]; R. Santos[a]; I. Mendes[a]; J. Prates[b]; M.J. Fraqueza[b]; C. Ferreira[b]; A.S. Barreto[b]; J.P. Lemos[b]

[b] – Faculdade de Medicina Veterinária CIISA, Lisboa, Portugal

Background

In Portugal the traditional lamb meat production systems are based on local breeds, raised on pasture for most of the year. Many of these products are protected by the EU with denominations of origin (PDO) or geographic indications (PGI). Consumer's normally consider certified meat as healthy food, produced in natural conditions and have high expectations concerning eating satisfaction. Certified meat is marketed at higher prices than undifferentiated meat and is required by high quality segments of the market. Particularly for these products, it is essential to control all the production processes in order to obtain the highest quality standards and to reduce variability. In Portugal, in spite of being recommended for several lambs with PDO or PGI the practice of low carcass cooling rates, the common practice is to cool carcasses as soon as possible in order to reduce evaporative weight loss and prevent spoilage.

Tenderness is one of the most important organoleptic characteristics, and only tender meat can assure consumer's satisfaction. The main factors affecting tenderness are sarcomere length, proteolysis of myofibrillar proteins and connective tissue (Koohmaraie *et al*. 2002). The rates of temperature and pH decline in the early *post mortem* play an important role in meat tenderness. A slow cooling rate before the onset of *rigor mortis* prevent cold shortening and stimulate the proteolysis of myofibrils and associated proteins (Lockner *et al*., 1980; May *et al*., 1992), increasing meat tenderness. The effect of rapid cooling of carcasses may be particularly important in small carcasses, such as lamb, and Geesink *et al*. (2000), in a trial with lamb *longissimus* muscle concluded that optimal temperature at the onset of *rigor mortis* is around 15 ºC. In these conditions muscle shortening was minimized and proteolysis during storage was unaffected.

Objectives

The objective of this trial was to evaluate if 4 and 8 hours at 12 ºC, before cooling lamb carcasses at 2º C affects tenderness, histological, biochemical, physical and microbiological traits of meat.

Materials and methods

Animals and sampling

Thirty Merino Branco ram lamb carcasses were used to conduct this trial. Lambs were slaughtered with four months of age in the abattoir of the Estação Zootécnica Nacional. After dressing and weighing, three groups of ten carcasses were assigned to three refrigeration conditions: 0 (cooling at 2 ºC immediately after slaughter), 4 (cooling at 2 ºC after four hours at 12 ºC) and 8 (cooling at 2 ºC after eight hours at 12 ºC). Temperature and pH of the *longissimus lumborum* (LL) and *semimembranosus* (SM) muscles were measured 4, 8 and 24 hours after slaughter, using a penetration probe electrode. Eight hours after slaughter, and at the third, seventh and tenth days, sampling to microbiological analysis were performed on carcass shoulder region by destructive method (2,5cm^2) according to the Directive 64/433/CEE. Three days after slaughter, carcasses were split in two halves and the muscles LL and SM of the right sides were vacuum packed and frozen at – 20 ºC until shear force determinations. The colour of *longissimus thoracis* (LT) was estimated in the L*, a* and b* system (Minolta CR-300 chromometer) at the level of the 13th dorsal vertebra, after one hour of exposition to the air. Samples of LT and SM were collected, vacuum packed and frozen at – 80 ºC to determine sarcomere length. A small portion of LT muscle was collected to determine water-holding capacity (WHC). In the left halves of the carcasses, LL was vacuum packed and frozen at – 20 ºC until sensory analysis.

Analytical procedures

Sarcomere length was determined by the method described by Sañudo *et al*. (2003). Water holding capacity was determined by the method proposed by Santos-Silva *et al*. (2002).

Concerning microbiological analysis, total psycrotrophic aerobic counts at 7ºC for 10 days (Plate Count Agar, Merck, Germany), *Enterobactereaceae* on VRBD agar (Merck, Germany) for 48h at 37ºC, *Escherichia.coli* at 44,5ºC in Tergitol BCIG agar (Biokar Diagnostics) for 24h, lactic acid bacteria counts on Man Rogosa Sharpe Agar (Oxoid, UK) incubated at 30ºC for 3 days and *Brochothrix termosphacta* count in streptomycin, actidione, thallous acetate agar (STAA, Oxoid, UK) incubated for 2 days at 30ºC. Counts were expressed as log cfu/cm^2.

For shear force determination, samples were thawed for 24 hours at 2ºC and cooked in an electric oven until the meat internal temperature reached 65 ± 5 ºC. Cores with a section of about 1 cm^2 were prepared in the muscle fibres direction. Shear force was determined using a texture analyser (TA-XT2i Texture Analyser, Stable Micro Systems) equipped with a Warner-Bratzler shear device and data were collected with specific software (Texture Expert Exceed, Stable Micro Systems). Measurements were recorded as the average value of a minimum of six replicates. For sensory analysis a trained panel of six members was used to compare tenderness of meat of the three experimental groups using a structured scale of ten points (0 – very tough; 10 – very tender). Meat was prepared as described for shear force determination. Three cores corresponding to the three cooling conditions were presented to the panellists simultaneously and served in hot plates in a total of 51 comparisons.

The data were analysed using the GLM procedure of SAS (1989). When the F-test was significant, the least-squares means were compared. For shear force, muscle temperature, pH and sarcomere length, muscle and refrigeration conditions were used as fix effects and cold carcass weight (CCW) as covariate. For muscle colour parameters and WHC, the refrigeration condition was the fix effect and CCW the covariate. For tenderness and microbiological traits both models included the refrigeration conditions, besides panellist (tenderness) and days after slaughter (microbiological traits).

Results and discussion

Shear force was higher ($p<0.05$) when carcasses were immediately cooled (group 0) and no significant differences were found between groups 4 and 8. Data for LL are in accordance to those obtained for sensory evaluation, as panellists considered meat of group 0 the tougher and of group 4 the most tender. These results agree with those of Marques de Almeida *et al*. (2003), suggesting that 3 or 4 hours delay of carcass cooling at 2 º C are enough to improve meat tenderness 3 days after slaughter. Jaime *et al*. (1993), comparing the effects of 3 cooling conditions on tenderness of lamb *longissimus* muscle, concluded that toughness 2 days after slaughter was higher in carcasses with faster temperature decline, although no differences were found after eight days of ageing. Thatcher and Gaunt (1992) observed higher shear force of meat from lambs chilled at 2º C compared to others chilled at 10 ºC.

As expected, the rate of temperature decline was higher, intermediate and lower for groups 0, 4 and 8 respectively, and in LL than in SM. These results for temperature explain the differences in the rates of pH decline, which was higher in groups 8 and 4 than in group 0 and in SM than in LD.

When muscle temperature reaches values below 10 ºC and pH is still above 6, cold shortening may occur. The values observed for pH and temperature could suggest a higher muscle shortening, particularly in group 0. However, the values of sarcomere length indicate that shortening was very moderate in the 3 groups and no differences were found between the three refrigeration conditions or the two muscles. The correlation coefficient between shear force and sarcomere length was low ($r=-0.06$) and not significant ($p>0.05$). Marsh and Leet (1966) demonstrated that up to 20 % of muscle shortening there is no effect in tenderness of muscle *sternomandibularis*.

Shear force values showed correlations coefficients of -0.40 ($p<0.05$) and -0.42 ($p<0.05$) with muscle temperature 4 hours after slaughter in LL and SM, respectively. Other authors have reported that temperature in the initial period after slaughter is the factor most highly correlated with tenderness (Lockner *et al*., 1980; May *et al*., 1992), which is probably related to a higher extension of proteolysis by endogenous peptidases (Yates *et al*., 1983). Although we do not dispose of data to confirm this hypothesis, the differences in *in situ* proteolytic activity may explain the results of this trial.

In the range of pH values above 5.5, meat with higher pH may have higher WHC (Purchas, 1990) and sow lower values of L* (Priolo *et al*., 2001). Also, higher rates of glycolysis, associated to lower rates of temperature decline, may affect negatively meat WHC (Hood and Joseph, 1985). In this trial the refrigeration conditions had no effect on LT colour and WHC. Thatcher and Gaunt (1992), also found minor effects on meat colour of ewe lambs chilled at 2 or 10 ºC.

The results for microbiological traits are presented in table 2. The counts on the day of slaughter (0) for total psycrotrofic bacteria (± 3 log cfu/cm^2) and the results obtained for *E. coli*, that was not detected at day 0 and showed low values during conditioning, indicate good hygiene in the abattoir. On day 0 the dominant Gram+ flora seems to be lactic bacteria. Only for this group of microbes, the counts were higher ($p<0,001$) when temperature decline was lower (groups 4 and 8) and this effect was still observed on day 3. However, on the 7th and 10th day the results were similar for the 3 refrigeration conditions, suggesting that the increase of population reached a stationary state corresponding to values of 3-4log cfu/cm^2. After the 7th day, the dominant flora is *Brochothrix thermosphacta* and the Gram– psycrotrophic bacteria. These populations are responsible for the spoilage of meat that is already evident at the 10th day, when the counts for total psycrotrophic are higher than 8 log cfu/cm^2, independently of the refrigeration conditions. The shelf life period, in the conditions of slaughter and refrigeration of this trial, was up to 7 days.

Conclusions

According to the results of this trial the rapid cooling of lamb carcasses results in tougher meat. The 4 hours delay in carcass cooling at 2 ºC, seems to improve tenderness, and have no negative effects on the physical traits of meat (colour and water-holding capacity). Although the delay of cooling increased the counts of lactic acid bacteria at the day of slaughter, it did not affect the hygienic conditions of meat after 7 days. In the conditions of slaughter and refrigeration of this trial, the meat microbial shelf life period was up to 7 days.

Background

Selective breeding in cattle has been very successful in increasing production indicators, but until now there is little information and subsequently limited knowledge to allow selection programs to be designed to improve product quality. Identification of the genes involved in aspects of carcass and meat quality and the quantification of their effects will provide the basic information to devise breeding programmes that enhance quality and take account of regional variations in preference.

The present study is part of an ongoing EU project, which will examine a total of 450 animals from 15 different breeds representing the genetic diversity of European cattle. This project will undertake a rigorous comparison of carcass and meat quality from this range of cattle breeds with animals raised under similar management conditions in order to minimise environmental variation and to identify and define genetically determined component of that variation.

Objectives

To assess the variability among 15 different European cattle breeds in carcass traits.

Materials and methods

The material consisted of 337 young entire males from 15 different European cattle breeds. The breeds used were as follows: From United Kingdom, Jersey, South Devon, Aberdeen Angus and Highland; from Denmark, Holstein, Danish Red Cattle and Simmental; from Spain, Asturiana de los Valles, Asturiana de la Montaña, Avileña-Negra Ibérica and Pirenaica; from Italy, Piemontese and Marchigiana and from France, Limousin and Charolais. All animals were intact bulls, which were fed *ad libitum* with a standardised diet composed of high barley proportion (about 80%), soya (9%) and chopped straw (10%) with appropriate minerals and vitamins. Energy density was approximately of 12.5 kJ/Kg dry matter.

The welfare regulations were taken into account when handling the animals. The bulls were slaughtered at the nearest EU licensed abattoir, to minimise the effect of the transport stress on meat quality. Slaughter was at 75% of mature bull weight, which in most cases was about 15 months of age. Stunning was by captive bolt pistol. Carcass dressing was carried out using a standardised project protocol that corresponded to commercial practice. Carcasses were chilled at 4 ± 1º C for 24 hours.

Immediately after slaughter, the following variables were recorded:

- Kidney fat weight.
- Hot carcass weight, measured without removing the subcutaneous fat.
- Dressing percentage, calculated according to the following formula: 100*hot carcass weight/slaughter live weight.
- Conformation score was graded according to the SEUROP classification (R. (CEE) 1026/91, R. (CEE) 2237/91 and R. (CEE) 2930/81) with a scale ranging from 1 (very bad conformation) to 18 (very good conformation).

- Fatness score was measured by UE classification, with a 15 points scale (1, very low fat to 15, very high fat).

Also, several standard measurements were taken on the left half carcass to evaluate carcass morphology, according to the methodology described by De Boer, Dumont, Pomeroy & Weniger (1974). Variables recorded were carcass length, internal depth of breast, limb length and limb thickness. The blockiness index was calculated. This index expresses the relationship between carcass weight (kg) and carcass length (cm). High values indicate high muscular development (Albertí *et al.,* 2001). Limb index expresses the relationship between limb thickness (cm) and limb length (cm).

The area of the *Longissimus thoracis* (LT) muscle, at 5^{th}-6^{th} rib level, was recorded by tracing: an acetate sheet was placed on the surface of the loin, and the border of the muscle marked on the sheet using glass marker. The area of the muscle was calculated by planimetry. Medium-lateral and dorso-ventral diameters (A and B, respectively), were also measured (Cañeque & Sañudo, 2000).

The 6^{th} thoracic rib joint was collected at 24 h post-mortem, and its' weight was recorded together with the *Longissimus thoracis* muscle, which was separated for instrumental analysis. The rest of the rib joint was dissected. Tissue composition for muscle, bone, fat and other components (tendons and noticeable blood vessels) were estimated from the rib joint according to the method described by Robelin & Geay (1975). Results are expressed as percentage of the entire rib weight.

Statistical analysis was performed using SPSS 11.0 software. An ANOVA procedure was carried out with breed as an unique effect.

Results and discussion

Global results are shown in Table 1.

Breed was a very important factor determining carcass quality, especially in carcass blockiness index (F=96.7), carcass weight (F=96.5), dressing percentage (F= 93.2), fatness score (F= 86.6) and limb length (F=84.8). Carcass weights ranged from 189.9 kg for Jersey to 386.6 kg for Charolais. In general, dairy breeds, such as Jersey, Holstein or Danish Cattle, or local breeds, such as Highland or Asturiana de la Montaña, produced small carcasses, while specialised beef breeds, as Charolais or Pirenaica produced higher carcass weights. Similarly, dressing percentage was lowest for Jersey (46.6%) while five specialised beef breeds (Charolais, Pirenaica, Asturiana de los Valles, Piemontese and Limousin) had values up to 60%. The breed purpose was also reflected in conformation scores, the highest score was for Piemontese (14.6) and the lowest for Jersey (4.4). On the other hand, dairy and local breeds showed the highest values for kidney fat weight, which was maximum for Highland (9.2 kg) and minimum for both Italian breeds (less than 1.5 kg). Nevertheless, fatness scores did not follow this behaviour, since Charolais or Limousin had the same fatness scores as some dairy or double purpose breeds such as Simmental, Holstein or Red Danish Cattle (about 8 points). The breed with the highest fatness score was the Aberdeen Angus (11.7) and at the lowest was Piemontese (3.6), indicating that fat deposition occurs in different ways in different breeds (Robelin, 1986, Micol *et al.,* 1993).

Biometric measurements on the carcass also showed significant differences among breeds, especially for limb length, which varied from 64.4 cm in Highland to 86.3 cm in Holstein, and for internal depth of breast, which varied from 33.3 cm in Asturiana de los Valles to 43.3 cm in Holstein. There were also, significant differences in the limb index ($F=30.9$; $p<0.001$) and in the carcass blockiness index ($F=96.7$; $p<0.001$). The loin area was greatest for Asturiana de los Valles breed (52.7 cm^2), followed by Piemontese (52.2 cm^2), while Holstein presented the lowest value (35.0 cm^2). These differences in the loin area were mainly due to differences in the dorso-ventral diameter, rather than in the medium-lateral dimension. Data for British breeds were not available.

From the dissection of the 6^{th} rib it can be seen that different breeds show important differences in muscle (ranged between 58.1% in Holstein and 79.9% in Piemontese breeds) and fat percentages (ranged between 3.2% in Piemontese and 23.0 % in Angus animals). These findings are in accordance with the carcass

measurements and conformation scores. The differences found in bone plus others were significant, but lower (F= 18.5) than those for fat and muscle (F= 52.4 and 56.9 respectively) thus, bone plus others ranged between 15.0% in Limousin and 23.1% in Holstein breeds. These results agree with the more precocious development of the bone tissue and of the "other" components, and subsequent their higher bio-stability, compared to fat and muscle tissues.

Conclusions

We can conclude that breed is an important factor in determining carcass quality. The information that is being generated by this project will be important for devising breeding strategies to meet the demands of the market.

Background

The international market for lamb meat tends to increase the commercial exchanges between geographical regions and countries. Europe is the greatest importer of lamb meat (Sañudo *et al*., 1998a) with almost 50% of the world market. In this sense, South American countries are looking for new markets for exporting their red meat products. These products must compete with those produced locally. At the same time, each country or region in Europe produces a specific type of lamb according to its production system characteristics (breeds, environments, infrastructures, feeding resources, etc.). The particular characteristics of these systems determine the type of product that is commercialised in each region, according to liking, preferences and cooking habits of the consumers (Hernando *et al*., 1996). Mediterranean countries, in general, produce lamb with lower carcass weights, while Central-Northern European countries produce animals with higher carcass weights. All these products are clearly appreciated in their own regions and producing countries, but they may not be appreciated so much in the overseas markets by potential consumers. According to Jeremiah (1988), there are some reasons to believe that significant differences may exist in the palatability attributes of lamb from different geographical sources due to differences in genetics, nutrition, slaughter weight and age and the extent of post-mortem ageing.

Objectives

The main objective of this study was to evaluate Spanish, German and British consumers' acceptability of lamb meat sourced from Uruguay and compared with their locally produced lamb at two different ageing periods.

Materials and methods

Consumers

Consumer tests were conducted in Spain, Germany and United Kingdom. In each of these three countries, two hundred consumers (in two different places of 100 consumers each) evaluated 4 different lamb meat samples: 2 local and 2 from Uruguay. Overall consumers were stratified in terms of sex, age and education level. Gender classification was almost equal (male-51%, female-49%), with smaller differences within each country. On the other hand, consumers were mostly concentrated on the two medium ranges of age (26-40 and 41-60 years of age, 32% and 39 % respectively), with an important variation in the extreme groups in each country; in average 17% (18-25 years of age) and 12% (61-75 years of age). The education level of the sampled population was in general very high (56% of people with University or college education level), 26% was located at the school to age 16 and 18% was at the school to age 18.

Animals and meat samples

Uruguayan lambs comprised light and heavy Corriedale lambs (11.1±1.4 kg and 19.6±2.2 kg carcass weight, respectively) reared on a pure extensive improved sward system and the meat aged for 20 days. In the case of the European lambs only one type by country was used, representative of each country where the comparative consumer tests were performed, aged for either 7 or 20 days. Samples taken from United Kingdom represented a common commercial lamb type (22.8±1.7 kg carcass weight) reared on grass-based

system with strategic use of concentrate. German samples were taken from crossbreed between Suffolk or Schwarzköpfe x Merino Landschaf (23.2±3.65 kg carcass weight) reared on grass complemented with concentrates. In Spain, lambs came from the Rasa Aragonesa breed, produced under an intensive system using concentrates and cereal straw *ad libitum* (10.2±0.6 kg carcass weight).

All meat samples were taken from the loin (*M. longissimus lumborum*). After thawing, they were sliced into 2 cm-thick steaks and grilled until the internal temperature reached 72ºC. Consumers evaluated tenderness, flavour and overall acceptability on 8-points category scales.

Statistics

Consumer test results were separately analysed for each country. The analysis of variance was performed using the GLM procedure of SAS for Windows version 8.1 (SAS, 2000). Lamb type was included as a fixed effect and consumer as a random effect. The session effect had been previously corrected.

Results and discussion

Tables 1, 2 and 3 show the results of the consumer tests carried out in Spain, United Kingdom and Germany, respectively.

Table 1. - Tenderness, flavour and overall acceptability of lamb by Spanish consumers. Least Square Means and Root MSE.

Lamb type	Tenderness*	Flavour*	Overall acceptability*
Light Uruguay	6.1	5.7 ab	5.8
Heavy Uruguay	6.2	5.5 bc	5.6
Spain 7d ageing	6.3	5.8 a	5.8
Spain 20d ageing	6.3	5.4 c	5.6
RMSE	1.28	1.56	1.44

a, b, c: LSMeans with different letters within tenderness, flavour and overall acceptability are statistically different (P<0.05). *: from 1, very tough and extremely disliked flavour and acceptability, to 8, very tender and extremely liked flavour and acceptability.

In Table 1, it can be observed that Spanish consumers preferred the flavour of the Spanish lamb meat aged for 7 days and of the Uruguayan light lamb (P<0.05), without differences in tenderness and overall acceptability (P>0.05). This could partially be explained by the similarity of live weight and age between the Spanish and the Uruguayan light lamb, even though they came from very different production systems.

German consumers (Table 2) gave higher ratings of tenderness to the Uruguayan heavy lamb and the German lamb aged for 20 days, with higher flavour ratings to both German lamb samples, and the highest overall acceptability given to the German lamb type aged for 20 days (P<0.05). At the same time, the flavour and overall acceptability of Uruguayan light lambs were the least preferred (P<0.05). In general, it seems clear that German consumers preferred their own products and those that have some similar characteristics to them (Uruguayan heavy lamb), even being consumers without or with a very small experience in lamb meat consumption. They rejected meat from Uruguayan light lamb, which was the only unweaned type. Thus, Kemp *et al*. (1981) found that differences in flavour between two groups of lambs could be explained by differences in feeding regimens when comparing lambs fed exclusively with maternal milk versus lambs supplemented with commercial pellets and hay *ad libitum*.

Table 2. - Tenderness, flavour and overall acceptability of lamb by German consumers. Least Square Means and Root MSE.

Lamb type	Tenderness*	Flavour*	Overall Acceptability*
Light Uruguay	6.1 b	5.7 c	5.7 c
Heavy Uruguay	6.6 a	6.0 b	6.1 b
German 7d ageing	6.2 b	6.1 ab	6.1 b
German 20d ageing	6.7 a	6.3 a	6.4 a
RMSE	1.14	1.18	1.07

a, b, c: LSMeans with different letters within tenderness, flavour and overall acceptability are statistically different (P<0.05). *: from 1, very tough and extremely disliked flavour and acceptability, to 8, very tender and extremely liked flavour and acceptability.

For the UK consumers (Table 3), flavour and overall acceptability of the British lamb aged for either 7 or 20 days and of the Uruguayan heavy lamb were similar, and they obtained the higher ratings(P<0.05). The highest tenderness ratings were for the Uruguayan heavy lamb and British lamb aged for 7 or 20 days (P<0.05), while the lowest ratings were given to the Uruguayan light lamb (P<0.05). In general it can be suggested that British consumers were able to recognise their own products (grass fed) for lamb meat flavour and overall acceptability. These results were probably due to the strong influence that age (older animals) and production and feeding systems has on flavour, and the relationship between flavour and consumer acceptability. In the same way, Sañudo *et al*. (1989), working with lambs of different origins (Spanish light lamb, New Zealand and French light lambs) tested in Spain, found that New Zealand lamb meat obtained the highest values for flavour intensity and the lowest ratings for overall acceptability. Crouse *et al.* (1983) and Solomon (1980) reported similar results.

Table 3. - Tenderness, flavour and overall acceptability of lamb by British consumers. Least Square Means and Root MSE.

Lamb type	Tenderness*	Flavour*	Overall Acceptability*
Light Uruguay	5.6 c	5.4 b	5.3 b
Heavy Uruguay	6.9 a	6.1 a	6.3 a
UK 7d ageing	6.5 b	6.1 a	6.2 a
UK 20d ageing	6.7 ab	6.2 a	6.3 a
RMSE	1.28	1.42	1.35

a, b, c: LSMeans with different letters within tenderness, flavour and overall acceptability are statistically different (P<0.05). *: from 1, very tough and extremely disliked flavour and acceptability, to 8, very tender and extremely liked flavour and acceptability.

In general, these findings are probably related to the consumption habits of the different consumers evaluated, which determine a lower acceptance of unfamiliar products. This can be clearly seen when Uruguayan light lamb was compared to German and British lamb types or when Uruguayan heavy lamb was compared to Spanish lamb samples. In a previous report using British and Spanish lamb carcasses, Sañudo *et al.* (1998b) showed that both British and Spanish panels found the odour and flavour intensity higher in the British carcasses and juiciness higher in the Spanish lamb types. However, the panels differed in their ratings of flavour quality and overall appraisal. The British panel preferred the flavour and overall liking of British lamb, whereas the Spanish panel preferred the flavour and overall appreciation of Spanish lamb.

Conclusions

Lamb meat acceptability depends on the consumption habits of the consumers, at least in countries with relatively high lamb consumption such as Spain and United Kingdom. Also, lamb meat tenderness was improved by ageing period, although only significantly in Germany, and, in general, more tender lamb meat was associated with higher acceptability at longer ageing times (20 days), especially in the older and heavier lamb types.

Overall acceptability seems to be better related to flavour than tenderness scoring, and this is in agreement with previous European studies (Dransfield *et al*., 1984) that showed increased focus on flavour and overall acceptability when all the meat being compared was tender.

Background

Pork quality is defined by CIE L* (lightness), ultimate muscle pH, and drip loss in Kauffmann et al. (1992). Pale, Soft, and Exudative (PSE) pork is a quality classification characterized as being very light colored, soft, and watery. Such meat is classified as low quality and undesirable to consumers due to its poor appearance, texture, and palatability (Pearson and Gillett, 1996). PSE meat also exhibits poor water holding capacity and texture in processed products (Solomon et al. 1998). PSE meat originates from a rapid decline in pH postmortem (45 min) at high muscle temperature (Briskey and Wismer-Pedersen, 1961). PSE meat was identified (Kauffmann et al, 1992) by ultimate pH< 5.6, CIE L* Value > 50, and drip loss > 5%, and red, firm, and non-exudative (RFN) or normal pork was classified as ultimate pH=5.6-5.9, 42<CIE L*< 50, and drip loss < 5 %. It is not guaranteed that a sample with a CIE L* value > 50 is PSE. However, in theory, the above-listed classifications would allow for two possible relationships between CIE L* value and ultimate pH. There would be either a strong linear relationship between CIE L* value and pH over the whole range of values or samples with a pH greater than 5.6 would generally have a CIE L* value greater than 50 and samples with a pH less than 5.6 would have a CIE L* value less than 50. For either example, it may be possible to utilize ultimate pH to predict with accuracy if a porcine *semimembranosus* muscle CIE L* value is greater than or less than 50. Unpublished data from the industry indicates that there may not be a clear relationship between ultimate pH and CIE L* in pork. This research was performed to first test the hypothesis that there is a relationship between CIE L* and ultimate pH for national pork development hogs and then to characterize that relationship if it exists.

Objectives

The main objective of this research is to demonstrate if there is a relationship between ultimate pH and lightness of porcine *semimembranosus* muscles in National Pork Development Hogs. A second objective is to utilize logistic regression to predict if the CIE L* value is greater or less than 50 based on ultimate pH.

Materials and Methods

Porcine *semimembranosus* and *adductor* muscles (n=384) were obtained from a pork processing plant in Virginia (United States) on 15 separate occasions to obtain a good representation of sample color. Samples were selected based on visual color as an attempt to obtain half of the samples as pale and half as normal. All samples were taken from National Pork Development (NPD) pork carcasses produced from market age pigs that weighed 110-125 kg. CIE L* values were measured using a chroma meter (Model CR-200, Minolta Camera Co., Ltd., Osaka, Japan) at three similar anatomical locations on each muscle. The chroma meter was calibrated using a standard Minolta calibration plate (white plate, No. 20933026; CIE L* 97.91, a* -0.70, b* +2.44) each time prior to testing. The pH of each *semimembranosus/adductor* muscle was also taken in triplicate by removing three 2-g samples from the three same similar anatomical locations that color was measured and homogenized (Virtishear Model.225318, The Virtis Company, Inc., Gardener, NY) for 10-20 s (3 short bursts) in 20 ml of distilled deionized water. pH was measured for the individual samples with a calibrated pH meter (Model AR25, Fisher Scientific, Pittsburgh, PA).

Statistical Analysis

The correlation coefficient was determined for the relationship between CIE L* and pH for all samples, those with CIE L* values less than 50, and CIE L* values greater than 50 (SAS 8.2, 2001). Logistic regression

was utilized to determine how well ultimate pH would predict if a sample had a CIE L* > 50 or a CIE L* value <50 (SAS 8.2, 2001).

Results and Discussion

There is a strong negative correlation (r= - 0.83) between ultimate pH and CIE L* values for porcine semimembranosus muscles (Figure 1). This relationship is accurate, but is also misleading. Separation of the data into two categories including ultimate pH>5.6 and ultimate pH<5.6, established a correlation of -0.45 and -0.45, respectively (Figures 2 and 3). This drastic decrease reveals that the relationship between CIE L* and ultimate pH is misleading. Furthermore, through the removal of outliers from the data, the correlation decreases from -0.45 to -0.40 for pH below 5.6 and from -0.45 to -0.046 for samples above a pH of 5.6. These results demonstrate that there is not a linear relationship between the data and that logistic regression may be appropriate to determine the relationship between a samples ultimate pH and CIE L* value.

The logistic regression analysis demonstrated that ultimate pH is effective ($p<0.05$) in determining whether the CIE L* value will be either greater or less than 50. The logistic regression model predicted that if the pH was less than 5.6, there is a 0.962 probability that the CIE L* would be above 50. At a pH above 5.6, the predicted probability that the CIE L* value is below 50 was 0.905. This research reveals that ultimate pH is a good predictor for whether CIE L* will be above or below 50. The relationship between these two variables is that of a categorical distribution where the probability that a sample would have a CIE L* value greater or less than 50 can be predicted based on pH value. Furthermore, predictions of whether CIE L * is greater or less than 50 can be predicted at any pH (Figure 4). Predictions can actually be made for any set of categories that are desired. Figure 4 reveals that as the ultimate pH approaches 5.4 and 5.9, the probability that a sample has a CIE L * value less or greater than 50 approaches 1. Therefore, from 5.9-7.0, the probability that the CIE L* value will be below 50 is 1, and the predicted probability that any sample with a pH below 5.4 having a CIE L* value is 1. At pH values of 5.6 and 5.7, the probabilities that a sample will be above 50 in CIE L* is 0.81 and 0.39, respectively (Figure 4). This evaluation reveals that there is a higher probability that a sample is pale than normal in this pH range. Therefore, ultimate pH is a useful indicator of product paleness when pH is higher than 5.8 and less than 5.5, but is ineffective in classifying porcine semimembranosus color from NPD hogs when the pH is between 5.5 and 5.8.

Conclusions

The ultimate pH of porcine *semimembranosus* muscles correlates well with CIE L* values. CIE L* values can be explained by ultimate pH when CIE L* values are divided into a categorical variable. Logistic regression is a useful tool in explaining the relationship between ultimate pH and CIE L* values.

THE EFFECTS OF RUMINALLY-PROTECTED DIETARY LIPID ON THE FATTY ACID COMPOSITION AND QUALITY OF BEEF MUSCLE

N.D. Scollan[1], M.Enser[2], R.I. Richardson[2], S. Gulati[3], K.G.Hallett[2], G.R. Nute[2] and J.D. Wood[2]

[1]Institute of Grassland and Environmental Research, Plas Gogerddan, Aberystwyth, SY23 3EB, UK; [2]Division of Farm Animal Science, School of Veterinary Science, University of Bristol, Langford, Bristol BS40 5DU, UK; [3]Faculty of Veterinary Science, University of Sydney, NSW 2006, Australia.

Background

Improving the nutritional value of beef by reducing saturated fat and increasing the content of polyunsaturated fatty acids (PUFA) is an important research target. Rumen biohydrogenation of dietary PUFA limits the ability to manipulate the ratio of polyunsaturated:saturated fatty acids (P:S), which for beef is typically 0.06 – 0.1 (Wood *et al*., 2003). However, feeding a ruminally-protected, PUFA-rich, lipid supplement produced from soya beans, linseed and sunflower oils mixed to give a 2.4:1 ratio of 18:2*n*-6:18:3*n*-3 resulted in major improvements in the P:S ratio (Scollan *et al*., 2003) with only small associated changes in the colour shelf life and sensory attributes of the meat (Enser *et al*., 2001). However, in that study, the protected lipid supplement (PLS, with an 18:2*n*-6:18:3*n*-3 ratio of 2:4:1) was less effective in increasing the deposition of *n*-3 relative to *n*-6 PUFA, resulting in a less favourable *n*-6:*n*-3 ratio in beef longissimus muscle. It is hypothesised that the ratio of *n*-6:*n*-3 PUFA in the lipid supplement has a large impact on the deposition of *n*-6 relative to *n*-3 PUFA in muscle.

Objectives

To determine the effects of including a ruminally protected lipid supplement, in the diet of beef cattle, with an 18:2*n*-6:18:3*n*-3 ratio of 1:1 on the fatty acid composition of muscle neutral and phospholipids and to relate this to meat shelf-life (colour and lipid oxidation) and flavour.

Materials and methods

Thirty two Charolais steers (initial live weight 507 (s.e. 10.3) kg) were fed on *ad libitum* grass silage plus one of four concentrates in which the lipid source was either Megalac (Mega, rich in palmitic acid; 16:0) or PLS (soya beans, linseed and sunflower oils resulting in a 1:1 ratio of 18:2*n*-6:18:3*n*-3): Concentrate 1, (Mega, control) contained 139g/kg Mega; Concentrate 2, (PLS1) contained 67g/kg Mega with 400 g/d PLS fed separately; Concentrate 3, (PLS2) contained 24g/kg Mega with 800 g/d PLS fed separately, Concentrate 4, (PLS3) contained no Mega and 1000 g/d PLS fed separately. Supra-nutritional levels of vitamin E were included in all diets (350 IU/kg concentrate). At 48h post-mortem, samples of m. *longissimus thoracis* at the 11th rib were removed and blast frozen for fatty acid analysis. Other samples of m. *longissimus lumborum* were removed and conditioned for 10 days in vacuum packs at 1ºC, then a joint was frozen for subsequent organoleptic assessment and steaks cut and packed in a modified atmosphere (O_2:CO_2, 75:25). These were displayed for 10 days at 4ºC under 700 lux for 16h out of each 24h to simulate commercial retail display. Colour was measured daily using a Minolta Chroma Meter. Lipid oxidation was determined as thiobarbituric acid reacting substances (TBARS) (Tarladgis *et al*., 1960) after 10d display. After thawing, steaks were cut from the frozen joint, grilled to an internal temperature of 74ºC and sensory assessments made by a 10 member trained taste panel using 100mm unstructured line scales. Lipid was extracted using chloroform/methanol and the neutral and polar lipids separated by silicic acid column chromatography. Fatty acid methyl esters were prepared by alkaline hydrolysis followed by methylation with diazomethane and analysed on a CP Sil 88, 100m x 0.25mm ID column (Chrompack, UK).

Results and discussion

Total lipid, total neutral lipid and total phospholipid fatty acids were not influenced by diet (Tables 1, 2 and 3). The content of the main saturated fatty acids (14:0, 16:0, 18:0) were not different in either lipid fraction, but 18:1*n*-9 was reduced in the neutral lipid (Table 1). On average, feeding PLS increased the content of

18:2*n*-6 and 18:3*n*-3 by a factor of 3.2 and 5.9, respectively in the neutral lipid. In phospholipid, on average, PLS increased the content of 18:2n-6 and 18:3n-3 by 1.86 and 2.31, respectively. Interestingly, in contrast to the neutral lipid, no further increases in either 18:2*n*-6 or 18:3*n*-3 were noted in phospholipid after the first increment of PLS (Table 2). These increases in C18 PUFA in phospholipid were associated with reductions in oleic acid, 18:1*n*-9 and DPA, 22:5*n*-3. The percentage of 18:2*n*-6 and 18:3*n*-3 in muscle total lipid on the highest level, PLS3, was 3.2 and 5.9%. This compares with 9.3 and 1.9% for 18:2n-6 and 18:3n-3 at the highest inclusion of a PLS (with a 2.4:1 18:2n-6 and 18:3n-3) in the study by Scollan *et al*. (2003). The P:S ratio increased markedly ($P < 0.001$) while the *n*-6:*n*-3 ratio was decreased ($P < 0.001$; Table 3).

The increase in PUFA in the meat, with increasing PLS fed, was associated with increased susceptibility to lipid oxidation as reflected in higher TBARS (Table 3) and colour deterioration (Figure 1). Colour acceptability (saturation index > 18) was decreased by approximately 2 days for PLS3 relative to Mega. The high levels of vitamin E fed to counteract the effects of increasing PUFA in the tissue were not sufficient to negate the negative effects on colour shelf life or lipid oxidation. There was a trend for the tenderness of meat samples to increase with an increase in the amount of protected lipid fed (Table 4). PLS2 and PLS3 samples were significantly juicier than samples from PLS1. There was a trend for beefy flavours to decline with increased supplementation. However, abnormal flavour increased significantly with increasing PLS. This was associated with a trend for greasy to increase, a significant rise in rancid and a trend for vegetable/grassy and dairy notes to increase. These trends in abnormal flavours resulted in a significant reduction in overall liking for PLS2 and PLS3 compared to PLS1 and control.

The fatty acid changes had marked effects on lipid oxidation, colour shelf life and beef flavour. These results provide very clear evidence that these characteristics are inter-related. Increasing concentrations of PUFA in meat to the extent seen here would therefore not be a commercial proposition without further antioxidant protection. This would include careful meat processing procedures as anything that increases oxidative susceptibility such as mincing or cooking would further increase lipid oxidation.

Conclusions

The protected lipid supplement rich in 18:2*n*-6 and 18:3*n*-3 resulted in large increases in these fatty acids in beef muscle. This resulted in a favourable increase in the P:S ratio and a beneficially lower *n*-6:*n*-3 ratio than that observed in our previous study (Scollan *et al*., 2003). The changes in fatty acid content of the meat had marked effects on lipid oxidation, colour shelf life and beef flavour. The high levels of vitamin E fed were insufficient to significantly reduce the negative effects of increasing PUFA in the meat on lipid stability and colour shelf life. There is a need to determine the role of antioxidants in enhancing the stability of meat which has enriched levels of PUFA.

IMAGE ANALYSIS FOR CHARACTERIZATION OF THE INTRAMUSCULAR CONNECTIVE TISSUE IN MEAT

Sifre-Maunier L., Taylor R.G., Berge P., Bonny J.M.
Unité de Recherches sur la Viande, INRA de Clermont-Ferrand 63122 Saint Genès Champanelle, France

Background

Image analysis is a promising approach to characterize the spatial organization of the intramuscular connective tissue (IMCT) using morphological features. A common approach is based on segmentation which consists in subdividing an image into its constituent parts (Pal and Pal, 1993). In meat science segmentation has been principally used to quantify fat distribution on steaks and to determine skeletal maturity of carcass (Tan, 2004). We developed and applied an adaptative segmentation for extracting IMCT thus permitting characterization of spatial organization from visible images of histological sections of muscles. It can also be used to quantify morphometrical parameters on segmented objects, such as size or network hierarchy parameters.

Objectives

This paper describes a practical approach, called Fuzzy Cards Thresholding (FCT), based on building reference maps: a) to set up thresholding rules based on the features calculated from the intensity histogram, b) to quantify the precision of the segmentation and to compare it with other methods. Once the optimal segmentation was obtained, morphometrical parameters characterizing the distribution of IMCT were quantified and compared within several muscle types.

Materials and methods

Animals and sample preparation Muscle samples were taken from 2-year-old Aubrac heifers (n=4). *Biceps femoris* (BF), *Infraspinatus* (IS), *Longissimus thoracis* (LT) and *Pectoralis profundus* (PP) were chosen for their different architectures, including fiber bundle size, IMCT thickness and hierarchy. Samples were aged 8 days *post mortem* at 4°C before cutting and staining. Muscles samples of 20×20×10 mm^3 were frozen with isopentane chilled by liquid nitrogen at -160°C. They were cut to make transversal sections of 0.01 mm thickness. Perimysial tissue was revealed with red Sirius stain, specific for collagen, which is the main connective tissue component. A second group of animals (8 Charolais cows) was submitted to the same treatment and used for collagen amount determination and to study the differences between muscles.

Optimization of thresholding using fuzzy reference maps The process is based on 4 steps: a) to build the fuzzy reference maps, b) to threshold the map at different confidence levels, c) to define the optimal threshold which minimizes the difference between the thresholded image and the reference card, and d) from n cards obtained on different animals and muscles, to define the thresholding rules according to the histogram features of the images.

Each sample image was digitalized with a transmitting light box and a CCD camera JAI CV-M300 coupled with a macroscopic objective leading to a pixel size of 6.8 $.10^{-4}$ mm² (figure 1). Visilog software (Noesis, France) has been used for image processing. The grey level histogram, in the whole field of view, was computed and features such as the mean, standard deviation, skewness and kurtosis were calculated from the histogram moments. Ten test images of 50 mm² of section were displayed at random to a panel of 20 non-trained judges. The judges had to draw (with a one-pixel-thick and 0 grey level line) what they thought to be IMCT (figure 2b). The thickest segments which everyone could identify had already been labelled by thresholding at a high level. The work of the judges was to trace the thinnest elements of the network which are more difficult to identify. Their digital drawings were averaged for each image to obtain the fuzzy reference maps for the perimysial network (figure 2c).

By construction, a fuzzy reference map is in grey levels. It has to be binarized in order to be compared with the result of our adaptive threshold method. When the reference map is thresholded, the resultant binary image (S_ε) is composed of the pixels selected by a percentage of judges called confidence level, ε. A high ε (ε

> 50%) corresponds to a consensual set of IMCT, which favours points selected by most of the judges. In this case, S_ε represents the thick segments, which are distinguished without ambiguity (figure 2d). On the contrary, for $\varepsilon < 50\%$, the thresholded reference map includes the thinner segments (figure 2e).
To evaluate the quality of the segmentation for a given ε, the total error E has been computed as a performance index. It is the sum of two error terms, the fraction *Eoo* of pixels of the image belonging to the object (perimysium) which are falsely attributed to the background and the fraction *Eob* of pixels of the image belonging to the background, which are falsely attributed to the objects. As *Eob* decreases and *Eoo* increases as function of threshold, *E* exhibits a local minimum, which is the optimal value of t (t*), that is a compromise between *Eoo* and *Eob* (figure 3). The t* value is obtained by minimizing the total error E which is the fraction of pixels which have been segmented improperly and it is determined for an a priori fixed confidence level.
Using SAS software (Statistical Analysis Systems Institute, 1995), a stepwise multiple linear regression (GLM procedure) was performed between t* values and histogram features for each reference image (n= 10) at different confidence levels (from 30% to 80%). Thus models were obtained that could predict the thresholding level of all the images taken in the same conditions as our test images, for each confidence level.
Validation of the method The validation was based on a comparison of our method with a reference method already optimized and proposed by Rosin (2001) for the segmentation of this type of images showing a unimodal histogram (RM). It considered a dominant population in the image that produces one main peak relative to the secondary population. This latter class may or may not produce a discernible peak, but needs to be reasonably well separated from the bulk peak to avoid being swamped by it.
Eight sections from 4 muscles of Charolais cows were used. They were stained, digitalized and then the collagen amount was determined as the amount of stain fixed by the collagen fibers and then eluted. (Lopez De Leon and Rojkind, 1985).

Results and discussion

The reference maps Each pixel of the reference map had a value corresponding to a grey level from 0 (black) to 255 (white). A black pixel (0) had a nil probability to belong to the perimysium (none of the judges designated it). A white pixel (255) had the maximal probability (all judges designated it). So the maps were fuzzy because a pixel was attributed a probability of belonging to the perimysium and not a cut decision. The decision happened when a confidence level was chosen. The pixels of the maps can only take a discrete number of intensities equal to the expert number. The maps give information on the location of the connective tissue and also on the error (confidence level, ε) made by keeping this pixel in the "perimysium" class of objects. In this way, the maps give different patterns according to ε. We observed that there was a natural correspondence between ε and the thickness of the thresholded segments.
Thresholding rules For each image the optimal threshold was determined at different confidence levels as shown in table 1. The optimal threshold increased when ε decreased. It segmented lighter and thinner objects, because low ε values accept pixels with a lower belonging probability.
The results of the multiple linear regressions are shown in table 1. They are all linear combinations of the mean and standard deviation or skewness. Models are very informative for each ε value from 30% to 80%. At high confidence levels (70%, 75% and 80%) which correspond to the thick network, the standard error was superior to 3 grey levels. Indeed the segmentation quality was less sensitive to the threshold choice because of the high contrast between myofibers and IMCT. The effective error had fewer consequences than at a small ε values, because it was far from the over segmentation zone.
Comparison with Rosin's method The performance index decreased when the confidence level increased and the quality of segmentation improved (figures 4 and 5). Indeed for high ε values, there were fewer pixels to detect and a higher contrast. RM performance index varies more than with our method (29.6% and 22.2% respectively). This was due to the fact that our method (FCT) adapts the threshold to the confidence level, while RM is adaptative to image context and gives a unique threshold whatever the value of ε. RM *Eoo* (segmentation on thin segments), was almost 2 fold higher at low ε, which indicated that it did not take into account thin segments. With FCT, *Eoo* and *Eob* decreased when ε increased and the indexes were lower than for RM. A better segmentation was obtained with FCT which could be adapted to ε. Indeed when ε decreased, the thinner frame had to be segmented, so the threshold needed to go towards the lighter grey

levels. *Eob* is higher but the performance index stayed inferior to RM. In fact, *Eob* is inherent to the quality of the image, and in particular to its background homogeneity.
The segmentation performance did not actually seem to be largely improved by decreasing ε. However, a slight difference in the performance index (E) could imply a big difference in the segmentation. Only few pixels belonging to the thinnest connective network were detected, but they may provide valuable information on the hierarchy of the network (figure 5). However ε was limited to 55% for this experiment.
Comparison with collagen amount determination
R^2 was the highest at high confidence levels and it decreased markedly with ε (table 2). Thick networks seemed to have more influence on collagen content, since they represented a large number of pixels. Moreover, detection of parasite pixels increased because of the error of the thresholding rules, and it depreciated the correlation when ε decreased.
Discriminating parameters between muscles Three variables were calculated: the area of the segmented network, its length and its average thickness, considered as the ratio between the area and the length (table 3). For ε = 80% (thickest segmentation), the thickness of the segments showed differences between muscles which present visually a thick network (BF, PP), as shown in figure 1, whereas there was no difference in thickness between muscles with thin connective tissue (IS, LT). In contrast, for ε =55% (segmentation of the whole network), IS and LT were discriminated. The values of thickness were in the same range as those published by Geesink et al (1995). Thickness seemed to be related with tenderness because BF and PP (tough muscles) have the thickest networks. The area of the network could not discriminate BF and PP, as the collagen amount did. BF had the largest area of IMCT at 80%, and the smallest at 55%. It had a thick network and few thin segments. In contrast, IS had the largest area of IMCT at 55%. The total length of the network, which was homogeneous to the network branching, segregated the 4 muscles at high confidence levels. PP and IS which showed the greatest degree of branching had longer networks than LT and BF.

Conclusions

We have developed an automatic and validated approach for global thresholding of unimodal images of the intramuscular connective tissue network in muscle and meat. Our method gives objective variables for characterization of the IMCT, and gives further insights into those factors which determine the tenderness of meat by studying the IMCT. It is intended to extend its application to the characterization of the fascicles delimited by the IMCT. As a generic method, it will be adapted to magnetic resonance images at a higher scale on the same samples.

Background

Texture, flavour and tenderness are attributes valued by consumers as very important in relation to the eating quality of meat. Different populations of consumers have different preferences for these quality attributes, something that affects the market for all types of meat. However, regardless of the consumer group, the consistency of meat quality is very important, and the product should be of the same quality every time it is purchased. In the Australian beef grading system Meat Standards Australia (MSA) these consumer important sensory quality attributes have been weighted in an overall score where tenderness represents 40%, flavour 20%, juiciness 10% and overall liking 30% (MSA, 2001).

Variation in meat tenderness and techniques developed to minimise this variation, have been investigated in several animal species over a long time period. However, there are very few studies performed on sensory quality attributes of deer meat (venison). Stevenson-Barry *et al* (1999) found a similar relationship between meat ultimate pH and tenderness of red deer (*Cervus elaphus*) venison (*M. longissimus*) to that reported for beef (Smulders *et al*., 1990; Barnier, *et al*., 1992). In contrast, reindeer (*Rangifer tarandus tarandus*) *M. longissimus* has been found to be extremely tender regardless of ultimate pH (Wiklund *et al*., 1997). This phenomenon has been related to the speed of post mortem proteolysis (Wiklund *et al*., 1997) and the small muscle fibre size (Taylor *et al*., 2002) in reindeer.

It is well known that the conditions during rigor development (*e.g.* muscle pH decline, temperature/pH relationship and carcass treatment) are very important in controlling meat tenderisation (Dransfield, 1994). Therefore, carcass suspension techniques have been studied for beef (Hostetler *et al*., 1970; Lundesjö Ahnström *et al*., 2003) where the variation in tenderness is considered to be the main reason for consumer dissatisfaction (Koohmaraie, 1996). To our knowledge, the effect of pelvic suspension on tenderness in deer meat has not been previously studied.

Objectives

The objective of this project was to study the effect of pelvic suspension on tenderness in fallow deer meat.

Materials and methods

Eight fallow deer bucks (18 months old, average live weight 42 kg, body condition score (BCS) 2-3 (Flesch, 2000), 7 fallow deer bucks (≥ 36 months old, average live weight 57 kg, BCS 2-3) and 10 fallow deer does (24 months old, average live weight 38 kg, BCS 2-4) raised at the University of Western Sydney, were included in the study. The animals were fasted for 16 h prior to slaughter, stunned with a captive bolt and bled using thoracic stick exsanguination within 10 s of the stun (ethics approval UWS 00.09). The dressed carcasses were split along the mid ventral axis approx. 45 – 75 min post slaughter. The left side of each carcass was assigned to Achilles tendon suspension (control treatment) and the right side of each carcass was assigned to pelvic suspension. At 2 days post slaughter, 9 selected muscles were collected from each carcass-half (*Mm. semimembranosus, adductor femoris, biceps femoris, semitendinosus, vastus lateralis, rectus femoris, psoas major, longissimus* and *supra spinatus*). The meat samples were vacuum packaged, frozen and stored at -20° C until analysis. Meat samples were cooked on a Silex grill for 4-7 min at 240° C and then wrapped in aluminium foil and allowed to rest for 5 min. Internal temperature was measured during and after cooking to 60-65° C, which is equivalent to medium doneness according to the method described by Shaw (2000). Meat samples were cut to a 1 cm^2 core, with a minimum of 5 replicate sub-samples taken from each muscle for analysis. Meat tenderness was measured using a Warner Bratzler Shear force attachment on a

Stable Micro System TAXT2. Texture analysis was measured by means of force versus time in compression with a crosshead speed of 0.8 mm/s and a trigger force of 10 g with a contact area of 1 mm and contact force of 5 g to determine peak force. The data for each experiment was analysed statistically by residual maximum likelihood (Patterson & Thompson, 1971), with the random effects given by reading within muscle within animal, and the fixed effects by hanging treatment, muscle and their interaction, using the statistical package GenStat (2002).

Results and discussion

The present results suggest that pelvic suspension of the carcasses had the greatest impact on meat tenderness in venison from the young male fallow deer (18 months old, Fig. 1), some impact on tenderness in venison from the older male deer (≥ 36 months old, Fig. 2) but no significant impact at all on tenderness in venison from the female deer (24 months old, Fig 3). In studies of beef, similar differences in effect of pelvic suspension on meat tenderness for bulls and heifers have been reported. The tenderness in meat from bulls was more improved as an effect of pelvic suspension compared with meat from the heifers (Fisher, 1994; Lundesjö Ahnström *et al*., 2003).

In the carcasses from the young fallow deer bucks, the tenderness of the following muscles was significantly improved ($p \leq 0.05$) as a result of pelvic suspension; *Mm. longissimus, biceps femoris, semimebranosus, adductor femoris* and *vastus lateralis*. These results are in good agreement with earlier studies on beef, where the tenderness of *Mm. longissimus, semimembranosus* and *adductor femoris* was positively affected by pelvic suspension (Hostetler *et al*., 1970; Bouton *et al*., 1973). For the older fallow deer bucks, significant effects of pelvic suspension on meat tenderness were found in *Mm. biceps femoris* and *semimembranosus*. The muscles that improved in tenderness as a result of pelvic suspension in the present study are all part of the most valuable cuts in a deer carcass; *M. longissimus* (striploin), *Mm. semimembranosus* and *adductor femoris* (topside), *M. biceps femoris* (silverside) and *M. vastus lateralis* (knuckle).

Conclusions

The positive effect of pelvic suspension on tenderness in venison from the young male fallow deer is important information to consider for the Australian deer industry. This type of animal represents the deer most likely to be supplied for commercial slaughter in Australia. In addition, the important commercial cuts from female deer were generally more tender than the same cuts from males. The slaughter of female deer therefore provides a good option for farmers wishing to supply chilled venison year-round, especially at times of the year when the quality of venison from male deer is negatively affected by the breeding season.

EFFECTS OF HIGH OXYGEN PACKAGING ON TENDERNESS AND QUALITY CHARACTERISTICS OF BEEF *LONGISSIMUS* MUSCLES

Oddvin Sørheim[1], Magnus Wahlgren[2], Bjørg Narum Nilsen[1] and Per Lea[1]

[1]Matforsk AS – Norwegian Food Research Institute, Osloveien 1, N-1430 Ås, Norway. [2]Norway Meat, PO Box 360 Økern, N-0513 Oslo, Norway

Background

High oxygen atmospheres, usually consisting of 70 - 80 % oxygen (O_2) and 20 - 30 % carbon dioxide (CO_2) are commonly used for retail meat packaging. The formation of bright red oxymyoglobin is beneficial, but pigment and lipid oxidation, premature browning of cooked meat, as well as microbiological spoilage, are more prone in high O_2 than anaerobic environments (Hunt *et al*., 1999; Sørheim *et al*., 1999; Jakobsen and Bertelsen, 2000; Tørngren 2003). Recent findings indicate that display of beef in high O_2 atmospheres negatively affects the development of tenderness of the meat (Tørngren, 2003). Little information exists on the extent and causes for the detrimental effect of high O_2 packaging on tenderness. Aitch bone suspension from the *obturator foramen* is a well-known method for stretching pre-rigor muscles in beef carcass sides, thereby reducing muscle contraction and toughening (Hostetler *et al*., 1972). If a detrimental effect of high O_2 display on tenderness development is confirmed, it may be desirable to combine this packaging technology with a method like aitch bone suspension to ensure a satisfactory tenderness and quality of the meat.

Objectives

To study the effects of aitch bone suspension and high O_2 packaging on tenderness and other quality characteristics of beef *longissimus dorsi* (LD) muscles.

Materials and methods

The experiment consisted of LD`s from 4 treatments.
Nine bulls were assigned to treatments A and B:
A – aitch bone suspension + 14 days of high O_2 display of steaks
B – aitch bone suspension + 14 days of vacuum display of steaks
Nine other bulls were assigned to treatment C and D:
C – aitch bone suspension + 14 days of high O_2 display of steaks (equal to A)
D – traditional Achilles tendon suspension + 7 days of vacuum storage of whole muscles + 7 days of high O_2 display of steaks.

The eighteen bulls were of different breeds and were sampled randomly at a commercial abattoir. The average carcass weight was 349 kg within a range of 264-426 kg. The carcasses were electrically stimulated with low voltage. The sides of the carcasses were assigned to two treatments with alternate left and right sides for each treatment. Aitch bone suspension was performed within 60 minutes p.m. The sides were chilled at an air temperature of appr. 4 °C to an average LD core temperature of 11 °C at 10 hours p.m. Two days after slaughter the sides were deboned, and the LD`s were cut in steaks 15 mm thick, except 35 mm for Warner – Bratzler (WB) analysis. Steaks were packaged either in 70 % O_2/ 30 % CO_2 in trays on a Ross Cryovac tray top-seal machine (Ross Cryovac) with film and tray oxygen transmission rates of appr. 15 $cm^3/m^2/24$ h. at 23 °C and 0 % RH, or in vacuum on an Intevac IN30 chamber machine (Intevac Verpackungsmaschinen, Wallenhorst, Germany) with polyamide bags with oxygen transmission rate of 40 $cm^3/m^2/24$ h. at 23 °C and 75 % RH. Meat for all analyses was packaged, except unpackaged meat for the first WB and sensory analyses at 3 days p.m. The meat was displayed in darkness at 4 °C for 15 days.

The following analyses were performed at 3, 10 and 17 days p.m.:

- Warner-Bratzler peak shear force was measured on samples heated in a circulating water bath at 70 °C for 50 min. to a core temperature of 69.5 °C and cut in strips of 10 x 10 x 35 mm with 10 replicates per sample (not at 10 days p.m.)
- Sensory analysis was performed with 11 trained assessors with a quality descriptive test (ISO 6564) for tenderness, hardness, juiciness, rancid taste and rancid odour on samples heated at 70 °C for 40 min. in a water bath to 70 °C core temperature with evaluation in red light for masking possible differences in premature browning (Hunt *et al*., 1999)
- L*a*b* (lightness, redness, yellowness) was analysed with a Minolta Chroma Meter CR-300 (Minolta Camera Co., Osaka, Japan) with 8 mm viewing port and illuminant D_{65} with 3 replicate measurements per sample (treatment D was not analysed at 3 days p.m.)

In the statistical methods, the emphasis was on comparing the effect of display time separately for each treatment, as opposed to comparing the treatments. Analysis of variance (ANOVA) was used for the analyses, with Tukey`s Multiple Comparison Test to determine in detail which groups or display times that were different (SAS System Release 8.2, SAS Institute Inc., Cary, NC, USA).

Results and discussion

a,b. Means in the same column with different letters are significantly different ($p < 0.05$).

Warner-Bratzler shear force (Table 1) and sensory tenderness and hardness values (Table 2) showed that treatment B with 14 days of vacuum display improved the tenderness of the meat ($p < 0.05$), but particularly during the first 7 days, as demonstrated by the sensory analysis. Over all, treatment B with a combination of aitch bone suspension and vacuum display gave the most tender meat. Meat of treatment A, with 14 days of high O_2 display, did not significantly change in shear force, tenderness and hardness during the display period ($p > 0.05$); neither did meat of treatment C change in shear force and hardness ($p > 0.05$). Meat of treatment D with 7 days of vacuum, followed by 7 days of high O_2 display, significantly increased in tenderness and decreased in hardness during the first 7 days of vacuum ($p < 0.05$), but did not change in tenderness or hardness during the subsequent high O_2 display ($p > 0.05$). Steaks of treatments A and C in high O_2 lost juiciness after 7 days display ($p < 0.05$), as well as steaks from treatment D between days 10 and 17 p.m. Vacuum packaging did not alter juiciness during display, either for treatment B or D ($p > 0.05$). The lack of tenderisation by high O_2 treatments is in support to a previous study by Tørngren (2003), who found that beef LD steaks displayed for 16 days in 80 % O_2 / 20 % CO_2 were less tender than steaks displayed in

vacuum or 50 % CO_2/ 50 % N_2. In a comparison of 100 % CO_2 and vacuum storage of beef, no differences in tenderness were found during storage (Bell *et al*., 1996), making it likely that O_2, and not CO_2, is the gas responsible for inadequate tenderisation.

Before display, meat assigned to all treatments was relatively tender, due to relatively high carcass weights, use of electrical stimulation and relatively slow chilling. Although meat treated with aitch bone suspension tended to be slightly more tender than meat from traditional Achilles tendon suspension at start of packaging, no significant differences were found in average peak force between treatments C and D ($p > 0.05$). However, aitch bone suspension reduced the standard deviation of the WB shear force within the group by both day 3 and 17 p.m. compared to Achilles tendon suspension, particularly by lower force of LD`s from the toughest carcasses. Previous studies showed that aitch bone suspension of beef and veal carcasses was significantly beneficial to tenderness at conditions inducing cold shortening, but to various degrees at slow chilling rates (Sørheim *et al*., 2001; Wahlgren and Kalbakk, 2002; Wahlgren *et al*., 2002). In these studies, aitch bone suspension also reduced the variation in WB shear force by improving tenderness of the toughest meat.

Table 3. Sensory analysis of rancid taste and odour of LD steaks during display at 4 °C. Scale: 1 = none, 9 = very much.

Time, days p.m.	Rancid taste Treatment				Rancid odour Treatment			
	A	B	C	D	A	B	C	D
3	1.1 b	1.1 b	1.1 b	1.0 b	1.1 b	1.1 b	1.1 b	1.1 b
10	2.9 a	1.1 b	2.3 a	1.1 b	1.8 ab	1.3 b	1.9 a	1.3 ab
17	3.5 a	2.5 a	2.4 a	2.4 a	2.4 a	2.5 a	2.0 a	2.1 a

For description of treatments, see materials and methods.
a,b. Means in the same column with different letters are significantly different ($p < 0.05$)

High O_2 display increased rate of development of rancid taste in the steaks (Table 3), as shown for treatment A and C as early as 7 days display, and for treatment D at 14 days of display ($p < 0.05$). An increased rancid odour developed in meat of treatment C after 7 days display ($p < 0.05$). The findings are in agreement with Jakobsen and Bertelsen (2000), where 55 – 80 % O_2 storage of beef LD steaks at 4 - 8 °C caused lipid oxidation.

Table 4. a* (redness) and b* (yellowness) values of LD steaks during display at 4 °C.

Time, days p.m.	a* Treatment				b* Treatment			
	A	B	C	D	A	B	C	D

For description of treatments, see materials and methods.
a,b,c. Means in the same coloum with different letters are significantly different ($p < 0.05$)

Packaging conditions affected meat colour (Table 4). a* redness values of the high O_2 treatments A, C and D decreased during display, but not below the a* value of the vacuum treatment B at 14 days. b* yellowness values were considerably higher for all O_2 treatments than the vacuum treatment at all sampling times ($p < 0.05$). L* lightness values were higher for treatment A than B at all sampling times ($p < 0.05$), but treatment C and D did not differ in L* values ($p > 0.05$) (results not shown). Although some redness was lost from high O_2 samples during the 14 days display, the meat was still fairly red and not discoloured at end of display. Vacuum samples had stable L*, a* and b* values at 3, 10 and 17 days p.m.

Conclusions

The study confirmed previous indications of reduced tenderness development in beef LD steaks displayed in high O_2 atmospheres. In addition, steaks displayed in high O_2 were less juicy. Steaks in vacuum improved in tenderness during the display period, and these steaks were ranked highest in final tenderness. The extent and

causes of the negative effect of high O_2 packaging on tenderness, as well as precautionary measures to reduce or avoid this effect, need to be addressed further. Aitch bone suspension did not significantly improve tenderness, probably because the meat was relatively tender by other tenderizing measures in the experiment, but the variation in tenderness was lower with aitch bone than Achilles tendon suspension. High O_2 display increased rancidity of the meat. The initial bright red colour decreased during high O_2 display, but not to the extent of discolouration.

Acknowledgements

The assistance of Gilde Felleslakteriet in Sem in slaughtering and high O_2 packaging is greatly acknowledged. The authors are grateful to the technical assistance of Grethe Enersen, Inger-Johanne Fjøsne, Håvard Johansen, Asgeir Nilsen and Karin Solgaard at Matforsk. Dr. Kjell Ivar Hildrum at Matforsk is thanked for valuable advice to the article.

EFFECT OF GENETICS ON MEAT QUALITY AND SENSORY PROPERTIES OF PORK

Background

The swine industry has achieved tremendous progress in genetic gains related to growth and feed efficiency as well as carcass fat reduction. As a consequence of these improvements there has been an increasing perception that the eating quality of pork has deteriorated over time. Some of these concerns are related to the reduction in fat content of muscle, i.e. intra-muscular fat, other concerns are related to the post-mortem biochemistry of pork, particularly the rate and extent of pH decline and the extent of myofibrillar proteolysis.

Objectives

Traits related to meat quality were investigated as part of a larger study, where overall carcass composition was studied in different PIC lines. Physico-chemical traits were compared between the different lines and related to sensory evaluations as well as correlated with each other. The literature provides us with many reports on the relationships between these predictive measurements and organoleptic parameters. However, this data set is quite unique in that it combines 10 different PIC lines of various phenotypic ranges.

Materials and methods

Animals came from the PIC genetic nucleus in Kipling Saskatchewan, Canada and was comprised of 30 market weight gilts from each of 10 lines for a total of 300 animals. The lines included the following basic genotypes: Landrace (Land), Large White (LW), Duroc (Dur), White Duroc (WDur), Berkshire (Berk), Hampshire (Hamp), Synthetic line (Syn), Crossbred Berkshire x Hampshire (BH), Pietrain hal negative (Piet-), Pietrain hal positive (Piet+).

Carcass Traits. Fat thickness (mm) and lean tissue depth (mm) were measured with a Hennessey Grading Probe at the 3rd/4th last ribs, 70 mm from the carcass mid-line approximately 40 minutes after harvest. Dissectible lean was determined as the weight of dissectible lean in the picnic, butt, loin, ham primal cuts plus the weight of the skinned trimmed belly and ribs as a percentage of cold side weight.

Muscle Quality Traits. The pH at 45 minutes (pH-45min) and 48 hours (pH-48h) post-slaughter, CIE L*, intramuscular fat (IMF), drip loss and shear value of the LT (*longissimus thoracis*) muscle were measured as described by Murray et al. (2001).

Sensory Traits. Perceived juiciness, flavor intensity, overall tenderness and overall palatability were assessed using a trained taste panel as described by Jeremiah et al. (1995).

Biochemical Measurements. LT muscle fiber types were determined by the combined SDH and myosin-ATPase method as described by Aalhus et al (1997). Samples, removed from LT muscles at 24 h post-harvest, were used to determine glycogen, glucose and lactate using a YSI Glucose-Lactate Analyzer and glucose-6-phosphate (Lang and Michal 1974). Glycolytic potential (GP) was calculated as (2*[glycogen + glucose + glucose-6-phosphate] + lactate) and is presented as μmoles lactate-equivalents per gram of muscle.

Statistical Analyses. Data were analyzed using the GLM procedure of SAS (2001) with statistical model slaughter day and line as classification variables. Least square means were compared by t-test. Correlation analyses made use of the CORR procedure (SAS 2001).

Results and discussion

Least squares means for meat and carcass traits are presented in Table 1. For most of the traits, Berk and Piet are at the two extremes. A number of line comparisons are highlighted below.

Carcass Traits. Based on both dissectible lean and backfat thickness, Berk carcasses are the fattest and Piet carcasses are the leanest. The genotypes used as sire lines, arranged in order of dissectible lean, are Dur, Hamp and Syn, with the Syn yielding significantly more dissectible lean than the Dur and having a much greater muscle depth than all lines except the Pietrain lines.

LT Quality Traits. Muscle traits differ significantly among genotypes, particularly for the Piet+, a halothane carrier animal that differentiates itself from the other genotypes for all of the muscle traits. Indeed this genotype shows the lowest pH-45min and pH-48h, the highest L* value, the greatest drip loss, lowest IMF and highest shear value. This is typical of what is expected for animals homozygous for the hal gene (Murray and Jones 1994). The Berk and the BH are at the other end of the spectrum for all of the traits. Interestingly the Dur shows intermediate pH values but has IMF levels as high as the Berk and the BH. It is also similar to the Berk in terms of shear value. This differs somewhat from the findings of Suzuki et al (2003) that Berkshire pigs had less IMF and lower drip than the Duroc pigs. Shear values are significantly higher for the Piet+, while the BH is the lowest, although not significantly different from the Berk or Hamp.

LT Sensory Traits. Sensory evaluation results indicate that the Piet has the lowest juiciness and palatability scores. Of interest is the fact that the Berk, BH and Duroc display sensory scores that are quite similar. The Hamp closely follows the Duroc. Similar studies (Brewer et al, 2002) support these observations.

LT Biochemical Measurements: Genotypes differ in their biochemical properties. The extremes in these measurements are depicted by the Piet+ and the Hamp, the latter having a lower proportion of red fiber and higher proportion of white fibers than the Piet+, the Berk being closer to the Piet+ for these traits. Klont et al. (1998) provides a good review of fiber type implications on meat quality. Residual glycogen is included to show that at 24 hours post-mortem metabolizable glycogen is present in all genotypes. GP is lowest for the Berk and highest for the Piet- which is closely followed by the Dur.

Correlation coefficients (Table 2) do not demonstrate a very high degree of association between the carcass, muscle quality, biochemical and sensory traits. The drip loss followed by pH-45min and IMF values seem to be the most related to juiciness, overall tenderness and overall palatability, although they explain at best approximately only 22% of the variation for a given trait (i.e. r=0.47 for pH-45min vs juiciness). Van Laack et al. (2001) found r values between IMF and shear value of –0.21 after 7 days of aging. Muscle quality traits are interrelated. The pH-48h is related to L* (r=-0.39) and drip (r=-0.33), as found by Huff-Lonergan et al. (2002). The pH-45min also show strong relationships with L* (r=-0.52) and drip loss (r=-0.68). The correlation between pH-48h and GP is quite high (r=-0.63) compared to the value of 0.39 reported by Huff-Lonergan et al. (2002).

Conclusions

Results from this study position the Duroc sire as potentially able to deliver fresh meat quality equivalent to the Berk, particularly with respect to marbling or intramuscular fat, in a carcass that has higher dissectible lean content. If IMF is not an issue the Syn genotype has the potential to deliver high meat quality at dissectible lean contents close to the Piet genotypes. Comparison of the ten PIC genetic lines of swine clearly demonstrates great diversity in carcass leanness, and muscle physical, sensory and biochemical traits. Appropriate combinations of these lines, along with a suitable nutritional regime, should produce the types of market pigs required to satisfy the diversity in current markets.

THE EFFECT OF INTRAMUSCULAR FAT ON EATING QUALITY OF PORK DEPENDING ON END POINT TEMPERATURE

M. D. Aaslyng and Støier. S
The Danish Meat Research Institute, Maglegårdsvej 2, DK-4000 Roskilde

Background

Intramuscular fat (IMF) has for long been known to increase the tenderness of meat. However, the extent of the effect of the IMF has been different in different experiments which might indicate that the effect depends on factors like aging time, end point temperature etc. This leads to a theory that the IMF fat increases the robustness of the meat towards a rougher treatment.

Objectives

The objective of this study was to investigate the effect of IMF on the eating quality of pork, *longissimus dorsi* (LD) and *biceps femoris* (BF), cooked to two end point temperatures to find out whether the IMF would increase the robustness of the meat. In LD the effect of fatty acid composition was also investigated.

Materials and methods

Biceps femoris: BF from two groups of slaughter pigs (DLY), one group fed with roughage (IMF 2.3%, std. 0.6) and one with feed without roughage (IMF 3.3%, std 0.8) (n=20 per group), was excised from one side the day after slaughter and frozen at -18°C without further aging. The meat was cooked as whole roasts in the oven at a temperature of 140°C until the meat had an end point temperature of 65°C or 75°C respectively. A trained sensory panel conducted a sensory profile with the following attributes: Hardness at first bite, tenderness, chewing time, sour flavour, piggy flavour, colour (light to dark grey), uneven colour. On another piece of meat the juiciness was assessed as juiciness after 3 chews (juiciness 1), juiciness after 10 chews (juiciness 2) and juiciness when the sample is ready for swallowing (juiciness 3). The attributes were assessed on a 15-cm line scale from nothing (zero) to very much.

Longissimus dorsi: LD was excised from both sides of slaughter pigs selected at random at a Danish abbatoir. The loins were vacuum packed and frozen without further aging (-18°C). They were divided into three groups (n=20) of low (0.8-1.3%), medium (1.6%-2.0%) and high (2.3%-4.1%) IMF. The fatty acid composition of the intramuscular fat was determined by GC-FID after extraction. The meat was pan-fried as 2-cm thick chops until an end point temperature of 65°C or 80°C. A trained sensory panel conducted a sensory profile with the following attributes: Hardness while cutting, hardness at first bite, tenderness, fibrous, crumbliness, chewing time, chewing rest, roasted meat flavour, sour flavour, piggy flavour. On a separate piece of meat the juiciness was assessed after 3 chews and after 20 chews. The attributes were assessed on a 15-cm line-scale from nothing (zero) to very much.

Results and discussion

Biceps femoris: There were no interactions between IMF content and end point temperature meaning that the effects of IMF was the same for both temperatures. The content of IMF caused a significant decrease in hardness at first bite, chewing time and the piggy flavour as well as increased the tenderness (Table 1). The IMF had no effect on the juiciness, sour flavour or appearance at either end point temperatures. Higher end point temperatures increased the darkness (6.9 to 8.0) and the uneven colour of the meat (5.0 to 5.6) as well as decreased the juiciness (both 1, 2 and 3 from 6.7/6.8/6.8 to 4.6/4.6/4.5) and the sour flavour (3.9 to 3.6) irrespective of the IMF.

Table 1. Effect of intramuscular fat on the sensory profile of *biceps femoris*

	2.3%	3.3%
Hardness at first bite	7.8	6.3
Tenderness	7.0	8.7
Chewing time	10.4	8.9
Piggy flavour	3.5	2.6

IMF increased the tenderness of BF even though it is a rather tough muscle in which the tenderness to a large degree is determined by the amount of connective tissue. As the tenderness did not decrease when cooked to a higher end point temperature the effect of the IMF on robustness was not seen. IMF did not affect the juiciness and even though the juiciness decreased by an increase of the end point temperature, the IMF had no effect on robustness with respect to this attribute. IMF reduced the piggy flavour irrespective of the end point temperature.

Longissimus dorsi: There was no interaction between IMF and the end point temperature except for juiciness. For the other attributes the effect of IMF was the same irrespective of the temperature (Table 2).

Table 2. Effect of intramuscular fat and end point temperature on the sensory profile of *longissimus dorsi.*

	IMF			End point temperature	
	Low (0.8-1.3%)	Medium (1.6-2.0%)	High (2.3-4.1%)	65°C	80°C
Hardness while cutting	7.7^{a}	6.9^{b}	6.6^{b}	6.6^{a}	7.5^{b}
Hardness at first bite	6.6^{a}	6.3^{b}	6.0^{c}	5.9^{a}	6.8^{b}
Tenderness	5.7^{a}	6.7^{b}	7.3^{c}	7.2^{a}	5.9^{b}
Fibrous	7.8^{a}	7.2^{b}	7.1^{b}	7.1^{a}	7.6^{b}
Crumbliness	0.4	0.3	0.3	0.3	0.4
Chewing time	9.7^{a}	8.9^{b}	8.4^{c}	8.5^{a}	9.5^{b}
Chewing rest	8.7^{a}	7.9^{b}	7.4^{c}	7.6^{a}	8.4^{b}
Roasted meat flavour	7.2^{a}	7.4^{b}	7.6^{b}	7.2^{a}	7.6^{b}
Sour flavour	5.4^{a}	5.2^{b}	5.0^{b}	5.8^{a}	4.6^{b}
Piggy flavour	0.9	0.9	0.9	1.1^{a}	0.7^{b}

Different letters in the same line for IMF respectively end point temperature show significant differences.

IMF increases the tenderness and decreases the hardness, chewing time and chewing rest irrespective of the end point temperature. The tenderness increased over the entire interval of IMF even though the difference was largest from low to medium IMF.

As for the BF an increasing IMF content will decrease the sourness of the meat. As the intensity of piggy flavour was very low, no effect of IMF was seen on this attribute but the roasted meat flavour slightly increased from low to medium IMF whereas a further increase in IMF did not further increase the roasted meat flavour.

There was a significant interaction between IMF and the end point temperature for juiciness both after 3 and after 20 chews (see Table 3). At the low end point temperature there was no difference between IMF groups whereas the group with low IMF had a lower juiciness compared to the other groups at 80°C.

Table 3. Effect of IMF in LD on juiciness depending on end point temperature.

End point temperature	65°C			80°C		
IMF-group	Low (0.8-1.3%)	Medium (1.6-2.0%)	High (2.3-4.1%)	Low (0.8-1.3%)	Medium (1.6-2.0%)	High (2.3-4.1%)
Juiciness, 3 chews	4.7[a]	4.7[a]	4.6[a]	2.7[b*]	3.1[c]	3.0[c]
Juiciness 20 chews	8.6[a]	8.4[a]	8.5[a]	5.5[b]	6.0[c]	5.9[c]

Different letters in same line shows significant differences *: significance only P=0.06

The fatty acid composition was analysed and given as percentage of the total fatty acid content. The phospholipids are more unsaturated compared to the triglycerides. As the amount of phospholipids are almost the same for all samples the amount of triglycerides will vary with increasing amount of intramuscular fat. The degree of saturation will therefore be larger in the samples with a high amount of IMF compared to those with a low amount of IMF. To investigate the effect of fatty acid composition on the texture we did a PLS-regression with the absolute content of fatty acids (% fatty acid*content of IMF) as X-matrix and the texture attribute as Y-matrix for each of the three IMF-groups.

The composition of fatty acids did only explain 26% of the variation in the group with low intramuscular fat but it explained 44% of the variation in the other two groups. The fatty acid composition seems therefore to have a larger influence on the texture in the triglycerides compared to the phospholipids. Table 4 shows the correlation between measured and predicted value of the texture attributes predicted from the fatty acid composition for each of the three IMF-groups.

Table 4. Correlation (calibrated) between measured and predicted value of the sensory attributes predicted from the fatty acid composition.

	Hardness at cutting	Hardness at first bite	Tenderness	Chewing time	Chewing rest	Fibrous	Crumbleness
Low IMF 0.8-1.3%	0.45	0.47	0.44	0.46	0.50	0.49	0.46
Medium IMF 1.6-2.0%	0.67	0.72	0.85	0.88	0.88	0.82	0.81
High IMF 2.3-4.1%	0.75	0.75	0.80	0.81	0.82	0.85	0.83

If the amount of intramuscular fat is above a certain level, the fatty acid composition can predict around 80% of the variation in texture.

The regression coefficients showed that it was not a single or a few fatty acids, which influenced the texture. The picture was that the saturated fatty acids had a positive influence on the tenderness whereas the unsaturated fatty acids decreased the tenderness.

Conclusions

Intramuscular fat increases the tenderness in both LD and BF irrespective of end point temperature. The juiciness was only affected in the LD where there was an interaction as there was no difference in juiciness at 65°C whereas the meat with a low content of IMF was less juicy at the low end point temperature. The IMF increases the roasted meat flavour (in LD) and decreases the piggy flavour (BF) and the sour flavour (LD and BF). However, the difference was between the low and medium IMF group as no further increases in IMF did not further affect/change the flavour. The fatty acid composition influenced the texture especially in the medium and high IMF groups. The meat in this experiment w as not aged and the influence of IMF might therefore be smaller had the meat been aged for a longer time.

It can therefore be concluded that the IMF increases the general eating quality of meat irrespective of the cooking temperature.

HOW DIFFERENT OPERATING CONDITIONS OF FILTER PAPER PRESS METHOD AFFECT MEAT WATER HOLDING CAPACITY MEASUREMENT

Tassone, S., Barbera, S. and Battaglini, L.M.
Dipartimento di Scienze Zootecniche - University of Turin, Via L. da Vinci 44 - 10095 Grugliasco, Italy

Background

Water Holding Capacity (WHC) is the ability of meat to hold fully or in part its own water (Honikel, 1987) and it is influenced by the change in volume of myofibril (Offer and Knight, 1988). This qualitative parameter - affecting technological traits, sensory attributes and nutritional constituents - is of primary importance for the Meat Industry which has considerable pressing problems in this area and needs answers to assure firm quality. It is known that meat WHC is a result of metabolic events prior to harvest and slaughter and following the immediate *post mortem* conversion of the muscle to meat in relation to different factors.
Present methods available to measure the WHC of meat and its products (Honikel, 1987; Trout, 1988; Barton-Gade *et al*., 1993), despite many efforts over the years, do not have a sufficient standardization, essential for comparison (Honikel, 1998). It has been particularly observed that the application of Filter Paper Press Method (Grau and Hamm, 1957) - which requires the compression of a little amount of meat on filter paper, the subsequent determination of the surfaces formed by meat and juice and the estimation of the difference between the areas - has been suffering a lot of interpretations and adaptations. Some Authors (Irie *et al*., 1996; Onega *et al.*, 2000; Fiems *et al*., 2003) utilized different filter paper types and amounts of meat; when considering the load, they put it under different pressures and compression times; sometimes they measured surfaces with the aid of a planimeter, at times outlining areas on the original by pencil, or by the use of an optical electronic system (Video Image Analyzer). Finally, Authors even applied different formulae to measure WHC (Wierbicki and Deatherage, 1958; Hofmann *et al.*, 1982; Van Oeckel *et al.*, 1999).
It was necessary to verify if investigations carried out according to different adaptations of Filter Paper Press Method could be directly comparable.

Objectives

The purpose of this study is to verify if different operating conditions (applied load, filter paper type and length of compression) could influence the results in the Water Holding Capacity measurements by Filter Paper Press Method thus hindering the comparing of data coming from different researches.

Materials and methods

The Filter Paper Press Method of Grau and Hamm (1957) for measuring WHC was adopted, but the procedure (load, time and surface measurement) was automated by using an instrument (BT-WHCi) that applies Video Image Analysis (VIA) to area measurement (Barbera, 2003). Water Holding Capacity was investigated on samples of different meats (beef, chicken and pork) obtainable on the market. Experimental data was gathered from the analysis of beef *M. longissimus thoracis et lumborum*, chicken *M. pectoralis major* and pork *M. longissimus dorsi*. The meat, chilled at 4°C and freed from external fat and connective tissue, was rapidly homogenised (Braun Multiquicksystem ZK100) for 10 seconds. A sample of 250 mg of homogenised meat was placed on a filter paper and compressed between two plexiglass sheets. Filter paper was dried in the oven at 105°C and maintained in a dryer until the analysis started. The meat and the liquid areas (mm^2) were measured by VIA, every minute for ten minutes.
Water release was measured in different conditions, referring to the following factors: load applied to compress the meat (294.2, 490.3 and 588.4 N); filter paper type - Whatman 1 (W1) and 42 (W42); animal type to test effectiveness of BT-WHCi, using three animals for each type.
The data were analysed using the SAS 8.2 package. Factorial analysis of covariance for each minute was performed on the three factors and meat sample weight as covariate. The dependent variables obtained were:

- **TAn** (mm^2) — Total Area, n=0 to 10 min;
- **M/Tn** (%) = Meat Area / TAn*100 — Ratio, n=1 to 10 min (Hoffman *et al.*, 1982);
- **LAn** (mm^2) = TAn - Meat Area — Liquid Area, n=1 to 10 min;

- **FWn** (mg of H_2O) = (LAn / 9.48) – 8 Free Water, n=1 to 10 min (Grau and Hamm, 1957).

These dependent variables are an example of a few different ways to express the Water Holding Capacity found in the quoted bibliography.

Results and discussion

A three-factor main effects model (load, filter paper and animal type) and meat sample weight as covariate, was used because interactions among main factors were not statistically significant. The problem to measure the particularly pale meat of pork and the even paler chicken meat was overcome changing the BT-WHCi light threshold (Fig. 1). The covariate (meat sample weight: 250.6±2.9 mg) was not significant, indicating a homogeneous sample preparation. The compression time effect was not submitted to statistic analysis, since the measurement is usually taken at a fixed time, but the increasing trend is clearly evident (Table 1). The loads were respected and variability was kept low: 294.4±2.7, 491.8±2.0 and 584.7±6.2 N. The dependent variable mean data are reported in Table 1, while animal type data were only partially reported in the text.

Total Area

The load effect was always significant and a higher load corresponded to a higher TA. No paper filter effect appeared until the 7th min; TA was significantly higher in W42 between 8th and 10th min. The increasing trend in time observed in TA indicated still available free water beyond the 10th min at 588.4 N load. Significant differences among animal types appeared at all minutes. Values were lower in pork and higher in beef. At the 5th min, Total Areas were: 1234, 1319 and 1397 mm^2 respectively for pork, chicken and beef. A different order was found for the Meat Area (Time 0') that was: beef, pork and chicken (678, 723 and 865 mm^2).

Meat Area / Total Area

The load effect started at the 5th min; M/T grew as the load increased. No effect was ascribed to the filter paper. Decreasing trend in time confirmed the presence of free water still available beyond the 10th min. M/T was significantly different among animal types throughout the ten minutes. Values were lower in beef and higher in chicken meat. The percentages at the 5th min were: 48.4, 59.2 and 65.6% respectively for beef, pork and chicken.

Liquid Area

The load effect appeared at the first min until the 7th min; values were higher with higher load. After the 7th min, no significant differences were seen in LA, though always positively correlated with load. The filter paper effect started at the 7th min with values significantly higher in W42. LA was significantly different among animal types throughout the total elapsed time. Chicken meat had the lowest values and beef the highest ones. The values at the 5th min were: 454, 511 and 720 mm^2 respectively for pork, chicken and beef.

Free Water

FW is a formula based on LA, consequently the effects of the load, the filter paper and the time were the same already observed in Liquid Area. Also FW showed significant differences among animal types throughout the ten minutes. In this case chicken had the lowest values and beef the highest ones. The values at the 5th min were: 39.9, 45.9 and 67.9 mg H_2O for chicken, pork ad beef, equivalent respectively to 16, 18 and 27% of Free Water.

These results confirm that load and paper filter significantly influence WHC values. Different applications of Grau and Hamm's method do not allow to ensure comparable data from researches. Moreover the way of the area measurement must be considered as an important source of variability (planimeter, outlining or not, VIA) which has been solved in this research. Finally, diverse formulae to express WHC complicate comparison, do not highlight considered factor effects and lead to different conclusions, such as evinced by M/T, TA, LA and FW.

Conclusions

The Filter Paper Press Method has the advantage to be rapid and simple but a proper standardisation is necessary. The obtained results clearly show that WHC values depend on: applied load, filter paper type, compression time, area measurement method and the dependent variable used to express it.

In this research all these factors have been kept under control so that it will be possible to define and standardize a set of working conditions and to automate it in a reliable way.

The application to different animal types, in particular chicken, shows that BT-WHCi also works under very difficult light conditions and last but not least, results can be directly comparable.

Many methods and different operating conditions of Filter Paper Press Method have been published in literature causing confusion to interpret data in this field. Now it will be possible to reassess the Filter Paper Press Method and to define the most useful operating conditions for it.
In this way an instrumental technique for rapid screening can be used to measure the meat Water Holding Capacity and improve meat quality control which is of great importance to the Industry and the Consumers.

EFFECTS OF INTRAMUSCULAR FAT DEPOSITION ON THE BEEF TRAITS OF JAPANESE BLACK STEERS

Ueda, Y. [1], Watanabe, A. [1], Higuchi, M. [1], Shingu, H. [1], Kushibiki, S. [2], Shinoda, M. [3]

Background

Marbling score is the most important factor for the carcass classification in Japanese market. Japanese Black cattle, known as "WAGYU", are characterized for their unique ability to deposit a large amount of intramuscular fat in muscles during the fatting period (Zembayashi et al.,1988). Matsuishi et al. (2001) reported that one of the main reasons why Japanese people preferred Wagyu beef was the preferable, sweet and fatty aroma that comes only from high marbling WAGYU. A higher price is therefore paid in Japan for carcasses with more marbling than for those with less marbling. Recently the production of beef containing significant marbling has been more strongly encouraged than previously, which seems to have occurred after the liberalization of beef imports in 1990 because of the need to distinguish domestic beef from imported beef.

Objectives

Beef quality traits as seen in the market place appear to have changed in the last decade due to this trend. Little is known about the effects of increased marbling on beef quality such as chemical composition and free amino acid content. The purpose of this study was to clarify the relationship between fat content and meat quality, and to determine any new trends or characteristics of recent Wagyu meat.

Materials and methods

Twenty-one Japanese Black steers were slaughtered, and a portion of *M. Longissmus thoracicus* (*LT* muscle) was taken from the carcasses and aged at 0°C for 15 days. The sample of *LT* muscle was minced. The moisture content was calculated by the weight difference between before and after freeze-drying. Crude protein was determined by Kjeldahl crude nitrogen analysis and crude fat by Soxhlet extraction. To evaluate the cooking loss and toughness, samples were cut into cubes (ca. 100g each). These samples were weighed before and after cooking, the difference being the rate of cooking loss. Then, the Warner-Bratzler shear force value of cooked sample was measured. Approximately 10 g of fresh muscle was homogenized with an equivalent weight of 5% sulfosalicylic acid and the solution was then used for the analysis of free amino acids by an auto amino acid analyzer.

Results and discussion

Moisture, protein and fat content

As the fat content increased from 4.8% to 39.0%, the moisture decreased linearly from 72.9% to 45.6%, and the coefficient of this correlation was 0.97 ($p<0.01$, Figure 1). In contrast, the protein level was relatively constant with ca. 18% to low fat content. A marked decrease was observed in the region of higher fat content (Figure 2). A linear, piecewise regression model was used to describe the relationship between fat content (x) and protein content (y) and equations were expressed by $y = -0.048x + 19.082$ and $y = -0.288x + 24.578$. The intersection point was $x = 22.867$ ($r^2 = 0.91$). It is generally accepted that the moisture content of bovine muscle has a negative correlation with fat content, and protein is relatively constant irrespective of fat content. Our result of the protein content with lower fat agreed with this statement, but markedly decreased protein has not been reported before. Gotoh et al. (1999) suggested that type I fibers were replaced by type IIB fibers in *LT* muscles during the fatting period. Type I fibers had the ability to accumulate intramuscular fat (Suzuki et al., 1978) and the diameter of type I fibers was shorter than that of type IIB fibers (Calkins et al., 1981). From these reports, *LT* muscles containing higher fat in this study would have a higher percentage of type I fibers, and fat would be present where fibers (protein) should be. The protein content

per unit mass consequently decreased and fat developed in the endomysium. This finding is applicable to beef containing 23% or more fat.

Cooking loss

Cooking loss was negatively correlated with fat content and the slope of the relation was weak in the area of low fat content, but a steep slope was observed in the high fat meat. This tendency was similar to the relation between fat and protein. A piecewise linear regression model was also applied and the relationship was expressed by $y = -0.116x + 25.247$ and $y = -0.662x + 40.555$ and the intercept of the two line segments was 28.02 ($r^2 = 0.97$). This indicates that the cooking loss remarkably decreases in meat including 28% of fat or more. A not significant but negative correlation ($r = -0.32$) was reported between fat content and cooking loss using beef with fat below 20% (Mitsumoto et al., 1995). Our result of a weak correlation in the region of low fat agreed with their report. However, a strong correlation was observed with fat of 28% or above in this study. Cooking loss mainly occurs by keeping the meat juice out of the contracted muscle fibers by heating, and the loss of holding capacity by protein denaturation. Therefore, cooking loss is lower in meat with lower moisture, and in addition, moisture release is lower with lower protein content. Markedly decreased cooking loss was consequently observed in meat with 28% fat content or above.

Tenderness

The results of SFV ranged from 2.08 to 4.56 kg/cm^2 and a significant negative correlation ($r=-0.83$, $p<0.05$) was observed between the SFV and fat level (Figure 4). This observation was different from the relation of protein content or cooking loss to fat content which was expressed by piecewise regression model (Figures 2 and 3). Adipose tissues in *LT* muscle appeared to disrupt the structure of intramuscular connective tissue (Nishimura et al., 1999). And matrix metalloproteinases (MMPs) which increased during adipocyte differentiation (Bouloumine et al., 2001) could improve the meat tenderness (Phillips et al., 2000). In addition to the above factors, the decreased diameter of muscle fibers would lead to the production of unique tender beef, due to the replacement of type IIB with typeI in beef with significant marbling (>23% of fat) in the present study.

Free amino acid content

Table 1 shows the correlation coefficient between fat content and each free amino acid and peptide, expressed as both wet meat and protein base. In the wet meat base, almost all free amino acids and Ans and Car content except Glutamine (Gln) had a significantly negative correlation with fat content ($p < 0.001$ - 0.05). In the protein base, although there was no significant relationship in some free amino acids, a significant negative correlation was still observed in several amino acids (Threonin, Serine, Alanin, Valine, Methionin, IsoLeucine, Leucine, Arginin). The same trend was found in Car. It can be seen that these negative correlations were due to a lower protein content to higher fat beef as mentioned above (Figure 2). However, this does not apply to meat with low fat (<23%), because of a relatively constant protein content (Figure 2). Lower levels of free amino acids were observed in muscles at 35 months than 25 months in cattle (Watanabe et al., 2004), and this suggested that the results of lower concentration would be due to a lower muscle growth rate. Therefore, the reason for the negative correlation between the fat content and most free amino acids can be explained by not only protein content but also animal maturity. On the other hand, Gln has a positive relationship to fat content in both wet and protein bases. Gln has the ability to stimulate the formation of lipids (Yatzidis, 2002) or lipogenesis (Lavoinne et al., 1987). Cornet and Bouset (1998) reported that red oxidative muscle had higher levels of Gln, and increased fat content lead to increased type I fibers (red oxidative muscle) as mentioned above. These reports could explain why Gln increases as fat increases.

Conclusions

The effects of intramuscular fat deposition on the chemical composition, tenderness, and free amino acid concentration in beef were studied using various classified carcasses of 21 Japanese Black (Wagyu) steers. Fat content ranged from 4.8 to 39.0% in *M. Longissmus thoracicus,* respectively. The protein content was relatively constant until there was ca. 23% of fat, and then decreased as the fat increased. Cooking loss was also constant until there was ca. 28% of fat, and markedly decreased with the fat increase. A weak correlation was found between the shear-force value and the fat content ($r=-0.83$, $P<0.05$). Most of the amino acids had a negative correlation to the fat content except glutamine, and this observation continued even when calculated by protein base. It is concluded that too much amount of fat in beef would be a possibility of leading to the protein content decrease. And consequently, it would influence the level of cooking loss and free amino acid content.

Background

Quality assurance of deer meat (venison) is essential to long-term product marketability and has been identified as a key challenge for the Australian deer industry. Consumer attitudes and preferences are increasingly important for all meat industries, and pasture based production systems (as used for deer and lamb) are often valued by consumers as more animal friendly and ethical compared with the intensive production of beef in feed-lots, pork and chicken. Technological meat quality attributes like pH and water holding capacity are related to the functional properties of meat during storage and processing. These quality parameters also have an indirect influence on the sensory quality of meat, such as tenderness, juiciness and flavour, valued by consumers as the most important in relation to the eating quality of meat.

Techniques for hanging carcasses (Achilles tendon suspension and pelvic suspension) have been studied for beef (Hostetler *et al*., 1970; Lundesjö Ahnström *et al*., 2003) where the variation in tenderness is considered to be the main reason for consumer dissatisfaction (Koohmaraie, 1996). The tenderness in meat from bulls was more improved as an effect of pelvic suspension compared with meat from heifers (Fisher, 1994; Lundesjö Ahnström *et al*., 2003). Similar results have also been reported for fallow deer (*Dama dama*), where pelvic suspension of the carcasses had the greatest impact on meat tenderness in venison from young male fallow deer (Sims *et al*., 2004). In addition, previous and recent research has demonstrated quality differences in meat from ruminants (beef, reindeer (*Rangifer tarandus tarandus*) and red deer (*Cervus elaphus*) that have been grazing pasture or fed grain-based feed mixtures (Daly *et al*., 1999; Wiklund *et al*., 2001a; 2003a; 2003b; Wood *et al*., 2003; Bruce *et al*., 2004). However, research in the area of venison quality has been very limited and further studies of the relationship between production system, slaughter handling techniques and consumer acceptance of the final products are essential.

Objectives

The objective of this study was to compare the effects of two different techniques for hanging carcasses (Achilles tendon suspension and pelvic suspension) on the water-holding properties of deer and lamb meat. In addition, the water holding capacity of long term chilled (up to 6 weeks post slaughter) deer and lamb meat was measured.

Materials and methods

Ten female lambs (F1 Merino/Border Leicester x Texel, 5½ months old) and 10 female fallow deer (15 months old) raised at the University of Western Sydney, were included in the study. The animals were fasted for 16 h prior to slaughter, stunned with a captive bolt and bled using thoracic stick exsanguination within 10 s of the stun (ethics approval UWS 04.01). The dressed carcasses were split along the mid ventral axis approx. 45 – 75 min post slaughter, and each carcass side was randomly assigned to either Achilles tendon suspension (control treatment) or pelvic suspension. At 1 day *post mortem* (*pm*), both *M. longissimus* (striploins) from each carcass were collected, cut in 5 pieces and randomly assigned to a treatment of 1, 3 or 6 weeks of refrigerated storage (+2° C), freezing (-20° C) or to be analysed as fresh meat. Drip loss was measured on the fresh meat samples after hanging meat samples in plastic bags for 2 days at + 2° C. All other samples were vacuum packaged. Purge (drip loss in the vacuum bags) was measured after 1, 3 and 6 weeks of refrigerated storage by the following procedure: (1) the weight of meat and vacuum bag was recorded before opening; (2) at opening, any surplus drip on the meat was removed using a paper towel and

the drip-free weight of the meat recorded. Thaw loss was measured using the same technique as described for the purge measurements after the meat samples had been removed from the freezer and thawed overnight at +2° C. Cooking loss was measured for all treatments (fresh, frozen/thawed and chilled-stored meat) after the vacuum packed meat samples had been heated to 70° C in a water bath. The samples were weighed in the same way as described for the purge measurements. The data was analysed statistically by analysis of variance, fitting species for the slaughter data, and species, hanging treatment and their interaction with animal as a blocking factor for the meat quality data, using the statistical package GenStat (2002).

Results and discussion

The lambs had higher live weights compared with the deer ($p \leq 0.01$), but lower carcass weights and dressing percentages ($p \leq 0.001$) (Table 1). pH decline registered 1-24 hours *pm* did not differ ($p > 0.05$) between the two carcass treatments or between species (Fig. 1), and the mean ultimate pH values recorded at 24 h *pm* in *M. longissimus* (LD) were 5.69 (lamb) and 5.68 (deer). However, after 1 week of refrigerated storage pH dropped below 5.60, and was significantly lower in the lamb than in the deer samples (Table 1). After 3 and 6 weeks of storage pH was not significantly different from ultimate pH (Table 1). These results are in good agreement with an earlier study of red deer meat, where the same pattern for pH variation over storage time was observed (Wiklund *et al*., 2001b). Mean temperature was higher in lamb than in deer LD at 1 hour ($p \leq 0.05$) and lower at 24 hours ($p \leq 0.05$) *pm*, but was not significantly different between species during the main intermediate period of decline.

Among the measured water-holding traits, the carcass suspension technique had an effect on drip loss and purge. Drip loss in fresh meat was significantly lower with Achilles tendon suspension, while purge in the vacuum bags during storage was lower with pelvic suspension, significantly so for 3 weeks storage (Fig. 2). The only significant difference between species was found in drip loss where the deer meat had better water-holding capacity than the lamb meat (1.67% versus 2.24% of drip loss). Cooking loss and freeze/thaw loss was not affected by carcass treatment ($p \geq 0.05$), although a significantly higher cooking loss in the deer samples compared with the lamb samples was registered in fresh meat (Fig. 3). The present results on the positive effects of pelvic suspension on purge in deer and lamb support earlier findings in beef (Lundesjö Ahnström *et al*., 2003), though in the beef study positive effects of pelvic suspension on cooking loss and freeze/thaw loss were also reported. The present values measured for drip loss and cooking loss in lamb samples were in good agreement with previously reported values for lamb LD (Hoffman *et al*., 2003).

Conclusions

Knowledge about the quality attributes of fresh chilled venison is of strategic importance to the Australian deer industry. Today most of the venison produced is sold frozen, but the demand for fresh meat is expected to increase in the future. Pelvic suspension of carcasses has been demonstrated to improve tenderness in meat from young fallow deer bucks, the type of animals most likely to be supplied for commercial slaughter in Australia. The present results indicate that pelvic suspension also could be positive for water-holding properties of fresh chill-stored fallow deer venison. Pelvic suspension is suggested to be a method that can be used to enhance consumer important quality attributes of venison. Sensory analysis (using a trained expert panel and consumer preference tests) of venison from the two different carcass treatments as well as similar studies on red deer venison are subjects recommended for further investigation.

THE SAFETY OF PASTEURISED IN-PACK CHILLED MEAT PRODUCTS WITH RESPECT TO THE FOODBORNE BOTULISM HAZARD

Michael W. Peck* and Sandra C. Stringer
Institute of Food Research, Norwich Research Park, Colney, Norwich, NR4 7UA, UK
tel: 44-1603-255000; fax: 44-1603-507723; email: Mike.Peck@bbsrc.ac.uk

Abstract

There has been a substantial increase in sales of pasteurised in-pack chilled products over the last decade. It is anticipated that this trend will continue. These foods address consumer demand in being of high quality and requiring little preparation time. The microbiological safety of these foods commonly depends on a combination of a minimal heat treatment, refrigerated storage and a restricted shelf-life. The principal microbiological safety hazard for pasteurised in-pack meat products is foodborne botulism, as presented by non-proteolytic *Clostridium botulinum*. This review provides a summary of research that has contributed to the safe development of these foods without incidence of botulism.

Key words:
Clostridium botulinum*, botulism, pasteurised, sous-vide, meat, chilled*

Introduction to pasteurised in-pack chilled products

Consumer demand for foods that require minimal preparation time compared with conventional meals, are of high quality, contain low levels of preservatives, and are only minimally processed has led to the development of foods that are pasteurised in-pack. These foods are also known as sous-vide foods, cook-chill ready-to-eat foods, and refrigerated processed foods of extended durability (REPFEDs). These foods are processed at a lower temperature (maximum generally within the range 70°-95°C) than, for example, canned foods. This heat process is intended to minimise loss of sensory and organoleptic quality. After heating, the food is cooled rapidly, and stored at refrigeration temperatures (1° - 8°C). These foods are not sterile, and product shelf-life is dependent on the heat treatment applied and storage temperature. In some circumstances intrinsic properties of the food (e.g. pH, water activity) may also contribute to an extended shelf-life. Typically, the shelf-life can be up to 42 days. Sales of pasteurised in-pack products and other chilled foods are currently increasing at a tremendous rate in many European countries. The European prepared chilled food sector showed a 50% increase in the period 1991-1996, to an estimated € 9,100 million (ECFF, 1998). In the UK alone, sales of prepared chilled foods increased by 45% between 1999 and 2003, to reach an estimated € 7,400 (Chilled Food Association, 2004).

Assessment of microbiological safety hazards associated with pasteurised in-pack chilled products

Pasteurised in-pack products are not sterile, and safety and quality is dependent on a combination of the minimal heat process, storage temperature, shelf-life and perhaps also intrinsic properties of the food (Peck,

1997). The mild heat treatment applied should eliminate cells of vegetative bacteria, but not bacterial or fungal spores. Thus, non-spore-forming pathogens such as *Listeria monocytogenes*, *Yersinia enterocolitica*, diarrheagenic *Escherichia coli*, *Campylobacter jejuni*, and salmonellae should be eliminated. By heating in-pack, post process contamination is prevented. Pasteurised in-pack products are frequently packed under vacuum or an anaerobic atmosphere. This restricts growth of microorganisms that require oxygen for growth, such as molds, but favours growth of microorganisms that can grow in the absence of oxygen. The storage of these foods at refrigeration temperatures prevents growth of mesophilic spore-forming bacteria, although growth may be possible if temperature abuse occurs. Overall, this minimal process favours spore-forming microorganisms that grow in the absence of oxygen at refrigeration temperatures. In particular, concern exists about the potential for growth and neurotoxin production by non-proteolytic *Clostridium botulinum* in the absence of a competing microflora, and the associated foodborne botulism hazard (Peck, 1997; Lund and Peck, 2000). It is essential that pasteurised in-pack products be developed without an associated increase in the incidence of foodborne botulism. Additionally, concern also exists about the hazard presented by psychrotrophic strains of *Bacillus cereus* (Carlin *et al.,* 2000). While food poisoning caused by *B. cereus* is serious, it is generally viewed as a less severe disease than foodborne botulism.

Recommendations and guidelines to ensure the safe production of pasteurised in-pack chilled products with respect to *C. botulinum*

Guidelines and a code of practice have been targeted at ensuring the safe production of these foods by preventing growth and toxin production by non-proteolytic *C. botulinum* (ACMSF, 1992, 1995; ECFF, 1996; Betts, 1996; Gould, 1996; Martens, 1997; Gould, 1999). Growth and toxin production by proteolytic *C. botulinum* is prevented by ensuring storage is below 10°C. Recommendations produced by the UK Advisory Committee on the Microbiological Safety of Food (ACMSF) on procedures to ensure safety with respect to non-proteolytic *C. botulinum* are summarised in Table 1. It is recommended that the heat treatments or combination processes deliver a safety a factor of 10^6 (a 6D [six decimal] process) with regard to spores of non-proteolytic *C. botulinum* (ACMSF, 1992; ECFF, 1996). Possible limitations of these recommendations are described in later sections. It is likely that for a majority of these pasteurised foods, safety will rely on either option (4) or (8), as detailed in Table 1.

Table 1 Recommended procedures to ensure the safety of pasteurised in-pack chilled products with respect to non-proteolytic *C. botulinum* (ACMSF 1992, 1995)

(1) storage at <3.0°C*
(2) storage at ≤5°C and a shelf-life of ≤10 days
(3) storage at 5°-10°C and a shelf-life of ≤5 days
(4) storage at chill temperature** combined with heat treatment of 90°C for 10 min or equivalent lethality (e.g. 70°C for 1675 min, 75°C for 464 min, 80°C for 129 min, 85°C for 36 min (ACMSF, 1992) (note that the European Chilled Food Federation (ECFF, 1996) recommended 80°C for 270 min, 85°C for 52 min)).
(5) storage at chill temperature combined with ≤pH 5.0 throughout the food
(6) storage at chill temperature combined with a salt concentration ≥3.5% throughout the food
(7) storage at chill temperature combined with $\leq a_w$ 0.97 throughout the food
(8) storage at chill temperature combined with a combinations of heat treatment and other preservative factors which can be shown consistently to prevent growth and toxin production by *C. botulinum.*

Notes:
* originally 3.3°C, but growth has now been demonstrated at 3.0°C (Graham *et al*., 1997)
** chill temperature is specified as 8°C in UK

Clostridium botulinum and foodborne botulism

Characteristics of Clostridium botulinum and other neurotoxin producing clostridia

Six physiologically and phylogenetically distinct Gram-positive spore-forming anaerobic bacteria can produce botulinum neurotoxin (Table 2), although the name of *C. botulinum* is retained to emphasise the importance of neurotoxin production (Lund and Peck, 2000). Some strains of *C. baratii* and *C. butyricum* also produce neurotoxin. For each of the six organisms, a non-neurotoxigenic phylogenetically equivalent organism is known (Hatheway, 1992). The different physiology of the six organisms is reflected in the circumstances in which they present a hazard. For example, proteolytic *C. botulinum* and non-proteolytic *C. botulinum* are responsible for most cases of foodborne botulism (Lund and Peck, 2000). Differences in the physiology of these two organisms are summarised in Table 3, and because of these differences they present a hazard in different types of foods. Proteolytic *C. botulinum* is a mesophile, and produces spores of high heat resistance. The canning process for low-acid foods is designed to inactivate spores of this organism, and botulism outbreaks have occurred when the full heat treatment has not been appropriately delivered. Spores of non-proteolytic *C. botulinum* are of moderate heat resistance, but this organism can multiply and form neurotoxin at temperatures as low as 3.0°C. Botulism outbreaks associated non-proteolytic *C. botulinum* have occurred most frequently with processed fish, with for example outbreaks involving vacuum packed smoked fish reported in Sweden and Germany. This organism is the principal concern for the safety of pasteurised in-pack chilled meat products.

Table 2. Characteristics of the six phylogenetically distinct clostridia that can produce the botulinum neurotoxin

Neurotoxigenic organism	Neurotoxins formed	Non-neurotoxigenic equivalent organism	Associated with foodborne botulism
C. botulinum Group I (proteolytic)	A, B, F	*C. sporogenes*	++
C. botulinum Group II (non-proteolytic)	B, E, F	no name given	++
C. botulinum Group III	C, D	*C. novyi*	-
C. botulinum Group IV (*C. argentinense*)	G	*C. subterminale*	-
C. baratii	F	all typical strains	+
C. butyricum	E	all typical strains	+

++ commonly associated, + rarely associated, - not known to be associated

Table 3 Characteristics of the two physiologically distinct clostridia most commonly responsible for foodborne botulism

	Proteolytic *C. botulinum* (*C. botulinum* Group I)	non-proteolytic *C. botulinum* (*C. botulinum* Group II)
neurotoxins formed	A, B, F	B, E, F
minimum growth pH	4.6	5.0
minimum growth temperature	10-12°C	3.0°C
maximum growth NaCl	10%	5%
spore heat resistance ($D_{100°C}$)	>15 min	<0.1 min
foods involved in botulism outbreaks	home canned foods, faulty commercial processing	fermented marine products, dried fish, vacuum packed fish
potential food problems	canned foods	pasteurised in-pack chilled products

Neurotoxins and characteristics of botulism

Foodborne botulism is a severe but rare disease. It is an intoxication resulting from consumption of pre-formed botulinum neurotoxin in food, with as little as 30 ng of neurotoxin sufficient to cause illness and even death. The consumption of as little as 0.1g of food in which a neurotoxin-producing clostridia has grown can result in botulism (Lund and Peck, 2000). There are seven botulinum neurotoxins (A to G), with the type of neurotoxin formed dependent on the producing organism (Table 2). The neurotoxins were originally distinguished on the basis of antigenic response. More recently, however, the amino acid sequence and mode of action of all the neurotoxins have been established (Dodds and Austin 1997; Lund and Peck, 2000). All seven botulinum neurotoxins comprise a heavy and light chain, and are often associated with other proteins (e.g. haemagglutinin, non-toxin non-haemagglutinin). The heavy chains deliver the light chains to the cytosol of the motor neuron, their site of action. The light chains possess zinc endopeptidase activity, and cleave protein components of the acetylcholine-containing synaptic vesicle docking/fusion complex. Each light chain cleaves a specific protein in this complex at a specific site. This cleavage prevents binding of acetylcholine-containing synaptic vesicles, preventing neurotransmitter release and leads to flaccid paralysis of the muscle. Typically symptoms of botulism are neurological and include, blurred vision, dysphagia (difficulty swallowing), generalised weakness, nausea/vomiting, dysphonia (difficulty speaking), dizziness/vertigo, and muscle weakness. Flaccid paralysis of the respiratory muscles can result in death if not treated. In many countries, equine antitoxin is administered in cases of foodborne botulism. Rapid treatment with equine antitoxin and supportive therapy has led to a reduction in the fatality rate to approximately 10% of cases, although full recovery may take many months or even longer. A fatality rate of 10% of cases is very high for a foodborne illness.

Incidence of spores of C. botulinum in foods and the environment.

Spores of proteolytic *C. botulinum* and of non-proteolytic *C. botulinum* are found in soils, sediments and the gastrointestinal tract of animals, and their distribution has been reviewed previously (Dodds, 1992a, 1992b; Dodds and Austin, 1997; Lund and Peck, 2000). Recently, information has been published on the incidence of spores in the environment and in foods in France (Fach *et al*., 2002; Carlin *et al*., 2004). Although often present in low numbers, their ubiquitous nature ensures that raw products cannot be guaranteed free of spores. Foods which are, or can become, anaerobic may allow growth of *C. botulinum* and must therefore be subjected to treatments that destroy spores, or stored under conditions that prevent growth and toxin formation.

Outbreaks of foodborne botulism

The name “botulism” was given to a disease reported in central Europe several hundred years ago that was frequently associated with consumption of blood sausage (“botulism” is derived from the Latin *botulus* meaning sausage). At the end of the nineteenth century, Emile van Ermengem, first isolated a causative organism from home made raw salted ham and the spleen of a man who later died of botulism. In the early part of the twentieth century, many outbreaks of botulism were identified across the world, and were frequently associated with the increased use of canning processes to extend shelf-life. By implementing effective control measures, the incidence of botulism is now lower than a century ago. Foodborne botulism involving commercial processing is uncommon, but on the rare occasions when commercial foods are involved, the medical and economic consequences can be high. It has been estimated that in the USA the cost per case of botulism is approximately $30 million, compared with $10,000-12,000 for each case of illness associated with *Listeria monocytogenes* and *Salmonella* (Setlow and Johnson, 1997). Today, most outbreaks of foodborne botulism are associated with home-prepared foods, where known control measures have not been implemented. For example, in Poland, 1301 outbreaks were reported between 1984-1987, and in Russia, 542 outbreaks were described between January 1998 and September 1999. These high incidences were associated with an increased reliance on the home bottling/canning of foods, reflecting difficult economic conditions. The incidence in Poland has fallen considerably in recent years. Many other countries have lower, but significant rates of foodborne botulism. For example, over the past 20 years, approximately 20-40 cases have been reported annually in Italy, Germany, France, and USA. Examples of recent outbreaks of foodborne botulism are given in Table 4 (see end of the paper). A recent finding has been the association of neurotoxigenic strains of *C. baratii* and *C. butyricum* with foodborne botulism. Outbreaks involving neurotoxigenic *C. butyricum* type E have been reported in China, India and Italy (Anniballi *et al.,* 2002). A suspected outbreak involving neurotoxigenic *C. baratii* type F, was reported in USA in 2001, and was associated with consumption of spaghetti noodles and meat sauce by a 41 year old

woman. A full recovery was eventually made, although 12 weeks were spent on a life support machine (Harvey *et al*., 2002).

Many cases of foodborne botulism have been associated with meat products (Hauschild, 1992; Lucke and Roberts, 1992). In France, Germany and Poland most cases of foodborne botulism are associated with consumption of meat dishes, while in Spain and Italy other foods are more frequently implicated (Lund and Peck, 2000). A large proportion of outbreaks in Germany and France are associated with home or farm salted ham. A majority of meatborne cases in Poland are associated with the home preparation of pork in glass jars (Lucke and Roberts, 1992). Several examples of recent outbreaks of meatborne botulism are included in Table 4. Commercial pasteurised in-pack chilled products have a good safety record with respect to foodborne botulism, although outbreaks involving clam chowder (USA, 1994) and vacuum packed fish (Germany, 1997) have occurred following temperature abuse. It is essential, however, that as new types of food are developed, they are developed safely with respect to the foodborne botulism hazard. Outbreaks involving home prepared vacuum packed fish are also reported (Table 4; see end of the paper).

Control of foodborne botulism hazard presented by proteolytic *C. botulinum* in pasteurised in-pack chilled meat products

Factors influencing growth and toxin formation

Providing that pasteurised in-pack chilled products are stored at an appropriate temperature, growth and toxin production by proteolytic *C. botulinum* is prevented. There is, however, concern that proteolytic *C. botulinum* may grow and form toxin in products that are temperature abused. The effect of individual environmental factors on growth of proteolytic *C. botulinum*, under otherwise optimum conditions, has been established. The minimum temperature at which growth and toxin production occurs is within the range of 10°-12°C. Growth and toxin formation have been described at 12°C in 3-4 weeks (Smelt and Haas, 1978; Peck, 1999), and Ohye and Scott (1953) determined growth rates at 12.5°C. Attempts to establish growth at 10°C or below have been generally unsuccessful (e.g. Ohye and Scott, 1953; Smelt and Hass, 1978; Peck, 1999). Although Tanner and Oglesby (1936) reported growth from vegetative inocula at 10°C, this observation was marred by a temporary rise in the incubator temperature to 20°C, and in the words of the authors "the results of this test may not be very significant". Growth from a spore inoculum was not observed at 10°C in 10 weeks (Tanner and Oglesby, 1936). It is generally accepted that growth is prevented at pH 4.6 or below, that 10% NaCl will prevent growth, and that the minimum water activity permitting growth is 0.93 and 0.96 with glycerol and NaCl, respectively, as the humectants (Hauschild, 1989; Lund and Peck, 2000). The use of other factors to control or prevent growth of proteolytic *C. botulinum* has been reviewed (Hauschild, 1989; Lund and Peck, 2000). The safety of some foods with respect to proteolytic *C. botulinum* may rely on a combination of factors rather than on one single factor. The effect of combinations of pH and NaCl concentration/water activity on time to growth has been determined in laboratory medium (Baird-Parker and Freame, 1967), vacuum-packed potatoes (Dodds, 1989) and in lumpfish caviar (Hauschild and Hilsheimer, 1979). Predictive models that quantify the effect of combinations of environmental conditions on the growth response of proteolytic *C. botulinum* have been developed (Baker and Genigeorgis, 1992; Lund, 1993; Dodds, 1993; Lund and Peck, 2000). These models provide information on interactions between two or more factors, allow predictions to be made for sets of conditions not tested (within the interpolation zone), and are of use in the targeting of challenge testing.

Heat resistance of spores of proteolytic C. botulinum

The relatively high heat resistance of spores of proteolytic *C. botulinum* makes their survival in low acid canned foods a subject of considerable importance. In response to outbreaks of botulism associated with the consumption of inadequately heat-treated foods, studies on the heat resistance of spores of proteolytic *C. botulinum* began in the early part of the twentieth century. From extensive research, it is generally accepted that a heat treatment at 121.1°C for 3 min (or heat treatments of equivalent lethality at other temperatures) will reduce the number of spores of proteolytic *C. botulinum* by a factor of 10^{12} (a 12D process), and this was adopted as the minimum standard for a "botulinum cook" for low acid canned foods (Stumbo *et al*., 1975). The heat resistance of spores of proteolytic *C. botulinum* is generally taken as $D_{121°C}$ = 0.2 min and z = 10°C (Stumbo *et al*., 1975), thus by extrapolation, at 91°C the D-value would be 200 min. The minimal heat treatments applied to pasteurised in-pack and related foods would, therefore, be unlikely to have any significant effect on spores of proteolytic *C. botulinum.*

Combinations of heat treatment, storage temperature and other factors that prevent growth and toxin production from spores of proteolytic C. botulinum

Studies on proteolytic *C. botulinum* have focused on assessing the hazard following temperature abuse. In one study, spores of a mixture of strains of proteolytic *C. botulinum* were inoculated into meat slurry (used as a model food) prepared under N_2, heated at 95°C for 23 min, cooled and subsequently incubated at refrigeration and abuse temperatures (Table 5). The heat treatment had only a marginal effect on time to growth. Growth and toxin production did not occur at 8°C, and at 12°C growth was observed within 21 days and toxin production confirmed (although time to growth was rather variable). At 16°C growth was first observed in 4-7 days, and at 25°C growth was first observed in 2 days (Table 5). These results indicate that if pasteurised in-pack products are abused at 16°C or higher (and possibly even at 12°C), then proteolytic *C. botulinum* is a serious concern.

Evaluation of time to growth and toxin formation in foods

Tests on time to toxin formation have been carried out with pasteurised in-pack pasta products subject to temperature abuse (Table 6). Also, while Del Torre *et al*. (1998) detected toxin formation in salmon-filled tortelli stored at 20°C for 30 days, toxin formation was not detected when this product was stored at 12°C for 50 days. Simpson *et al.* (1995) detected toxin formation after storage at 15°C for 14 days, when a spaghetti and meat-sauce was inoculated with 10^3 spores/g of proteolytic *C. botulinum*. These data emphasise the danger presented by proteolytic *C. botulinum* if these food products are temperature abused.

Table 5 Effect of heat treatment, subsequent incubation temperature and inoculum concentration on time to growth from spores of proteolytic *C. botulinum* types A, B and F in meat slurry (Plowman and Peck, unpublished data)

Incubation temperature	Heat treatment	Incubation time (days) to first observation of growth for each inoculum concentration	
		10^3 spores/tube	10^6 spores/tube
8°C	None	not tested	>60
12°C	None	49	21
	95°C/23min	56	28
16°C	None	6	4
	95°C/23min	7	4
25°C	None	2	2
	95°C/23min	2	2

Table 6 Examples of reported time to toxin formation in pasteurised in-pack chilled products inoculated with a low concentration of spores of proteolytic *C. botulinum* (Glass and Doyle, 1991; Del Torre *et al.,* 1998)

Pasta filling	Product details			Time (days) to toxin formation at specified temperature[a]	
	a_w	pH	atmosphere (CO_2:N_2:O_2)	20°C	30°C
Cheese	0.94	5.7	80:20:0	-[b]	70-NT
Meat	0.95	6.2	0:100:0	-	35-42
ricotta/spinach	0.95	5.9	15:83:2	30-50	-
Salmon	0.95	6.1	15:83:2	15-30	-
Meat	0.95	6.2	15:83:2	30-50	-
Artichoke	0.96	5.6	15:83:2	50-NT	-

[a] - last negative test and first positive test are given (NT = no toxin detected), inoculum spore concentration 1-7 x10^2 spores/g

[b] - not determined

Control of infant botulism hazard presented by proteolytic *C. botulinum* in pasteurised in-pack chilled meat products

Infant botulism is an infection. An immature intestinal flora in infants is unable to prevent colonisation by proteolytic *C. botulinum* (and also neurotoxigenic strains of *C. baratii* and *C. butyricum*), allowing ingested spores to germinate leading to cell multiplication and neurotoxin production. Infants aged between two weeks and six months are most susceptible. Symptoms typically include extended constipation and flaccid paralysis. Infant botulism is rarely fatal. Two sources of spores have been identified, honey and general environmental contamination (e.g. soil, dust). It is estimated that between 10 and 100 spores are sufficient to bring about infection. The first clinical cases of infant botulism were described in USA in 1976, although subsequent investigations revealed earlier cases. Infant botulism has now been reported in twelve European countries, and about half of these were associated with a history of honey consumption (Aureli *et al*., 2002). In view of this association, there are recommendations in several countries that jars of honey should carry a warning indicating that the product is not suitable for infants less than twelve months of age. A disease similar to infant botulism also very rarely affects adults, and occurs when competing bacteria in the normal intestinal flora have been suppressed (e.g. by antibiotic treatment).

It is anticipated that the heat treatment delivered to pasteurised in-pack chilled products will bring about little reduction in numbers of spores of proteolytic *C. botulinum*. While the foodborne hazard is controlled by storage at chilled temperature, the infant botulism hazard is not controlled (since spores will remain in the food, but will be unable to germinate and lead to growth in the food). Thus, there is a concern that these minimally processed foods may represent a risk of infant botulism (and possibly also infectious botulism in susceptible adults). This concern is particularly great for pasteurised in-pack products that are specifically targeted at infants less than twelve months of age.

Control of foodborne botulism hazard presented by non-proteolytic *C. botulinum* in pasteurised in-pack chilled meat products

Factors influencing growth and toxin formation

The minimum temperature at which growth and toxin production have been described is 3.0°C (Graham *et al*., 1997). In this study, vials containing 10 ml of PYGS (peptone, yeast extract, glucose, starch) medium were inoculated at 10^4 spores/ml, and growth was observed at 3.0°C after seven weeks, 3.1°C after six weeks, and 3.2°C after five weeks. The presence of toxin was confirmed. Earlier studies had demonstrated growth and toxin production at 3.3°C within five weeks (Schmidt *et al*., 1961; Eklund *et al*., 1967a, b). Growth and toxin production have not been detected during incubation at 2.1-2.5°C for 90 days (Ohye and Scott, 1957; Schmidt *et al*., 1961; Eklund *et al*., 1967a, b; Graham *et al*., 1997). Maintaining pasteurised in-pack products at a temperature of <3.0°C might be possible in some circumstances (e.g. institutions, catering establishments), but there is doubt as to whether temperatures in this range can always be maintained throughout the distribution chain, particularly in products intended for domestic use. Indeed, regulations require foods in this group to be held at 0°-3°C in Spain, 0°-4°C in France, ≤7°C in Belgium and ≤8°C in the UK (Martens, 1997). Thus, retail products should contain additional hurdles. It is generally recognised that growth and toxin production do not occur below pH 5.0, at a NaCl concentration above 5%, and that the minimum water activity permitting growth is 0.94 and 0.97 with glycerol and NaCl, respectively, as the humectants (Baird-Parker and Freame, 1967; Hauschild, 1989; Graham *et al*., 1996b; Lund and Peck, 2000). The effect of other preservative factors on growth of non-proteolytic *C. botulinum* has been reviewed elsewhere (e.g. Hauschild, 1989; Lund and Peck, 2000). The effect of redox potential and oxygen concentration on growth from unheated spores has been quantified (Lund, 1993). Furthermore, in studies with a model food system (meat slurry), an initial aerobic atmosphere (20% oxygen) did not restrict growth compared to a control atmosphere of nitrogen (Peck, 1999). In these circumstances, although the atmosphere was aerobic, the model food was sufficiently reduced so as to support growth and toxin production by non-proteolytic *C. botulinum*. The use of oxygen as a preservative factor is therefore cautioned, since despite the presence of oxygen, the food itself may be sufficiently reduced and support growth and toxin production by non-proteolytic *C. botulinum* (Snyder, 1996).

In some foods, safety with respect to non-proteolytic *C. botulinum* may be dependent upon more than one preservative factor. For example, although a sub-optimal pH or NaCl concentration might not prevent growth individually, they might in combination. The effect of combinations of pH and NaCl concentration on time to growth at chilled temperatures has been reported (Graham *et al*., 1997). An important development in describing the effect of combinations of preservative factors has been that of predictive models. Predictive models for non-proteolytic *C. botulinum* have been developed in foods and whilst they may predict well for some food groups, they may be of limited use in other types of food. Other models have been developed in laboratory media and may be rather more generic in application. These models provide information on interactions between two or more factors, and can be used to reduce the amount of challenge testing required to ensure product safety. Models have been developed that deliver growth curves, describe the effect of single and multiple factors on the probability of growth, or on time to toxin production at a single inoculum level (Baker *et al*., 1990; Baker and Genigeorgis, 1992; Dodds, 1993; Meng and Genigeorgis, 1993; Lund, 1993; McClure *et al*., 1994; Graham *et al*., 1996b; Whiting and Oriente, 1997; Lund and Peck, 2000; Fernandez *et al*., 2001). Where tested, predictions from these models generally compare well with observed growth and toxin production in independent datasets, giving the user confidence that these models can be used to target, more effectively, challenge testing. Some of these models are freely available through predictive modelling packages [Growth Predictor (www.ifr.ac.uk/Safety/GrowthPredictor/default.html), Pathogen Modeling Program (www.arserrc.gov/mfs/PMP6_Start.htm)]. Published (and in some cases also unpublished) original growth and death curves are compiled and also available free of charge in ComBase (www.combase.cc).

Heat resistance of spores of non-proteolytic C. botulinum

Spores of non-proteolytic *C. botulinum* are of moderate heat resistance, and are considerably less heat resistant than those of proteolytic *C. botulinum*. For example, heating spores for one min in phosphate buffer (pH 7.0) at 85°C, followed by enumeration of survivors on a nutrient medium gave in excess of a 5D kill (Peck *et al*., 1992a). Studies of spore heat resistance by thermal death time methods and by enumeration of survivors have led to estimates of D-values in phosphate buffer, the highest of which have generally been within the range of $D_{82.2°C}$ = 0.5-2.4 min (Lund and Peck, 2000). The measured heat resistance of spores of non-proteolytic *C. botulinum* can be influenced by the menstruum in which the spores are heated and the nutrient medium used for enumeration of survivors. When spores were heated in a model food (meat slurry, pH 6.5), heat treatments at 70°C for >2545 min, 75°C for 1793 min, 80°C for >363 min, 85°C for 36 min, and 90°C for 10 min were necessary to prevent growth from an inoculum of 10^6 spores of non-proteolytic *C. botulinum* (Fernandez and Peck, 1997). Thus, the heat treatments advocated by the ACMSF and the ECFF at 70°-80°C (Table 1) failed to reduce the number of spores of non-proteolytic *C. botulinum* by a factor of 10^6 (a 6D process). The advocated heat treatments were, however, adequate when combined with refrigerated storage and a restricted shelf-life (Fernandez and Peck, 1997).

The heat treatments described in the previous paragraph result in sub-lethal injury to spores of non-proteolytic *C. botulinum*. In particular, the heat treatments inactivate the spore germination system (Peck *et al*., 1992b; Lund and Peck, 1994). A proportion of these heat-damaged spores are permeable to lysozyme, and are able to germinate and give growth in/on media containing lysozyme, giving biphasic survival curves (Sebald and Ionesco, 1972; Alderton *et al*., 1974; Smelt, 1980; Peck *et al*., 1992a, 1992b, 1993; Lund and Peck, 1994; Stringer and Peck; 1996; Peck, 1997). Lysozyme can diffuse through the coat of a proportion (for most strains 0.1 - 1%) of heat-damaged spores, inducing germination by hydrolysing peptidoglycan in the spore cortex (Gould, 1989). Treatment of the heated spores with sodium thioglycollate disrupts the coat of a majority of the spores allowing lysozyme access to the cortex, inducing germination and subsequent growth of vegetative bacteria from a majority of sub-lethally heat-damaged spores. The straight line obtained with thioglycollate-treated spores provides evidence of the mode of action of lysozyme (Peck *et al*., 1992b, 1993; Lund and Peck, 1994; Peck, 1997). Following heat treatment in phosphate buffer, D-values for lysozyme-permeable spores were: $D_{85°C}$ = 100 min, $D_{90°C}$ = 18.7 min, $D_{95°C}$ = 4.4 min (Peck *et al*., 1993). These D-values are approximately two orders of magnitude greater than those obtained when spores were recovered in the absence of lysozyme. Lysozymes from several sources increase the measured heat resistance of spores of non-proteolytic *C. botulinum*, including; hen egg white lysozyme, other type c lysozymes (e.g. from other bird's eggs), other enzymes (chitinase, papain), fruit and vegetable extracts, egg yolk emulsion and horse blood (Peck and Stringer, 1996; Stringer and Peck, 1996; Stringer *et al*., 1999). Lysozyme activity has also been detected in many raw foods, and in most cases the activity is higher than that required to

increase the measured heat resistance of spores of non-proteolytic *C. botulinum* (Peck *et al*., 1992a; Lund and Peck, 1994; Peck and Stringer, 1996). Proposals have also been made to add hen egg white lysozyme and other lytic enzymes to foods as a preservative factor (Nielsen, 1991; Fuglsang, 1995), and enzymes capable of initiating germination may also be produced by other microorganisms (Lund and Peck, 1994). Because of this widespread occurrence of enzymes with lysozyme activity and the relatively high heat stability of lysozyme (Proctor and Cunningham, 1988; Lund and Peck, 1994; Peck and Fernandez, 1995), the effect of lysozyme on sub-lethally heat damaged spores is potentially important in foods that rely on heat-inactivation of spores of non-proteolytic *C. botulinum* for safety. In studies with a model food (meat slurry) with no added lysozyme, heat treatments of 85°C for 36 min, 90°C for 10 min and 95°C for 15 min each prevented an inoculum of 10^6 spores of non-proteolytic *C. botulinum* leading to growth and toxin formation at 25°C in 60 days (Peck *et al*., 1995; Peck and Fernandez, 1995; Graham *et al*., 1996a; Fernandez and Peck, 1997). When hen egg white lysozyme was added to this model food prior to heating (at 625-2400 units/ml), and heat treatments of 85°C for 84 min, 90°C for 34 min or 95°C for 15 min were applied, growth was observed at 25°C after 13, 14 and 32 days, respectively (Peck *et al*., 1995; Fernandez and Peck, 1999). A similar effect may also have been noted with endogenous lysozyme in crabmeat. Enzymes with lysozyme activity have been found in crabmeat, and it is estimated that the concentration is approximately 200 µg/g prior to heating (Lund and Peck, 1994). Heat treatments at 88.9°C for 65 min, 90.6°C for 65 min, 92.2°C for 35 min, or 94.4°C for 15 min were required to prevent growth and toxin formation from 10^6 spores of non-proteolytic *C. botulinum* when the heat treatment was followed by enrichment at 27°C for 150 days (Peterson *et al*., 1997). These heat treatments are substantially greater than those advocated by the ACMSF (1992) and ECFF (1996). The effect of intrinsic properties of foods and other environmental factors on the thermal inactivation of spores of non-proteolytic *C. botulinum* has been studied, and predictive models of thermal inactivation have been produced (Juneja and Eblen, 1995; Juneja *et al*., 1995a, 1995b; Peck and Stringer, 1996; Lindstrom *et al*., 2003).

Combinations of heat treatment, storage temperature and other factors that prevent growth and toxin production from spores of non-proteolytic C. botulinum

It is important to define combinations of preservative factors (e.g. heat treatment and subsequent storage at refrigeration temperatures) that provide an appropriate degree of protection against growth and toxin production by non-proteolytic *C. botulinum*, since the microbiological safety of most pasteurised in-pack products relies on such a process. In studies in which meat slurry was used as a model food, the effect of heat treatment at 65°-95°C combined with subsequent storage at 5°-25°C on time to growth from an inoculum of 10^6 spores of a mixture of strains of non-proteolytic *C. botulinum* was determined (Table 7). Growth was confirmed by the presence of *C. botulinum* neurotoxin. In tests where lysozyme was not added, heat treatments of 70°C for 2545 min, 75°C for 464 min, 80°C for 70 min, 85°C for 23 min, and 90°C for 10 min each prevented growth within 42 days when combined with storage at 8°C (Table 7). The heat treatment at 70°C is greater than that in current recommendations, while the heat treatments at 80°C and 85°C are lower (ACMSF, 1992; ECFF, 1996). A predictive model was developed that described the effect of heat treatment and storage temperature on time to growth (Fernandez and Peck, 1997). The model provided a good description of the data used to generate it, and predictions from the model compared well with observations of time to growth/toxin production in independent experiments (Fernandez and Peck, 1997).

Table 7 Combined effect of lysozyme, heat treatment and subsequent storage temperature on time to visible growth from 10^6 spores of non-proteolytic *C. botulinum* types B, E and F in meat slurry (Peck *et al*., 1995; Peck and Fernandez, 1995; Fernandez and Peck, 1997; Fernandez and Peck, 1999)

[a] not tested, [b] no growth at day 60

In view of previous comments, it is also appropriate to consider foods that contain lysozyme (Table 7). When relatively gentle heat treatments (e.g. heating at 70°C or 75°C) were applied, a large number of spores survived the heat treatment as measured by recovery in the presence and absence of lysozyme (Fernandez and Peck, 1999). In these circumstances, addition of lysozyme prior to heating had little effect on time to growth in a model food system (Fernandez and Peck, 1999). When more severe heat treatments were applied (e.g. heating at 85°C to 95°C), few or no spores were recovered in the absence of lysozyme, while a substantial number of spores were able to germinate and give growth in the presence of lysozyme (Fernandez and Peck, 1999). Following these heat treatments growth was observed more rapidly and over a wider range of conditions when hen egg white lysozyme was added prior to heating, than when no addition of lysozyme was made (Fernandez and Peck, 1999). From these results combinations of heat treatment and storage temperature required for a specific shelf-life can be estimated for a product suspected to contain lysozyme. These data have been used to develop a predictive model that describes the effect of heating temperature (70°-90°C), heating time (10-2545 min), and storage temperature (5°-25°C) on time to growth with lysozyme added prior to heating (Fernandez and Peck, 1999). Predictions from this model also compared well with the experimental results used to produce it, and with independent reports of time to growth/toxin production (Fernandez and Peck, 1999).

In some pasteurised in-pack products, factors other than heat treatment and subsequent refrigerated storage may also contribute to ensure safety with respect to non-proteolytic *C. botulinum*. The combined effects of heat treatment, pH, NaCl concentration, lysozyme addition, and subsequent storage temperature on time to growth from 10^6 spores of non-proteolytic *C. botulinum* in meat slurry have been described (Figure 1; see the end of the paper). In these tests, meat slurry was prepared at different pH values (pH 5.6-6.5) and different NaCl concentrations (0.6% - 4.9%, salt-on-water). Hen egg white lysozyme was either not added (Figure 1a; see the end of the paper), or was added at 1,200 units/ml prior to heat treatment (Figure 1b; see the end of the paper). Spores from eight strains of non-proteolytic *C. botulinum* types B, E and F were then added in equal numbers to give a final concentration of 10^6 spores per tube of meat slurry. The heat treatment applied were the equivalent of approximately 20 min at each of 80°C, 85°C, 90°C and 95°C (see Graham *et al*., 1996b). After rapid cooling, the tubes were incubated at 5° - 16°C for 90 days. Tubes were observed for growth, and the presence of toxin production confirmed. In the absence of added lysozyme, growth and toxin were observed in tubes that were not heated and tubes heated at 80°C for 20 mins, but not in tubes heated at 85°C or higher (Figure 1a; see the end of the paper). For tubes heated at 80°C for 20 mins, combinations of pH, NaCl concentration and shelf-life were identified that prevented growth from 10^6 spores of non-proteolytic *C. botulinum* (Figure 1a; see the end of the paper). In the presence of added lysozyme, growth and toxin were observed in tubes that were not heated and tubes heated at 80°C for 20 mins, 85°C for 20 mins and 90°C for 20 mins, but not in tubes heated at 95°C for 20 mins (Figure 1b; see the end of the paper). Again combinations of pH, NaCl concentration and shelf-life were identified that prevented growth from 10^6 spores of non-proteolytic *C. botulinum* (Figure 1a; see the end of the paper).

It is important to recognise that the heat treatments advocated by the ACMSF (1992) and ECFF (1996) do not, in themselves deliver a 6D process. For many pasteurised in-pack products, it is necessary to identify a combination process that achieves a 6D process. This will probably include a consideration of storage temperature and shelf-life, and possibly also intrinsic properties of the food or mild preservatives that may be added. It should be noted that in some circumstances, the recommendations of the ACMSF (1992) and ECFF (1996) appear to leave only a small margin of safety, but in other circumstances might lead to unnecessary overprocessing. By adopting effective combination processes it should be possible to avoid potentially dangerous situations and maintain an organoleptically acceptable product. The identification of appropriate combinations of mild preservative factors is an important step forward in the development of rational processes for pasteurised in-pack meat products.

Table 8 Examples of reported time to toxin formation in foods inoculated with a low concentration of spores of non-proteolytic *C. botulinum* (Lund and Peck, 2000)

Food[a]	Inoculum (spores/g)	Time (days) to toxin formation at specified temperature					
		4°C	5°C	8°C	10°C	12°C	16°C
cod[1]	5x10[1]	18	-	8	-	6	-
turkey[2]	10^2	-[b]	-	8	-	5	2
salmon[3]	10^2	21	-	6	-	3	-
catfish[4]	10^2	46	-	6	-	-	3

[b] tests not carried out at this temperature

6 days at 8°C (Table 8). Other studies have evaluated the safety of pasteurised in-pack chilled meat products. In one study, it was found that the heat treatments applied by industry failed to eliminate small or large numbers of spores of non-proteolytic *C. botulinum* (Table 9). Two of these heat processes (applied to beef cubes and beef liver cubes) followed recommendations made by the ACMSF (1992) and ECFF (1996), but failed to deliver a 6D process. Neurotoxin was formed when two of these products (pork cubes and ground beef) were stored at 8°C, but not at 4°C (Hyytia-Trees *et al*., 2000). During growth, non-proteolytic *C. botulinum* does not produce off odours to the same extent as some other bacteria (e.g. proteolytic clostridia). Comparisons of time to spoilage with time to toxin production by non-proteolytic *C. botulinum* have shown that toxin production often occurs in the absence of spoilage (Peck, 1997).

Process risk modelling for safety of pasteurised in-pack products

A relatively recent development has been that of process risk models for these foods (Barker *et al*., 1999; Carlin *et al.,* 2000; Barker *et al*., 2002, 2004). These process risk models have used a probabilistic modelling approach to assess the risk of foodborne botulism presented by non-proteolytic *C. botulinum* by considering the entire food chain. In process risk modelling, recent developments in mathematics and computing are utilised to assess the magnitude of the risk, and to identify hazard scenarios for each operation in the process. Probabilistic modelling approaches used have included Markov Chain Monte Carlo methods and Bayesian Belief Networks. This information can then be used to identify and prioritise steps to minimize detrimental events and to maximize awareness and process control. This includes the development of a probabilistic framework that accounts for complex combinations of information that relate to a single hazard and which incorporates an intrinsic representation of uncertainties.

Table 4. Examples of recent outbreaks of foodborne botulism (modified from Peck, 1997; Peck, 2004)

Year Country	Food associated with outbreak	Cases: Total (fatal)	Toxin type: Neurotoxigenic organism
1989 UK	Commercially produced hazelnut yoghurt	27 (1)	Type B: Proteolytic *C. botulinum*
1991 Egypt	Commercially produced uneviscerated salted fish ("faseikh")	>91 (18)	Type E: Non-proteolytic *C. botulinum*
1993 Italy	Commercially produced aubergine in oil	7 (0)	Type B: Proteolytic *C. botulinum*
1993/4 Switzerland	Commercially prepared, dry-cured ham	12/0	Type B: *C. botulinum*[a]
1994 USA	Commercial vacuum packed clam chowder soup	2/0	Type A: Proteolytic *C. botulinum*
1994 USA	Commercial black bean dip	1/0	Type A: Proteolytic *C. botulinum*
1994 USA	Restaurant, potato dip ("skordalia")	30 (0)	Type A: Proteolytic *C. botulinum*
1996 Italy	Commercially produced mascarpone cheese	8 (1)	Type A: Proteolytic *C. botulinum*
1997 Germany	Commercially vacuum packed smoked fish ("Raucherfisch")	2 (0)	Type E: Non-proteolytic *C. botulinum*
1997 Iran	Traditionally made cheese preserved in oil	27 (1)	Type A: Proteolytic *C. botulinum*
1997 Argentina	Home-cured ham	6 (0)	Type E: Non-proteolytic *C. botulinum*
1997 Germany	Home vacuum packed smoked fish ("Lachsforellen")	4 (0)	Type E: Non-proteolytic *C. botulinum*
1998 Croatia	Ham	20 (0)	[b]
1999 Morocco	Commercially produced Mortadella sausage	78 (20)	Type B: *C. botulinum*[a]
2001 USA	Fermented beaver tail and paw	3 (0)	Type E: Non-proteolytic *C. botulinum*
2001 Canada	Fermented salmon roe (two outbreaks)	4 (0)	Type E: Non-proteolytic *C. botulinum*
2001 USA	Commercially produced chilli dish	16 (0)	Type A: Proteolytic *C. botulinum*
2002 South Africa	Commercially produced tinned pilchards	2 (2)	Type A: Proteolytic *C. botulinum*
2002 USA	Muktuk (from Beluga whale)	8 (0)	Type E: Non-proteolytic *C. botulinum*
2003 France	Halal sausage	4 (0)	Type B: *C. botulinum*[a]
2003 Ukraine	Home prepared canned corn	6 (0)	Type B: Proteolytic *C. botulinum*
2003 South Korea	Commercially produced canned sausage	3 (0)	[b]
2003 Norway	Home prepared "rakfisk"	4 (0)	Type B or E: Non-proteolytic *C. botulinum*[c]
2003 Germany	Home prepared dried fish	3 (0)	Type E: Non-proteolytic *C. botulinum*

Introduction

The consumption of marinated meat has been steadily rising in Finland. Marinating is especially used for poultry products. It has been estimated by the Finnish meat processing industry that about 80% of poultry sold at the retail level is marinated. These products are variable containing skinned meat strips and fillets and skin-on leg and breast fillet cuts. For consumers they are convenient in meal preparing since only heat treatment is need without further handling or spicing of the meat. As an additional advantage of easy handling, although *Salmonella* carriage in Finnish poultry is scarce, reduced risk of food cross contamination with pathogenic bacteria should be mentioned.

The word “marinate” comes probably from the Latin word “marine” to Italian, Spanish and French languages referring to soaking/pickling in salt brine. What is being meant by marinating today varies a great deal between different countries. Sometimes salting, adding phosphates and some spices is considered as marinating. Some marinating procedures have been targeted to tenderize poorer quality meat (Young and Lyon 1997a and b). In Finland, marinades are nowadays complex sauces which have a great effect on product appearance and taste. They are water-oil emulsions typically containing salt, sugar and acids (acetic, citric), rheology-improving additives (like xanthan gum and guar gum), antimicrobial agents (like sorbate and benzoate) spices and aroma strengtheners. The pH of these marinades is usually acidic, less than 5, so sugar is needed to cut the edge of the acidic taste. Basic flavor is often obtained using pepper, onion and tomato base together with other added spices. There is a big selection of different flavors, including curry, Chinese-type, Italian-type, honey and barbecue marinades. The amount of marinade added on meat is variable among product types, 20 to 30% (wt/wt) being quite typical for meat strips.

Aims of packaging and marinating technology

Marinated Finnish meat products are usually packaged under modified atmospheres (MA) to prevent the growth of aerobic spoilage organisms. Modified atmosphere packaging (MAP) of meat usually results in the dominance of psychrotrophic lactic acid bacteria (LAB) if proper cold-storing is applied to control the growth of *Enterobacteriaceae* (Borch et al. 1996, Smolander et al. 2003). In addition to the LAB, *Brochothrix thermosphacta* has also been associated with spoilage in some countries (Borch et al. 1996) but this species has not been detected to form a major part of the spoilage population in Finnish MAP marinated broiler meat strips (Susiluoto et al. 2003) .

The main aims of marinating have been considered to be tenderizing, flavoring and enhancing safety and shelf life of meat products due to inhibition of microbial growth. The growth of microbes has been considered to be suppressed by the acidic pH and the use of sorbates and benzoates in the marinades. In the period 1997 to 2000 the National Technology Agency of Finland supported in the first study program (Uudistuva elintarvike tutkimusohjelma) a project associated with meat marinating technology. During these studies, marinating was surprisingly not found to increase the shelf life of these products and also the effect on tenderizing was not as good as anticipated. It was actually found that there were higher bacterial levels in the marinated products than in the corresponding non-marinated products. In 1997, severe spoilage problems

were noticed in certain marinated poultry products. This prompted our interest to study and identify the specific spoilage organisms in the Finnish products. During the same time, the group of Professor Hänninen (Department of Food and Environmental Hygiene, University of Helsnki) started to analyze the effect of marinating on *Campylobacter*. Since then these studies have been carried out in collaboration with the Finnish meat industry and with support obtained from the Academy of Finland and National Technology Agency. Our work has targeted beef, pork and poultry products. Currently we have the best knowledge of the microbial ecology associated with marinated poultry products. Some of these studies are presented in the following paragraphs in order to elucidate the microbial complexity associated with marinating.

Microbial ecology in marinated poultry products

Specific spoilage LAB in marinated poultry

In our first study (Björkroth et al. 2000), LAB associated with gaseous spoilage of MAP, raw, tomato-marinated broiler meat strips were identified. We use a 16+23S rDNA RFLP (ribotyping) database for LAB identification since the psychrotrophic LAB species cannot be identified using traditional phenotypical tests. A mixed LAB population dominated by a *Leuconostoc* species resembling *L. gelidum* was found to cause the spoilage of the product. *Lactobacillus sakei, Lactobacillus curvatus* and a Gram-positive rod phenotypically similar to heterofermentative *Lactobacillus* species were the other main organisms detected in this spoilage population. Increase in pH together with the extreme bulging of packages was considered to suggest a rare LAB spoilage type called "protein swell". This spoilage is characterized by excessive production of gas due to amino acid decarboxylation and the rise of pH is attributed to the subsequent deamination of amino acids. However, in recent studies (not yet published) we have shown that these LAB are not able to decarboxylate the major meat-associated amino acids. The rise in pH values is likely to result from the buffering capacity of the meat. A polyphasic taxonomy approach, including classical phenotyping, whole-cell protein electrophoresis, 16+23S rDNA RFLP, 16S rDNA sequence analysis and DNA-DNA reassociation analysis, was used for the identification of the dominating *Leuconostoc* species. 16S rDNA gene sequences of two spoilage strains possessed 98.8 and 99.0% sequence similarity with the *L. gelidum* type strain. DNA-DNA reassociation, however, clearly distinguished these two species. These same strains showed only 22% and 34% hybridization with the *L. gelidum* type strain. Based on these results, a separate species status was proposed for these *Leuconostoc* strains, and the name *Leuconostoc gasicomitatum* was given to this spoilage-associated species. Recently also the unidentified Gram-positive rod has been shown to be a new psychrotrophic *Lactobacillus* species, *Lactobacillus oligofermentans* (Koort et al. 2004b).

In another study (Susiluoto et al. 2003) we wanted to evaluate if LAB in retail, MAP, marinated broiler meat strips on sell-by day commonly harbor *L. gasicomitatum.* A total of 32 packages, 3 to 5 packages of 7 differently marinated broiler meat products, were studied at the end of the producer-defined shelf life (at 6ºC, 7 to 9 days depending on the manufacturer). Bacteria were cultured on MRS and Tomato Juice Agar (TJA), Rogosa SL agar (SLA), Plate Count Agar (PCA) and Streptomycin Thallium Acetate Agar (STAA) for the enumeration of LAB, lactobacilli, total bacterial count and *B. thermosphacta*, respectively. The average CFU/g of the 32 packages was 2.3×10^8 on PCA. The highest bacterial average, 3.1×10^8, was recovered on TJA, the corresponding CFU/g averages on MRS and SLA being 2.3×10^8 and 1.3×10^8, respectively. Despite the high LAB numbers detected, radical spoilage changes such as unpleasant odor, slime production and formation of gas were not seen. *B. thermosphacta* did not form a significant part of the bacterial population since none of the levels exceeded the spoilage threshold level of 10^5 CFU/g reported in previous studies for this organism. In order to characterize the dominating LAB population, 85, 85 and 88 colonies from MRS, TJA and SLA, respectively, were randomly picked, culture purified and identified to species level. Fifty-six of the 170 isolates picked from the non-selective LAB media (MRS and TJA) were identified as *L. gasicomitatum,* followed by *Carnobacterium divergens* (41 isolates), *L. sakei* (31 isolates) and *L. curvatus* (20 isolates) species. SLA proved not to be completely selective for lactobacilli because the growth of *Leuconostoc* spp. was not inhibited, *Carnobacterium* spp. were the only species not detected on SLA. This study confirmed that *L. gasicomitatum* commonly occurs in MAP, marinated poultry products.

Initially contaminating and spoilage LAB in the products and processing environment

In order to show which of the initial LAB contaminants are also causing spoilage of a MAP, marinated broiler leg product at 6ºC, LAB were enumerated and identified on the 2nd and 17th day following

manufacture. A total of 8 fresh and 13 spoiled packages were studied for LAB levels. In addition, aerobic mesophilic bacteria and *Enterobacteriaceae* were determined. The average CFU/g values in the 8 fresh packages were 1.3×10^3, 9.8×10^3 and 2.6×10^2 on MRS, PCA and Violet Red Bile Glucose agars (VRBG), respectively. The commercial shelf life for the product had been set as 12 days and all packages analyzed on the 17th day were deemed unfit for human consumption by the sensory analysis. The corresponding CFU/g averages in the spoiled product were 1.4×10^9, 1.1×10^9 and 3.9×10^7 on MRS, PCA and VRBG agars, respectively. For characterization of the LAB population, 104 colonies originating from the fresh and 144 colonies from the spoiled packages were randomly picked, purified and identified to species level. The results showed that enterococci (35.7% of the LAB population) were dominating in the fresh product whereas carnobacteria (59.7%) dominated among the spoilage LAB. *Enterococcus faecalis*, *Carnobacterium piscicola* and *Carnobacterium divergens* were the main species detected. In general, when the initial LAB population is compared to the spoilage LAB, a shift from homofermentative cocci towards carnobacteria, *L. sakei/curvatus* and heterofermentative rods (*L. oligofermentans*) was seen in this marinated product. A novel *Enterococcus* species, *E. hermannienesis* (Koort et al. 2004a), was also described from the enterococci present in the initial population.

After the three studies showing many novel LAB species in these marinated products we wanted to study what is the role of the broiler chicken as a source of these spoilage LAB. We made four slaughterhouse visits during which carcasses and air of the slaughterhouse and adjacent processing facilities were sampled. These results showed that the broiler skin or mucous membranes were not major sources of the spoilage LAB but they are commonly found in the air in the processing rooms suggesting environmental contamination of the processing facilities (Vihavainen et al. 2004). We think that the cold processing facilities favour the adaptation of the psychrotrophic strains in the processing facilities because the marinades themselves have not been found to harbour spoilage LAB.

Survival of Campylobacter spp. in marinated poultry products

Marinating has been considered to increase safety of poultry products. Perko-Mäkelä et al. (2000) studied the survival of *Campylobacter jejuni* in plain marinade and in both marinated and non-marinated drumsticks and sliced breast meat strips during storage at 4ºC. The marinade had a pH of 4.5 and NaCl content of 5.9% (wt/wt). Inocula consisted of a cocktail of 7 *C. jejuni* strains. In the plain marinade, the *C. jejuni* inocolum level was initially log 5.4 CFU/ml and within 24 hours a log 2.4 CFU/ml decrease in *C. jejuni* level was noticed. After 48 hours no *Campylobacter* were detectable in the marinade. However, the fate of *Campylobacter* in both marinated and non-marinated meat products was quite different in comparison to the situation in the plain marinade. Surprisingly there was no difference between the marinated and non-marinated products. When an inoculum of log4 to log5 CFU/ml was added to 300g product, the organisms were detectable at least for 9 days. With a smaller inoculum level of log1 to log2 CFU/ml, *Campylobacter* were detected for at least five days. These results show that marinating may not necessarily have an effect on the survival of enteric pathogens, like *Campylobacter*. This may also be due to the buffering capability of meat quickly neutralizing the pH of the acidic marinade. The change in the acidic pH towards neutrality results in dissociation of the lipophilic acids making their antimicrobial effect nonexistent.

Conclusions and further studies

Marinating is changing the spoilage LAB population initially present in the product. We have detected many novel species in these products. Currently we think that addition of marinades is favoring the growth of some psychrotrophic LAB which are rarely detected in non-marinated meat products. *L. gasicomitatum* has also been detected from carrots and a spoiled fish product (Lyhs et al. 2003) but not from the skin or membranes of broiler chicken. As a psychrotrophic organism it does not survive in gastro intestinal tract and we currently consider this species as an environmental bacterium well-adapted in the cold processing facilities. The use of MAP and marinating is favoring the growth of this bacterium and to lesser extent also *L. oligofermentans*. In order to control *L. gasicomitatum* and *L. oligofermentans* growth in these products we should understand the metabolism of these species better.

Background

Bacterial or other microbial contamination is the major cause of most incidents of food-borne illness. Among food groups, animal origin products are the most likely sources of pathogens threatening human health. To develop more accurate and non-time-consuming methods for evaluating hygiene quality of meat products is an important issue for securing day-to-day health of the consumers.

Objectives

In the present study, we compare the activities of succinate dehydrogenase and hexosaminidase in raw meat samples collected from healthy animals (normal pork) or diseased animals (abnormal meat). We also utilize cultured murine macrophage cell line as biodetecting model for evaluating the microbe contamination in raw pork.

Materials and Methods

Sample collection and preparation: Normal pork samples are obtained from the local meat market immediately after slaughter. Abnormal pork samples are collected from the animal died from illness in a local pig farm. Muscle proteins are extracted from *M. longissimus dorsi* according to the method reported previously by Kuo (1989), and used for enzyme activities and TNF measurements. For immune cell response assay, the extracts are added to the cell culture medium, and the cytokines released from the cell and cell viability are measured after the treatment. Microbiological assay: Microorganism growth is analyzed by FDA method. Immune response assay: Raw 264.7 cells, murine macrophages, are used for immune response assay. The cells are cultured in Dulbecco's modified essential medium (DMEM, GIBCO BRL, Rockville, MD) supplemented with 10 % feta bovine serum and incubated in an incubator at 37℃ with 5% CO_2. To determine the effects of muscle extracts on the immune cells, Raw 264.7 cells are treated with medium containing extract for 48 hours. Cytokine measurement: TNF in the medium is measured by enzyme-linked immunosorbent assay (ELISA) kit (Neogen). Cell viability: Cell viability after treated with muscle extract is determined by MTT assay. Succinate dehydrogenase (SDH) activity and Hexosaminidase activity: SDH activity is measured based on the procedure reported by Colowick *et al*. (1957). Hexosaminidase activity is assessed according to the method reported previously by Ching et al.(2001).

Results and Discussion

The data show that the level of volatile basic nitrogen (VBN), pH value and bacterial number are higher in abnormal pork than in the normal samples (Table 1); however, VBN concentrations in the early stage still remain at normal range. After 24-hour storage at room temperature, the level of VBN accumulation in the abnormal pork are higher than the normal pork but total bacterial counts of the abnormal pork are not higher than the standard values set by FDA, suggesting that total bacterial counts are not only an appropriate indicator for determining the quality of pork.

The results from enzyme activity assay demonstrate the alterations in the levels of cellular enzymes in the abnormal pork. The activity of HSA in abnormal tissue is much higher compared with the one in normal sample. The enzyme activity increases in the abnormal pork during storage, and reaches the level of absorbance 0.729 at 12 hour after storage, while the activity in the normal sample remains constantly at low level. The activity in the abnormal pork is 2 fold higher than the normal sample at every time point tested. The abnormal pork also exhibits significantly higher activity in SDH activity compared with the normal pork

at the early stage (within 6 hours) of storage. However, the activity in the abnormal pork decreases when storage period is prolonged. There is not significant difference in the activity of SDH between two groups of sample after 12 hour storage.

It is well known that microbial infection induces the production of TNF that can serve as an indicator for the infection. The abnormal pork tested in this study is obtained from the animal died from illness, and shows higher level of TNF compared with normal pork sample, indicating the previous infection before slaughter (Table 2). The level in the normal tissue does not change during storage. The TNF level in the abnormal pork is 2 folds higher than the level in the normal tissue at 12 hour after storage. The data from MTT assay further demonstrate the cytotoxicity of the extract from the abnormal pork in the cultured immune cells. Raw 264.7 cells treated with the extract of the abnormal pork shows lower cell viability after activation with LPS compared with the culture treated with the extract from the normal pork, suggesting the application of immune inhibition in Raw 264.7 cell as biodetecting model for evaluation of hygiene quality of pork.

Conclusions

In conclusion, this preliminary study provides evidence for establishing new cellular indicators, including HSA activity, TNF production, and immune cell cytotoxicity, for discriminating abnormal pork from normal pork. This study also suggests viability of Raw 264.7 cells may be an appropriate indicator for biodetecting model for hygiene quality evaluation of pork. These parameters are quite stable within 24 hours, and are suitable for the hygiene quality evaluation in Taiwan. Since the traditional meat markets in Taiwan sell fresh raw meat only in the morning, within 6 hours after animal slaughter. Evaluating the hygiene quality of frozen and refrigerated products by detecting these parameters is an interesting subject for the future studies.

Background

One of the most popular cooked blood sausage in Spain is *Morcilla de Burgos*, which is produced in the region around Burgos in the north of Spain. It consists of a mixture of onion, rice, animal fat, blood, salt and different spices such as black pepper, paprika and cumin. The product is cooked for 45-50 min at 94-95ºC, air cooled to 8-10ºC and finally chilled stored at 4ºC. This product is commercialised as a fresh product with a shelf-life of around 8-10 days, however, the use of vacuum packaging and modified atmosphere packaging has recently increased in order to extend the shelf life and widen the present market. (Santos et al, 2003). The typical way to consume this product is by deep frying in vegetable oils (mainly olive oil), roasted or boiled as part of other traditional dishes.

In a technical study made on *morcilla de Burgos* (Anonymous, 1983), it was underlie the good sanitary quality of this product, since from 67 samples analysed by traditional microbiology tests there were not detected any strain of *Staphylococcus aureus*, *Salmonella* spp., *Shigella* spp., *Escherichia coli*, or *Bacillus cereus*.

There are also another previous work that has studied the microbiology of *morcilla de Burgos*, basically the spoilage microbial population and some indicator species of the microbiological quality of the product, such as *S. aureus*, *Clostridium perfringens*, enterobacteria, pseudomonads, enterococi and moulds, without obtaining positive results in these species. (Santos 2001).

The recent advances achieved in molecular biology techniques have developed numerous genetic procedures as PCR and Real-Time PCR, which have been applied successfully to food analysis, principally in the detection of pathogenic microorganisms.

Objectives

Although there is some information about the basic microbiology of *morcilla de Burgos*, as it was mentioned above, little is known about the presence of foodborne pathogens in this product. The aim of this preliminary study is the detection of 5 species of pathogenic bacteria in this blood sausage, comparing traditional microbiology test, *versus* PCR and RT-PCR, in order to obtain a sensitive and reliable method that can assure the food safety of these kinds of products.

Materials and methods

Samples

This initial study was done with 4 *morcilla* producers, 6 samples of each one were analysed. All samples were vacuum-packed, and 3 *morcillas* were stuffed in natural beef casing and the other one in pork casing. The samples were purchased in local supermarkets and were transported to the laboratory in refrigeration conditions in iceboxes.

Microbiology assay

For detection of *Staphylococcus aureus*, *Listeria monocytogenes* and *Yersinia* spp. The pathogenic species studied were*: S. aureus* by means of homogenization of the sample and directly plated in Baird Parker agar (Oxoid LTD, Basingstoke, Hampshire, England) with supplement of egg yolk-tellurite emulsion (Oxoid), incubated at 37ºC for 72 hours; *Yersinia* spp was grown after alkaline treatment of the homogenised sample, in CIN agar (Oxoid) at 30ºC for 48 hours; *L. monocytogenes* enrichment of 20 g of sample in 180 ml of Fraser broth base (Oxoid) with ½ Fraser selective supplement (Oxoid) at 37ºC for 20-24 hours, incubation in Fraser broth base (Oxoid) with Fraser selective supplement (Oxoid) at 37ºC for 24 hours and finally cultivated in Palcam agar (Oxoid) at 37ºC for 48 hours.

PCR assays

For detection of *Salmonella* spp., *S aureus* producing enterotoxins A and D (SEA and SED), *L. monocytogenes* and *Y. enterocolítica*, 20 g of each sample was inoculated into 180 ml TSBYE medium. The samples were incubated at 37ºC ± 1ºC overnight (16 – 20 h), with shaking at 150 rpm. A portion of the sample (1 ml from the upper phase) was mixed with 1 ml of sterile phosphate buffered saline (PBS) and centrifuged at 12000 rpm for 5 min. The pellet was washed three times with PBS, then resuspended in 500 µl of water, incubated in a boiling water bath for 10 min, and immediately cooled in ice water. A 5 µl portion of each sample was added to 45 µl of PCR mixture containing 75 mM Tris HCl (pH 9), 50 mM KCl, 2mM $MgCl_2$, 0.2 mM of each dATP, dTTP, dCTP, dGTP, 0.5 µM each primer, and 1 U of Tth DNA polymerase, (Biotools DNA polimerase, Madrid. Spain.). The PCR was conducted in a Mastercycler gradient, (Eppendorf AG, Hamburg. Germany.) The amplification condition was one cycle of 94ºC for 3 min, then 30 cycles of 94ºC at 50-58ºC depending upon the primers used (see table 1) for 30 s and at 72ºC for 1 min, and finally, one cycle of 72ºC for 90 s. A positive and a negative control were used for each PCR reaction. The PCR products (10 µl of each) were separated by electrophoresis in 2% agarose gels. To stain the gel with ethidium bromide during 10 min, and the result was observed in UV light (Wang et al, 1997, Rosec at al, 2002).

RT-PCR assay

For detection of *L. monocytogenes*, samples were prepared as it was described above for PCR, 5 µl portion of each sample was added to 45 µl of PCR mixture containing 1x TaqMan universal PCR master mix (part number 4304437; Applied Biosystems, Foster City. U.S.A.), 0.3 µM concentrations of each primer, and 0.2 µM concentration of fluorogenic probe. DNA amplification was carried out in MicroAmp optical 96-well reaction plates (part number N801-0560; Applied Biosystems), sealed with MicroAmp optical caps (part number N801-0935; Applied Biosystems.). The cycling program consisted on heating for 2 min at 50°C, and then 10 min at 95°C followed by a two-stage temperature profile of 15 s at 95ºC and 1 min at 60ºC, repeated for 40 cycles. Amplification, data acquisition, and data analysis were carried out with an ABI Prism 7000 sequence detector (Applied Biosystems).

Results and discussion

Table 2 shows the results obtained for all pathogenic species evaluated. No positive samples were found for *S. aureus* enterotoxin D producer, *Salmonella* spp, and *Y. enterocolitica*, with any of the techniques used. In case of *S. aureus* producer of enterotoxin A, 10 positive samples were found by PCR, distributed between all the manufacturers, and in *L. monocytogenes* 9 positive samples were obtained by PCR and 15 positive results with RT-PCR distributed between all the manufacturers as well. Both species did not show positive results with conventional microbiology tests.

The different results obtained between traditional microbiology tests, and those of molecular biology, can be due to the different sensibility of those techniques, the use of different enrichments culture media or the growth of competitive flora. RT-PCR is 100 times more sensitive than the PCR and 1000 times more than the traditional microbiology tests used in this study. These results indicate that pathogenic bacteria detected in this study are in very low quantities. (Llanos et al, 2003).

Despite of the strong thermal treatment of 45-50 minutes at 94 º C, it is surprising, the presence of *S. aureus* producing enterotoxin A that used to be related to bad hygienic practices, and *Listeria* spp. which is an ubiquitous microorganism, and it is very extended in nature. The presence of these microorganisms can be due to a contamination in post cooking steps of cooling and manipulation during packing.

Conclusions

The molecular biology techniques used, are extremely sensitive to discover the presence of pathogenic microorganisms in low quantities *versus* the microbiological conventional technologies.

It could be very interesting to develop a more accurate HACCP system along the production line, especially in the cooling step, in manipulation before packaging, to try to keep the product in refrigeration, without breaking the cold-chain, and consuming the product according to the traditional culinary ways that imply some thermal treatment that warranties the inactivation of *S. aureus* as *L.monocytogenes*. However, other strategies, carried out in previous studies by our group, such as post-packaging short pasteurization could be very useful to obtain an acceptable sanitary quality of these kinds of products. Further studies will be developed in that sense.

INFLUENCE OF THE ONION VARIETY ON THE SHELF LIFE OF THE BLOOD SAUSAGE "MORCILLA DE BURGOS"

Diez, A. M.; González, L.; Ena, J. M.; Jaime, I.; Rovira, J.;

Department of Biotechnology and Food Science. University of Burgos. Pza. Misael Bañuelos s/n. 09001. Burgos. SPAIN.

Background

Morcilla de Burgos is a popular cooked blood sausage produced in the region around Burgos, in the north of Spain. *Morcilla* is made of a mixture of chopped onion, rice, animal fat, blood, salt and different spices such as black pepper, paprika and cumin. Physicochemical and sensory properties of this traditional product were investigated in order to support the claim for a Protected Geographical Indication.
Three types of *morcilla* could be differentiated according to their sensorial and physical-chemical characteristics, composition and geographical origin (Santos et al., 2003). Due to the high percentage of onion included in this product (between 15% and 70%), especially in two of the types, this ingredient is determinant of their sensory properties (Santos et al., 2002) and probably it will have a great influence on shelf-life of the product.
"Horcal" is a regional variety of onion, grown in river banks. This onion has an elliptical shape and bigger size compared with others kinds of onions. This variety is the most often used as ingredient of *Morcilla de Burgos*, since, according to traditional manufacturers, its less firm texture and mild pungent flavour gives to *Morcilla* a sensibly better sensory quality. However, its crop is seasonal with a short period of storage and it must be substituted by other varieties of onion when *morcilla* manufacturers run short of "Horcal" onion of suitable quality. In this case, the variety most often used is "Grano" or "Valenciana", with globular shape. Besides, it is smaller than "Horcal" variety and its sensory properties also differ, since it is firmer and more pungent than "Horcal" onion.

Objectives

The aim of this study is to know the effect of the variety of onion used in the manufacture of the blood sausage "Morcilla de Burgos" on their sensory characteristics and shelf-life of the product.

Materials and methods

Samples: Two batches of 60 *morcillas* were made with the same formulation with the only difference of the kind of onion added. One batch was made with a local variety of onion *Allium cepa L.* var. horcal and the other batch with *Allium cepa L.* var. grano. Sausages were vacuum-packaged in the factory, after cooking and cooling. *Morcillas* were kept in refrigeration at 4ºC, during storage. Samples for microbiological and physical-chemical analysis were taken after manufacture (day 0) and at days 7, 14, 21, 33 and 63 of storage. At each sampling time two *morcillas* were analysed, randomly chosen. Initially samples for microbiological analysis were taken, under sterile conditions, and later, from the same *morcillas*, samples for physical-chemical analysis were taken. All analysis were made in duplicate.

Microbiological analyses. The microbiological parameters analysed were Total Viable Count (TVC) using pouring-plate method on PCA agar (Oxoid. Basingstoke, UK), incubated at 30ºC for 48h; Lactic Acid Bacteria (LAB) on MRS agar (Biokar Diagnostics. Beavais, France) incubated at 30ºC for 48h in aerobic conditions; *Pseudomonas* spp. (PSD) on Pseudomonad agar (Oxoid) supplemented with CFC (supplement Oxoid), incubated at 30ºC for 48h; *Clostridium perfringens* on TSN agar (Biokar Diagnostics. Beavais, France.), using the pouring method, and incubated at 37ºC for 48h; anaerobic conditions were achieved by pouring an agar sealing tap around 20mm high on solid TSN agar, after sample inoculation. Samples consisted of 25g of *morcilla* slices with casing (Santos, 2001).

Physical-chemical analysis. Along storage time pH was measured with a penetration probe in four different points for each sample.

Organic acids analysis was done after some preliminary steps as desiccation and fat removing. Five grams of *morcilla* were placed on a plate and kept in a desiccator cabinet for 24h at 105ºC. Then, fat were extracted for 6 h by Soxhlet method and finally organic acids were extracted from the dry and defatted sample. The organic acids were extracted by miliQ water (1:3, w/v), heated till boiling, clarified by centrifuge at 13000 rpm for 10 minutes and the supernatant was membrane filtered (0.45 µm) before injection.
Chromatographic analysis was carried out using a Hewlett-Packard Series HP 1100 with diode array detector and Chemstation software. Aliquots from each extract (20 µl) were injected onto a 30 cm x 7.8 mm i.d. Supelcogel C-610H (Bellefonte, PA), which was maintained at 40 ºC with a column heater (Bio-Rad Ca, USA), and eluted using 0.1 M H_3PO_4 at a flow rate of 1ml min^{-1}. The eluate was monitored at 210 and 280 nm.

Sensory analysis comprises two different steps. First, sensory differences between *morcillas* made with different kinds of onions were determined at the beginning of storage by consumer analysis. A triangle test was done by a panel consisting of 40 not trained panellists. Panellists were asked to found overall differences between samples. Additionally, panellists evaluated the intensity of odour and taste, soft texture and presence of onion. *Morcilla* was served to the panellist in slices of 1 cm thickness and cooked in microwave till 70ºC in the core. The second step evaluated the influence of onion on self-life of the *morcilla*. At the 22nd day of storage, 34 sausages of each type were examined by a trained panel of 5 panellists and graded them in three groups: acceptable, medium and rejected. Visual parameters of the sealed packs were evaluated and visual and odour parameters were tested after opening the packs. "Acceptable" corresponds to sausages without defects, "Medium" sausages present some small changes, but they would not be rejected by consumers and "Rejected" corresponds to sausages with remarkable defects. The typical sensory changes occurring in spoilage of "Morcilla de Burgos" are blowing of the packs, development of drip, slime formation and souring of the product (Borek, 2002).

Results and discussion

At the beginning of storage, *morcillas* made with "horcal" and "grano" varieties show differences. Piruvic acid concentration is higher in *morcilla* with "grano" onion (Table 1), in agreement with Llamazares et al. (2003). Piruvic acid is the main responsible for the pungency of onion (Bedford, 1984; Schwimmer and Weston, 1961), and therefore it would have also a significant contribution to pungency in the *morcilla*. Their concentration could be considered an index of hot taste of product.
According to sensory discriminatory tests both kinds of *morcilla* were significantly different ($\alpha = 0{,}01$). If specific parameters are considered the intensity of odour and taste of both kinds of *morcilla* were not significantly different, but differences were found in the presence of onion and texture. With the descriptor "presence of onion" panellists evaluated distinguishable particles of onion and also smell and taste of onion, being more intense in *morcilla* with grano variety than with horcal variety. Concerning texture, *morcilla* with horcal onion was softer than *morcilla* with grano onion. These results suggest the high influence of onion variety on sensory properties of onion since grano variety is firmer and more pungent than horcal variety.
Table 1 shows physical-chemical parameters of both types of *morcilla* along storage period. These results were expected, since the increase of concentration of lactic acid and the decrease of pH can be related to the development of lactic acid bacteria throughout the 63 days of storage. Lactic acid increases along storage, altough until the day 14 it is not detected due to the level of detection of the analytical method used. Differences were found between *morcillas* with the two varieties of onion. A more rapid formation of lactic acid and the fall of pH in *morcillas* with "horcal" onion was observed. Pyruvic acid, present in onion, also decreases, since it can be used as nutrient by LAB. Piruvic acid increases in the first days of storage and later decreases progressively along time in a similar rate in both types of sausages.
Concerning to microbiological data, table 1 shows the results for all parameters analysed, except for *Clostridium perfringens* because no colonies were identified during the study. Total Viable Counts (TVC) and Lactic Acid Bacteria (LAB) present a progressive increase along storage. Some differences were founds between both *morcillas*, since initial number and rate of growth were slightly higher in *morcilla* with horcal onion.
Pseudomonads present a growth until to reach a maximum count, afterwards counts suffer a decrease due to the lack of oxygen because of vacuum packaging. The initial development of these microorganisms owning to the low concentration of retained oxygen in the vacuum package and after 14 days, when oxygen is depleted, their decline comes about. The pattern of PSD development is similar in sausages with both kinds

of onion, but in *morcilla* with "horcal" onion counts are around 1000 ufc/g higher than in sausages with "grano" onion.

The change in the rate of growth of lactic acid bacteria and in the production of lactic acid and fall of piruvic acid concentration happen one week before of sensorial deterioration of *morcilla* and this coincide with pH fall. This evolution is mainly similar for *morcilla* made with both kinds of onions, however, it differs the time when the changes in *morcilla* characteristics come about. In *morcilla* made with "horcal" onion spoilage takes place at the days 14 to 21, as in *morcilla* made with "grano" onion takes place the days between 21 to 33.

Results obtained in sensory evaluation of spoilage parameters are shown in table 2. Panellists evaluated acceptability of *morcillas* at the day 22 of storage. Overall appearance of packages and *morcillas* showed different signals of spoilage as blowing, slime, sour, pungent and acid odour, pink and green colours. These sensory changes came about one week earlier in horcal than in grano onion *morcillas*.

The main deterioration process is the blowing of the package; later pink spots appear, followed by slime production with milky appearance together with the change in the texture of the product and also the modification of odour characteristics. The sausage becomes soft and presents a release of acid odour.

This results agree with other researchers (Mattana et al., 1980, Lin et al., 1995, Llamazares et al., 2002) that found potential preservation of onions depends on variety; usually smaller onions and with higher contents of dry matter have longer shelf-life. These onions are firmer and more pungent than onions of bigger size. Oxygen is necessary for the formation of compounds responsible for pungency. Smaller onions present a low resistance to penetration of oxygen, with easier development of these compounds. The smaller superficial area led to lower initial contamination, and so preservation of these onions is better, in agreement with results obtained in this study for "grano" onion.

Conclusions

The variety of onion used in the formulation of cooked blood sausage *morcilla* has a notable effect on physical-chemical and sensory characteristics of the product. The only difference of the kind of onion used leaves to significantly different its sensory properties.
On the other hand, the type of onion has also a remarkable influence on *morcilla* preservation, since sausages made with "horcal"onion are spoiled around one week earlier than the sausages manufactured with "grano" onion. It could be due to the amount of sugars, fibre, alcohols, aldehydes, aromatic compounds, and the different compounds coming from the onion as potential nutrients of the microorganisms.

AN APPLICATION OF BLEND OF NATURAL ANTIOXIDANTS IN DRY-FERMENTED SAUSAGES

Dragoev, S.[1] and Balev, D.[1]

[1] Department of Meat and Fish Technology, University of Food Technology, Plovdiv, 4002, 26 Maritsa blvd., Bulgaria

Background

One of the main reasons for limitation of the quality and acceptability of dry-fermented meat products is the lipid peroxidation. This process causes discoloration, appearance of unusual odour and taste and generation of potential toxic compounds (Morrissey et al., 1994; Gray et al., 1996). The investigators examine this problem a long time ago. In the most contributed form this process has not actuality for scientists, but in the poorly developed form - warmed over flavor (WOF) it exists as a problem for some foods, including meat products (Spainer et al., 1992). The "Lukanka" type dry-fermented sausages, traditional for Bulgaria and Balkan's region, are an interesting model for study of this subject, because they are made by mincing, grinding, and mixing of meat raw materials with salt, additives and spices, and after that filling in casings, fermentation (known as maturation), and drying. The sausages are exhibited on significant impact of prooxidant factors during their processing. As a result of those three types of lipid derivatives are formed: primary products - hydroperoxides, secondary products expressed as free malondialdehyde (free MDA) and oxidized cholesterols. The protection of the sausages against lipid peroxidation must start from the beginning of meat storage and to continue during sausage processing. The oxygen intake, exposure to light, and the high temperature must be restricted during the sausage maturation (Lai et al. 1995). The manners for restriction of lipid and pigment peroxidation showed above are not useful or are insufficient effectively, during processing of "Lukanka" type dry-fermented sausages. This is a reason to add different antioxidants and synergists to the minced meat. Those types of blends have not universal application, because their effect depends on the proximate composition of oxidized substrate (Raharjo et al., 1993; Trout and Dale, 1990). The effective stabilization of the lipids in dry-fermented sausages can be realized only after determination of the impact of endogen pro- and antioxidant factors.

Objectives

The objective of this study is to estimate the efficiency of previously developed blend of natural antioxidants (Dragoev et al., 2004) on the progress of peroxidation processes in "Lukanka" type dry-fermented sausages.

Materials and methods

The model system of "Lukanka" was prepared from: 1) chilled beef type CL 95 stored 72 h *post mortem* at 0 – 4 ^{O}C and frozen to minus 5^{O}C 6 h before grinding and 2) chilled pork sort 50/50, stored 72 h *post mortem* at 0 – 4 ^{O}C and frozen to minus 10^{O}C 6 h before cutting, and 3) frozen bacon to minus 10^{O}C, stored 24 h *post mortem*, before using. The experiments were carried out with "Monastiry's lukanka" which is largely covered representative of dry-fermented sausages in Bulgaria, and is distinguished with comparatively high fat content. The last one is a precondition for the most expressive changes of lipid fraction in comparison with other assortments lukanka. The recipe of the "Monastiry's lukanka" control sample is: beef thigh or shoulder blade - 55 kg, pork sort 50/50 semi fatty meat - 25 kg , bacon from the back - 20 kg, salt – 2.200 kg, potassium nitrate – 0.040 kg, black pepper – 0.300 kg, cumin – 0.200 kg, and red pepper – 0.200 kg.
Some parallel samples were processed: Control sample – without antioxidants; The first experimental sample with addition of 0.124 % or 1.24 g/kg blend of natural antioxidants № 1 (liquid form), which contains 48.39 % LRSE 2 – liquid rosemary extract purchased from "Aromena" Ltd - Sofia (Bulgaria). This preparation represents a 28 – 30 % non distillated alcohol extract with flavonoide concentration 2.12 – 2.64 %. The rosemary extract was combined in the blend with 35.48 % chemical pure routine bought from E. Merck (Darmstadt, Germany) and 16.13 % pure sodium erythorbate under trade mark "Eribate", provided from F.I.A. Food Ingredients Anthes GmbH (Teising, Germany); The second experimental sample with addition of 0.112 % or 1.12 g/kg blend of natural antioxidants № 2 (dry form), which contents 3.58 % DRSK – powder rosemary concentrate, containing approximately 42 % flavonoides, mixed with 78.57 % DKFK - dry powder extract of flower bud of the Japanese acacia (*Sophora japonica*), produced in the Department of

Biotechnology in the University of Food Technology – Plovdiv, Bulgaria. The extract contents 53.33 % quercetine - agucone of the natural glycoside routine and 17.85 % pure sodium erythorbate under trade mark "Eribate", provided from F.I.A. Food Ingredients Anthes GmbH (Teising, Germany).
For analysis were purchased following reagents: 2-thiobarbituric acid, distillated pure chloroform and methanol - from Sigma Chemical Company Ltd. (St. Louis, USA, Deisenhofen, Germany); potassium iodide, sodium thiosulfate and silver iodide were purchased by Fluka Chemie AG (Buchs, Swaziland). All rest chemicals and dissolvents were AR and GPL grade and were supplied by Aldrich Chemical Co (Steinheim, Germany).
The samples of "Monastiry's lukanka" were processed using traditional Bulgarian technology expresses in following. The beef was minced by grinder through bars with diameter of holes 5 mm. The beef, pork and bacon were cut to particle size 3 - 4 mm. The salt and spices were added during cutting. The casings were filled with mass using vacuum filler. The pieces of "Lukanka" were formed by clips automat. The separated pieces were dried 2 days at temperature 8 – 9^{O}C and humidity 95 – 90 %. The drying process continues next 18 days at temperature 9 – 11^{O}C and humidity 85 – 75 %. The dry finish product was packaged and labelled.
The total lipids were extracted from the minced sausages by the Bligh and Dyer method (1959).
The oxidative stability of the extracted lipids was determined by Rancimat method (Ranfft et al., 1988), using apparatus Metrohm 679 Rancimat (Metrohm AG, CH – 9100, Switzerland).
The hydroperoxide concentration was determined when the peroxide value (POV) was established using standard iodometric method, presented as meqvO_2.kg^{-1} lipids (AOAC, 1990).
The content of secondary derivatives express by free malondialdehyde was determined using as indicator TBARS (Thiobarbituric acid reactive substances). The water-acid extraction method was used (Schmedes and Hølmer, 1989). TBARS were presented as mg MDA.kg^{-1} sausage.
Microbiological status. The characterization of the microbiological status of the sausages was made by determination of total number of aerobic micro organisms, and oxidase reducing bacteria (ORB). Those indexes were established by standard cultural methods (Boshkova, 2000).
The results were processed statistically by standard methods using computer program Excel.

Results and discussion

Oxidative stability of lipids. The addition of blend of natural antioxidants (in two examined variants) stabilizes sausage lipids (Fig. 1). On the 30th d the induction period of the lipids of experimental samples is approximately 5 times longer then those of the control sample. Two forms of blend of natural antioxidants identically stabilize the extracted lipids.

Figure 1. Oxidative stability of lipids, extracted from "Monastery's lukanka" processes from 1 d stared at 4^{o}C raw materials when is added the blend of natural antioxidants

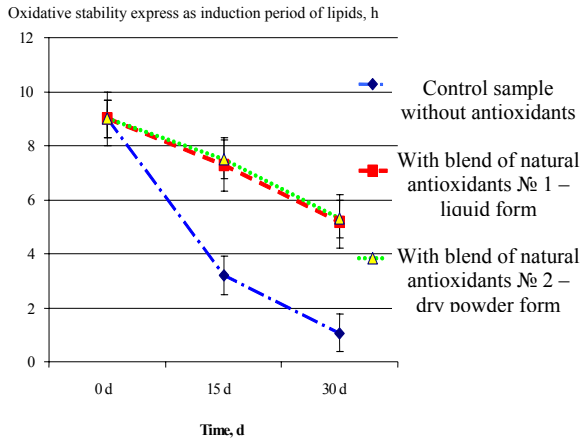

Figure 2. Peroxide value (POV) of lipids, extracted from "Monastery's lukanka" processes from 1 d stared at 4^{o}C raw materials when is added the blend of natural antioxidants

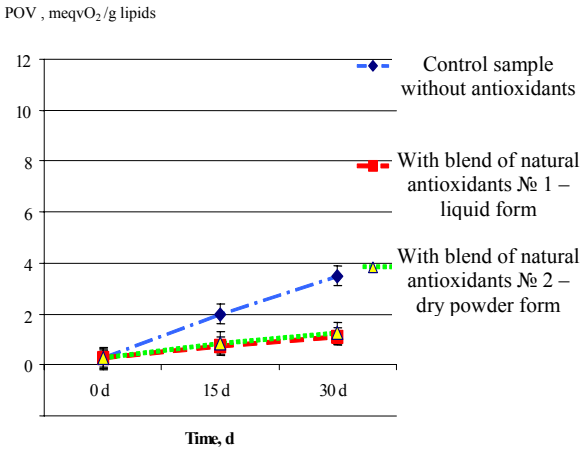
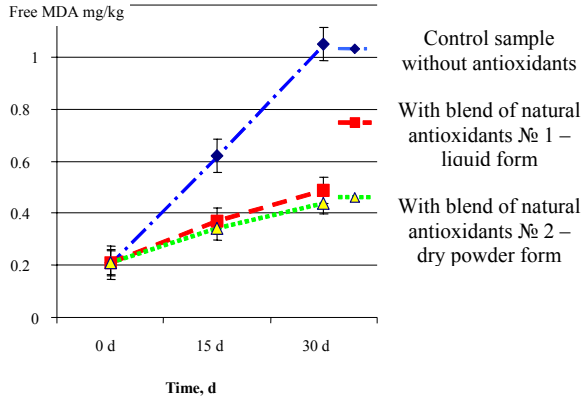


Peroxide value (POV). The addition of blend of natural antioxidants in the mentioned above concentrations in a significant degree suppress accumulation of the primary derivatives of lipid peroxidation (Fig. 2). On the 15th day of drying the hydroperoxide levels in the experimental samples are approximately two times lower than those in control sample, and on the 30th day three times lower. During all examined periods of time two

experimental forms of blend of natural antioxidants do not show statistically different results ($p > 0.05$) regarding hydroperoxide levels.

Thiobarbituric acid reactive substances (TBARS). The addition of blend of natural antioxidants retards dissemination of the chain and transformation of hydroperoxides in secondary derivatives of lipid peroxidation during maturation of the sausages (Fig. 3). The levels of free MDA are almost double time reduced. The accumulation of secondary derivatives of lipid peroxidation delays identically from the two forms of examined blend of antioxidants. The levels of free MDA on 15th d of maturation in the experimental samples are around 40 % lower in comparison with control sample. The level of free MDA in sample № 1 – liquid form of blend on 30th d is lower approximately with 52 % in comparison with the control sample, but in sample № 2 – dry form of blend it is lower around 57 %. Two experimental forms of the blend of natural antioxidants do not show statistically significant differences ($p > 0,05$) regarding TBARS levels, but are statistically significant lower ($p < 0,05$) in comparison with control sample.

Figure 3. TBARS of lipids, extracted from "Monastery's lukanka" processes from 1 d stared at 4°C raw materials when is added the blend of natural antioxidants



The results obtained by us are confirmed by data reported from other investigators (Fernandez and Rodriguez, 1991; Johansson et al., 1994; Chiretti et al., 1997; Chizolini, 1998; Novelli et al., 1998; Zanardi et al., 1998) which are examined typical for Spain, Italy or France dry-fermented sausages and hams. In this case, the indexes of lipid oxidation are within the confines of POV around 2 - 4 meqvO2/кg lipids and TBARS around 0.1 – 0.3 mg MDA/kg.

Microbiological analysis. The tendency of decreasing of the total number of aerobic microorganisms, both in control samples, as well as in two experimental samples were determined (Fig. 4). The addition of blend of natural antioxidants contributes to

Figure 4. Changes of total number of aerobic micro organisms in "Monostery's lukanka" at addition of the blend of natural antioxidants

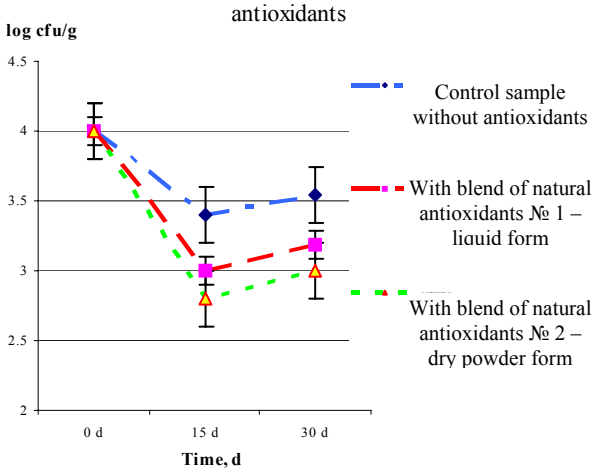


Figure 5. Percentage of ORB in samples "Monastery's lukanka" when is addied the blend of natural antioxidants

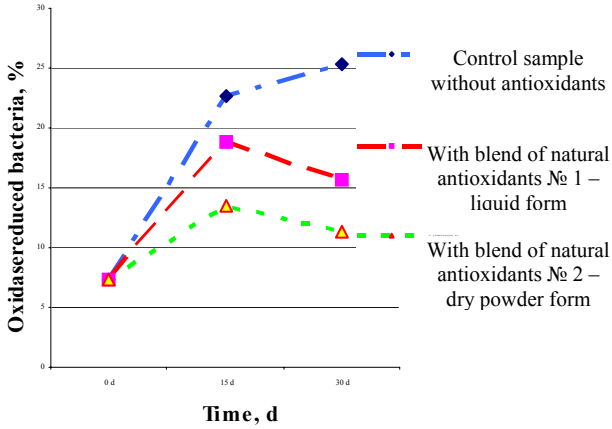

statistically significant ($p < 0.05$) decrease of the total number of aerobic microorganisms in "Monastiry's lukanka". The differences of the total number of aerobic micro organisms between two samples with addition of the blend of natural antioxidants are not statistically significant ($p > 0.05$). The percentage of oxidase reducing bacteria increases during maturation of the sausages (Fig.5). In the control sample (30 d) their percentage is statistically significant higher ($p < 0.05$) in comparison with those determined in two experimental samples. The results obtained show, that when the blend of natural antioxidants is added the percentage of oxidase reducing bacteria significantly decreases and the oxidative processes also delay. This increasing is the most significant (around 10 %) on the 15th d. One reason for the considerable decreasing of the hydroperoxides (Fig. 3) in the experimental samples in comparison with the control one is very likely due to decreasing of the percentage of oxidase reducing bacteria.

Conclusions

The two experimental samples of the blend of natural antioxidants stabilized the sausage's lipids and reduced the levels of hydroperoxides and TBARS. The examine blend of natural antioxidants, independently from its forms (liquid or powder), has not clearly bactericide action, because weakly influences on the changes of total number of aerobic micro organisms. The addition of the blend of natural antioxidants mainly affects on the percentage of oxidase reducing bacteria.

A TECHNOLOGICAL STUDY ON THE LIPID PEROXIDATION IN GROUND MEAT AND PROLONGTION THE SHELF LIVE. CHEMICAL AND MICROBIOLOGICAL PROPERTIES

Dragoev, S.[1] and Balev, D.[1], Stoychev D. [2]

[1] Department of Meat and Fish Technology, University of Food Technology, Plovdiv, 4002, 26 Maritsa blvd., Bulgaria
[2] - Exelpack Ltd. - Sofia, Office Plovdiv, Bulgaria

Background

In the muscle hydroperoxides accumulate in lipids during refrigeration storage of ground meat at 0 - 4^{O}C (Dragoev and Danchev, 1997). After 5 days at these conditions their levels increase over admissible health recommendations. The secondary products of lipid peroxidation quickly accumulate when the light and oxygen are impact on the ground meat. As a result of this: the lipid oxidative stability considerably decreases, concentration of the haematin iron increases, polyunsaturated fatty acids (PUFA) reduce their levels, and the colour and appearance of the final product changes (Dragoev, 1999).
During the first month of storage of the frozen ground meat at -18ºC, the velocity of formation and development of hydroperoxides are comparatively low, but after that the primary derivatives of lipid peroxidation quickly transform in aldehydes and ketones (Dragoev et al., 1998). The lipid peroxidation processes extends at next boiling (Cheach and Ledward, 1996; Farouck et al., 1991; Raharjo et al., 1993) or cooking (Smith and Alfazar, 1995) of the meat.
In connection with indicated above the investigation of the antioxidative ability of some organic acids as lactic, acetic, and citric and their salts are with an indisputable interest.

Objectives

On the base of bibliography the purpose of this study is to determine the impact of pure sodium lactate parallel with a blend containing sodium acetate, citrate and L-ascorbate on the lipid peroxidation and microbiological status of ground meat.

Materials and methods

Prime and raw materials were purchased from the local market. The liquid sodium lactate type “Purasal S” (produced by “Purac”AG - Germany) was supplied by “Exelpack” Ltd – Sofia. The blend based on sodium acetate “Bombal” (produced by “Van Haas” Ltd - Germany) was furnished by “JVN” Ltd – Sofia.
The meat raw materials were cut on cutter machine type “Müller” (Germany). During the technological process 2 % salt, 3 % soy granulate, previously hydrated with 3 volumes water and the relevant preserving agents were added.
The following samples were prepared: **0** – control sample without preserving agents; **1** – experimental sample with addition of 1,2 % sodium lactate; **2** – experimental sample with addition of 2,0 % sodium lactate, and **3** – experimental sample with addition of 0,5 % blend (composition) containing sodium acetate, sodium citrate and sodium L-ascorbate. The ground meat – mix of beef and bacon = 3:1 w/w were divided in quarters. Each part was stored at two temperature regimes: standard at 0 - 4^{O}C, and irregular at 8 - 10^{O}C. The experiments were made on 0, 4 and 7 d. The samples on the 0 d were examined immediately after preparing the ground meat.
Peroxide value (POV). POV was determined using standard iodometric method, after extraction of total lipids following Bligh and Dyer recommendations (1959).
Thiobarbituric acid reactive substances (TBARS). TBARS were estimated by Schmedes and Hølmer method (1989) and presented as mg free malondialdehyde (MDA)/kg meat.
pH value. The pH was measured by pH-meter MS 2004 (Microsyst, Bulgaria), completed with combined temperature/pH-electrode Sensorex Combination Recorder 450 CD (pH Electrode Station, CA 90680, USA).
Microbiological status. The characterization of the microbiological status of the ground meat was made by determination of:

- *Total number of aerobic microorganisms* was established by cultural method (Boshkova, 2000), and presented as colony forming units per gram ground meat (cfu/g)
- *Coliforms number (CFN).* A definite quantity of ground meat was sowed on the special solid medium. On it coliforms develop typical colonies after cultivation at 37^{O}C. After examinations which conform the presence of coliforms the growing colonies in 1 g ground meat were counted. CFN was calculated by formula: CFN = N. 10 ^{n}, where CFN – the number of cfu coli forms/g; N – number of colonies at the respective dilution; 10^{n} – degree of dilution.
- *Determination of the coagulase positive staphylococcus strains.* Initially an enriched growth on the liquid medium was completed with aim to keep under the concomitant microorganisms. After that the samples for the second time were grown on the solid selective medium (Boshkova, 2000).

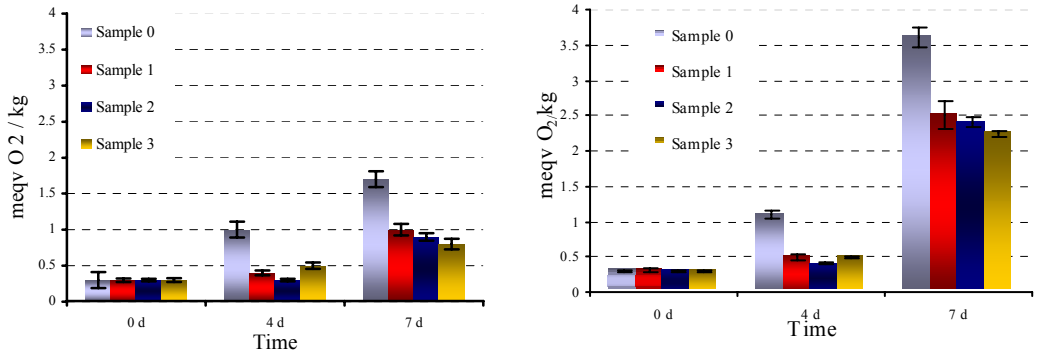
The results were processed statistically by standard methods using computer program Excel.

Results and discussion

Peroxide value (POV). At temperature of storage 0 - 4ºC the accumulation of hydroperoxides in examined samples is restricted in comparison with the control sample 0. In sample 0 (without preserving agents) on the 4th day significant amounts of primary derivatives of lipid peroxidation were found. On the 7th day the POV levels are higher – around 1.5 meqv O_2/kg (Fig.1). The sample 3 – with 0.5 % blend based on the sodium acetate on the 4th day shows POV levels similar of those of samples 2 and 1 – with sodium lactate, but on the 7th day sample 3 contains the least amounts of hydroperoxides.

Figure1. Changes of peroxide value (POV) of ground meat during storage

at 0 - 4ºC at 8 - 10ºC

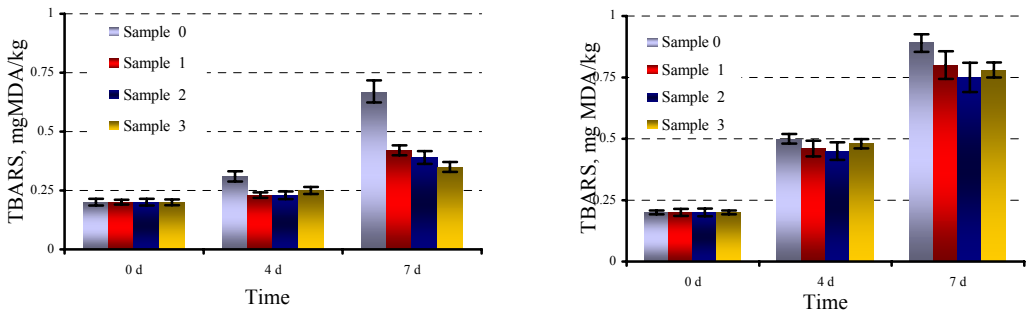


At temperature of storage 8 - 10ºC the situation is different (Fig.1). According POV the experimental samples – 1, 2 and 3 are good to the 4th day. On the 7th day the quality of every sample deteriorate. These results are confirmed by data for sensory analysis (Dragoev et al., 2004). The control sample 0 is the most unstable, while between lipid hydroperoxide levels of the experimental samples 1, 2 and 3 there are not statistically significant differences ($p > 0,05$) (Fig.1).

Thiobarbituric acid reactive substances (TBARS). At temperature of storage 8 - 10ºC the used additives do not prevent the development of deep lipid peroxidation process in ground meat (Fig. 2). The best restriction of TBARS development at 8 - 10ºC shows the addition of 2.0 % sodium lactate (sample 2).

Figure2. Changes of TBARS express as free MDA of ground meat during storage

at 0 - 4ºC at 8 - 10ºC



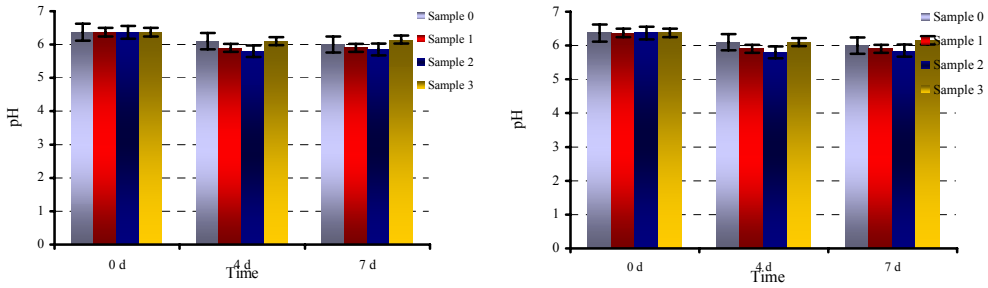
When the ground meat was stored at 0 - 4ºC TBARS slowly increases in comparison with temperatures 8 - 10ºC (Fig. 2). O the 7th day TBARS levels are least in sample 3 – with 0.5 % blend based on the sodium acetate. In the control sample 0 the TBARS is approximately two times higher than in three experimental samples.

The conclusion can be done, that the type and quantity of added preserving agent do not conduct significant differences regarding to oxidative changes of ground meat. Every experimental sample - with 1.2 % sodium lactate (sample 1), with 2.0 % sodium lactate (sample 2) and with 0.5 % blend based on the sodium acetate (sample 3) suppress but can not prevent the development of lipid peroxidation in ground meat. The observed changes are in agreement with results of previous our studies (Dragoev and Danchev, 1997; Dragoev et al. 1998)

pH value. The pH of ground meat decreases in order of 5.8 – 6.1 at 0 – 4^{O}C and 5.1 – 5.4 at 8 – 10^{O}C (Fig. 3). Those results show that the extension of shelf-life of ground meat when the preserving agents are used is a result mainly of the enhanced acidity. It probably oppresses the growth of the putrefactive microorganisms.

Figure3. Changes of pH of ground meat during storage

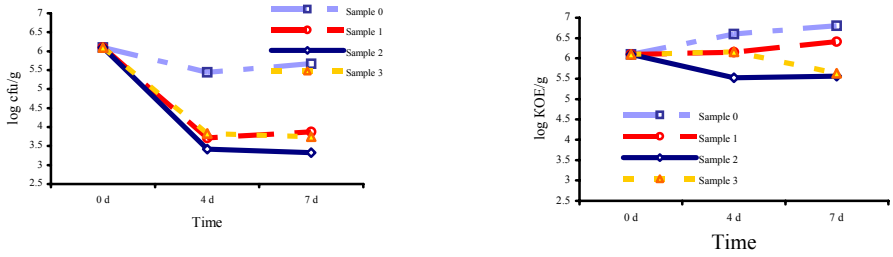
at 0 - 4ºC at 8 - 10ºC



At 8 - 10ºC both the sodium lactate and the blend based on sodium acetate (Fig.3) in practice do not decrease pH of ground meat (fig. 3). The decisive factors of this process are the temperature and initial microbial contamination. The samples with sodium lactate show a little lower pH on the 4th and 7th day of storage, which give them some advantage. Those results do not confirm the sensory properties of ground meat (Dragoev et al., 2004). The samples with sodium lactate - 1, and 2 do not have better flavor and aroma in comparison with control sample 0 and experimental sample 3 – with 0.5 % composition based on sodium acetate.

Figure4. Changes of total number of aerobic microorganisms of ground meat during storage

at 0 - 4ºC at 8 - 10ºC



Microbiological analysis. The results obtained show that the lactate affects significantly quickly on the total number of aerobic microorganisms in comparison with acetate blend, independently from temperature of storage. In spite of higher pH the samples with addition of 2.0 % sodium lactate have a smaller total count of microorganisms (Fig 4).

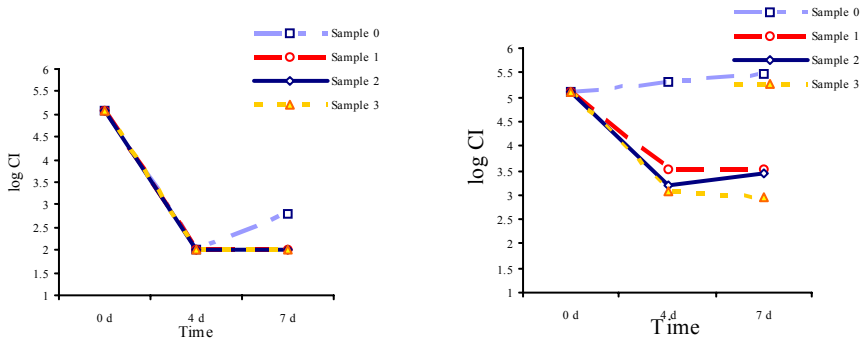
On the 7th day of storage at 0 - 4^{O}C the total number of aerobic micro organisms of ground meat is the best in sample 2 – with 2.0 % sodium lactate, followed from the sample 3 – with 0.5 % blend based on the sodium acetate, and sample 1 - with 1.2 % sodium lactate. On the 7th day of storage at 8 - 10^{O}C control sample 0 don't correspond to the norms for total number of aerobic microorganisms (cfu/g) (Fig. 4).

The tendency determined for the total number of aerobic microorganisms of the samples with preserving agents (Fig. 4) is the same for the CFN at the same conditions (Fig. 5). The control sample doesn't suit requirements for number of coli forms in 1 g meat.

At 0 - 4 ^{O}C the microbiological indices of samples are very good. Every sample, including the control one, correspond to the requirements of the total number of aerobic microorganisms and coliforms. At this temperature the experimental samples are distinguished with good microbiological status. The study implemented for the coagulase positive staphylococcus bacteria demonstrates the supremacy of sodium lactate over acetate composition.

Figure5. Changes of coliform number (CFN) of ground meat during storage

at 0 - 4ºC at 8 - 10ºC



Conclusions

The sodium lactate and the blend containing sodium acetate, sodium citrate, and sodium L-ascorbate can be successfully used as preserving agents with antioxidant action for prolongation of the shelf-life of ground meat at temperature of storage 0 - 4 ^{O}C. In those conditions the shelf-life maximum of ground meat is 7 d.

Background

The development of *Listeria monocytogenes* growth models starts with the initial recovery, proceeds with determining growth and finishes with determining the influence of different factors on growth. If there is no prevalence of Listeria on the product, it can be inoculated with this pathogen. For a comparison of growth between different products it is important to start with consistent low inoculation levels because (i) microbial growth can be dependent on initial numbers and (ii) in practice Listeria contamination will start at low numbers. To study Listeria growth with, for instance, different packaging techniques (Cagri et al. 2002), surface treatments (Naidu et al. 2003), or ingredient compositions (Sabia et al. 2003) different inoculation techniques are used. In the present study, two simple, safe and cost effective methods are compared. The first method consists of inoculating the surface using a horizontal glass plate (HGP). The second method blends the Listeria inoculum into the meat sample (BM) while the meat is chopped.

Objectives

This study was conducted to compare two inoculation methods for *Listeria monocytogenes* on meat; one by surface inoculation of an intact cooked slice of beef and the other by mixing the inoculum while chopping the cooked beef.

Materials and methods

Sample preparation: Beef longissimus steaks (2.5 cm thick) were vacuum packed, heated in a water bath at 70°C for 60 minutes and chilled on ice water. Products were stored for 1 or 2 days at 4°C until used for one of two treatments.
Inoculation: The treatment with surface inoculation (HGP) was carried out using a glass plate (30x30 cm) with a welded metal rim (height = 1 cm) put horizontally using a levelling table. Thirty mL of inoculation suspension was pipetted on the glass plate area, making sure it covered the whole area. The inoculum suspension contained 140.000 CFU/mL *Listeria monocytogenes* ATCC7644 (fresh overnight culture in Brain Heart Infusion broth at 37°C), and a surfactant (Tween 80, 0.01%) was added to facilitate even spreading on the glass plate. The resulting inoculation surface contained 3.67 log CFU/cm^2. One side of the cooked steaks was gently pressed on the glass plate, making sure there was good surface contact. The steaks were again vacuum packed. At the start of the experiment 25 steaks were inoculated, 10 were used at day 0 and after storage at 4°C for 5, 8, 12, 15 and 25 days, 3 steaks were sampled per day.
For the second treatment (BM), 2.0 kg of the cooked meat was chopped until course, using a commercial chopper (RK 30 SL, Kilia, Kiel, Germany). Subsequently, 20 mL of the inoculum containing 10.000 CFU/mL *Listeria monocytogenes* was evenly poured in the chopper. The meat was chopped until very fine. The chopped meat was vacuum packed in portions of 200 g. Ten portions were sampled on the day of inoculation. The others were stored at 4°C for 5, 8, 12, 15 and 25 days. Two portions were sampled per day.
Microbiological analyses: Samples for microbiological analyses were taken with a sterile cork borer, diluted (1:10 w/w) and stomachered in Peptone Physiological Salt solution (2 min). *Listeria monocytogenes* colonies were counted on Rapid L. mono agar (BioRad) after 24 h at 37°C. Total Aerobic Psychrophylic bacteria were counted on Plate Count Agar (Merck) after 3 days at 20°C. BM samples were analysed in duplicate and HGP samples were analysed in triplicate to compensate for possible uneven distribution.
Data was analysed using Microsoft Excel and a two sided T-test was performed.

Results and discussion

The results from the two different inoculation methods (Table 1) were significantly different for recovery percentage ($p<0.05$). For HGP the recovery can be calculated per cm^2, based on the surface of the cork borer (5 cm^2). The HGP method has on average a recovery percentage of 21.8 (SD 4.8) and an inoculation level of 1.67 log CFU listeria/g (SD 0.07) versus a recovery percentage of 15.6 (SD 6.7) and an inoculation level of 1.15 log CFU listeria/g (SD 0.19) for the BM method. Inoculation levels are not statistically compared because the initial loads are not comparable.
The low recovery for BM is possibly explained by a by a damaging effect of the shear forces which occur by chopping at high speed (4000 rpm). The recovery percentage for the HGP method can be explained by the efficiency of transfer of microorganisms from the glass surface to the meat surface. The results of the total aerobic psychrophyles count confirmed the results found with the Rapid L. mono agar, indicating that the selectivity of Rapid L. mono agar had no influence on the results (data not shown).
The growth of Listeria in the vacuum packed beef occurred approximately at the same rate for both inoculation methods (Figure 1). The slope of the growth is 0.02 Log CFU Lm/day for both inoculation methods (0.0219 for HGP and 0.0196 for BM). This rate of growth is low for *Listeria monocytogenes* in cooked beef product compared to the ARS ERRC Pathogen Modelling Program (http://www.arserrc.gov/mfs/PATHOGEN.HTM). The ARS ERRC Pathogen Modelling Program has been developed with broth models. A study form Duffy et al. (1994) has modelled the growth of Listeria in cooked beef. In this study relative long lag phases were determined and growth is modelled over a 35-day period. The products prepared by Duffy et al. contained 2% added water and gelatine for better slicing quality. In this study water loss from the cooking process was not used for the inoculation methods. The slower growth of Listeria monocytogenes in this study can be explained by a lower moisture content in the samples.

Conclusions

The method of surface inoculation using a horizontal glass plate (HGP) resulted in a significantly higher recovery of 21.8% versus 15.6% ($p<0.05$) for the method whereby the meat was chopped (BM) and at the same time the Listeria inoculum was blended in.
The low percentage for the BM method can be explained by a damaging effect of the shear force, which occurs during the chopping process. An inoculation method should not deactivate microorganisms, unless aimed for, because it can have an effect on the growth characteristics. Therefore the BM method is less suitable. An effect of the inoculation method on growth rate was not observed in this study.
For the HGP method there were no indications of a damaging effect on *Listeria monocytogenes*. In addition, the HGP method resulted in the lowest standard deviation in inoculation levels. For easy inoculation with *Listeria monocytogenes* the HGP method is therefore preferred.

Background

Modified atmosphere packaging (MAP) with low storage temperature are important hurdles contributing to microbial and lipid oxidation stability of meat products and increasing their shelf life. Also the use of MAP improves product presentation, facility of storage, distribution, sale and utilisation (Ohlsson, 1994). The success of these technologies depends on the specificity of gas mixtures related to the product, type of meat, the nature and initial quality of meat, the temperature control, the barrier properties of the packaging film and the efficacy of the equipment (Taylor, 1996).
The use of CO_2 enriched atmospheres extends the shelf life of raw poultry by inhibiting the psychotrophic gram-negative bacteria and *Pseudomonas spp.*. Although later meat spoilage and changes on organoleptic characteristics are observed because slower-growing microorganisms (*Carnobacterium spp., Brochotrix thermosphacta, Lactobacillus spp*.) proliferate (Blakistone, 1999).
Apart the CO_2, O_2 and N_2 gas mixtures used on raw meat packaging only carbon monoxide (CO) has been adopted and studied on red meat (Sorheim *et al*., 1997) but its use is interdicted by law. However, Argon (Ar) is one of the gases authorised by the Directive 95/2/CE (1995) to be in contact with food. It's inert, odourless and tasteless, more dense and soluble than N_2. A study of sliced cooked ham packaged with Argon report advantages on oxidation control and microbial proliferation extending the product shelf life (Fachon, 2002).
It is important to clarify the influence of mixtures with Argon on the behaviour of spoilage flora and lipid oxidation of turkey meat.

Objectives

The aim of this work was to study the effect of Ar/CO_2 packaging atmosphere on spoilage flora and lipids oxidation stability of sliced turkey meat stored under refrigeration at 0±1ºC.

Materials and methods

The sampling of breast muscles from turkey carcasses (BIG 6 and BUT 9), selected for deboning according to plant criteria, was performed on different slaughter days under commercial conditions. The breast muscles were sliced with 1.5 cm thickness and a surface area of approximately 90-100cm^2. Scallops were transported in a refrigerated box to the laboratory and in less than one hour were packaged according to different study conditions.
Samples have been individually packaged in an aerobic atmosphere (polystyrene trays wrapped in an oxygen permeable polyvinyl film) and in four different modified atmospheres (MA) containing different gas mixtures as G1=100% N_2, G2=50% Ar/50% N_2, G3=50% Ar/50% CO_2 and G4= 50% N_2/50% CO_2 in "HBX-070" bags (a multilayer film EVOH-based) sealed with a packaging machine (EVT-7-CD, Tecnoprip, Barcelona). The aerobic atmosphere and MA packaged meat have been immediately stored (0±1ºC in the dark) for 12 and 25 days respectively. Each study condition was repeated at least nine times.
On days 0, 5, 12, 19, and 25 the following analyses were carried out:
Microbiological analysis: Total psycrotrophic aerobic counts at 7ºC for 10 days (Plate Count Agar, Merck, Germany), anaerobic count at 7ºC for 10 days (Brewer Anaerobic Agar, Merck, Germany), *Enterobactereaceae* counts in Violet Red Bile agar (VRB agar, Merck, Germany) at 37ºC for 2 days, *Pseudomonas spp*. counts (CFC agar base, Oxoid, UK) after incubation at 30ºC for 2 days, lactic acid bacteria (LAB) counts on Man Rogosa Sharpe Agar (Oxoid, UK) incubated at 30ºC for 3 days and *Brochothrix termosphacta* count in streptomycin, actidione, thallous acetate agar (STAA, Oxoid, UK) incubated for 2 days at 30ºC. Counts were expressed as log cfu/g.

Lipid oxidation evaluation by thiobarbituric acid test (TBA) was performed according to NP-3355 (1990). The total fat content was determined by Soxhlet method according to NP-1224 (1982).

Total fatty acids analysis: Lyophilised muscle samples were weighed into a culture tube and fatty acids were extracted and methylated by the method of Rule (1997). Quantification of fatty acid methyl esters was performed using 2 mg of nonadecanoic acid (C19:0) as internal standard, with analysis conducted by GLC using 30-m fused silica capillary column Omega Wax 250 (Supelco, Bellefonte, PA, USA) with a 0.25-mm internal diameter and a 0.25-mm film thickness. A Varian CP-3800 chromatograph (Varian Analytic Instruments, Walnut Creek, CA, USA), working with helium as gas carrier (1.3ml/min) and a flame ionisation detector, was used. The initial column temperature of 150ºC was held 11 min., increased to 220ºC at 3ºC/min and held 20min.The injector and detector temperature were 250ºC and 220ºC respectively. Peak identification was based on co-chromatography with known standards of fatty acid methyl esters (Sigma, St Louis, MO, USA). All results are presented (weight%) of total fatty acids assuming direct proportionality between peak area and fatty acid methyl ester weight.

Statistical analysis: Data was analysed using SPSS 11.5 for Windows. The comparison between gas mixtures package conditions, for microbial parameters, was performed by model adjustment of a one-way ANOVA for each day. For the parameters total fatty acid and TBA an ANCOVA model was adjusted to each day, considering as covariates the total fatty acid content (mg/g dry mater) and the total fat content (%) respectively. If *F* test from ANOVA or ANCOVA was significant, a LSD test post hoc multiple comparisons for observed Means has been performed. The comparison between days, considering each gas condition, was made by t-test for dependent samples.

Results and discussion

The evolution of microbial flora on sliced turkey meat packaged on different MA study conditions is reported on Figures 1 and 2. The initial contamination of sliced turkey meat (day 0), for total psicrotrophic counts, was approximately 4.6-4.9 log cfu/g. The aerobic packaging of sliced turkey meat allowed psycrotrophic counts to reach 6.9 log cfu/g on 5th day of storage and a higher level on the 12th day, about 9.9 log cfu/g, out of limit microbial criteria acceptability (7 log cfu/g). The facultative anaerobic flora also reached high levels. The dominant flora was *Pseudomonas spp*. followed by *Brochothrix termosphacta* and *Enterobactereaceae*, stated also by Santé *et al.* (1994).

The anaerobic conditions created by packaging with all gas mixtures (G1-4) delayed significantly ($p<0.001$) the development of dominant flora when compared with the aerobic packaging on the 12th days of meat storage. This inhibition of flora development regards particularly the meat packaged on G3 and G4 mixtures with CO_2. In what concerns the lactic acid bacteria (Figure 2, f), a slower growing microorganism group, there was an exception since that all gas mixtures packaging did not have any inibiting effect as it was stated by other authors (Saucier *et al.*, 2000; Blakistone, 1999).

The microbial development on meat MAP conditions G1 and G2 was similar (Figure 1 and 2). Ar, in mixture G2, does not add a microbial inhibitory effect. Despite the delay of flora development, with G1 and G2 gas mixture, had been relevant in particular to *Brochothrix termosphacta* (Figure 2-d), it was the presence of CO_2, on mixtures G3 and G4, which added a significant bacteriostatic effect on *Pseudomonas spp.* (Figure 1-b) and *Enterobactereaceae* (Figure 1-c) development during storage period.

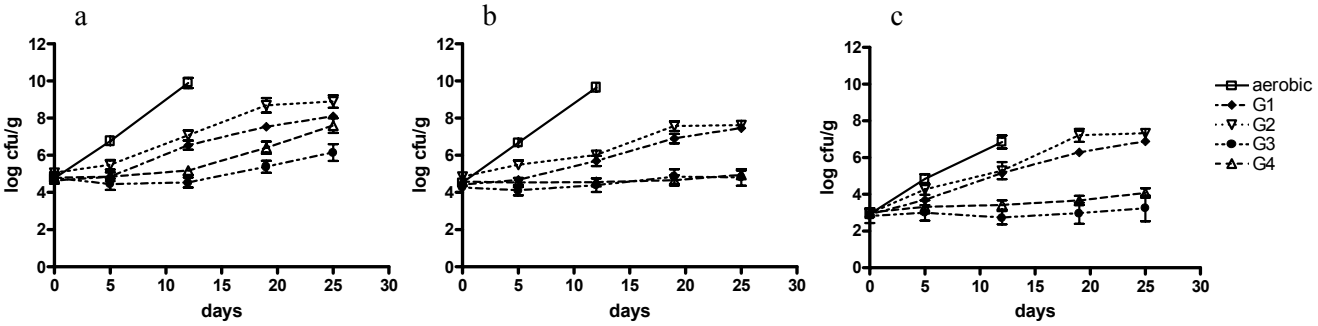

Figure 1: Evolution of total psycrotrophic flora (a), *Pseudomonas spp*. (b) and *Enterobactereaceae* (c) on sliced turkey meat packaged in an aerobic atmosphere and in four different MAP gas mixtures: G1=100% N_2, G2=50% Ar/50% N_2, G3=50% Ar/50% CO_2 and G4= 50% N_2/50% CO_2.

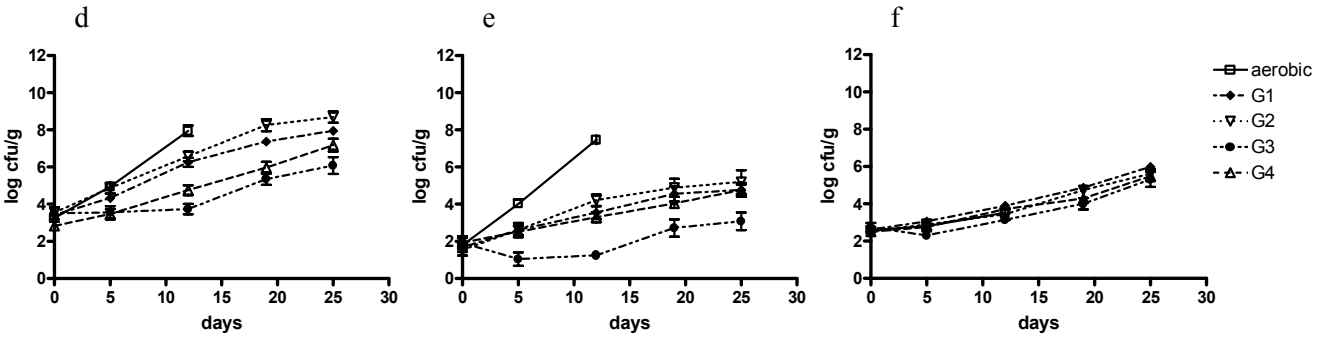

Figure 2: Evolution of total anaerobic flora (d), *Brochothrix termosphacta* (e) and Lactic acid bacteria (f) on sliced turkey meat packaged in an aerobic atmosphere and in four different MAP gas mixtures: G1=100% N_2, G2=50% Ar/50% N_2, G3=50% Ar/50% CO_2 and G4= 50% N_2/50% CO_2.

The mixture G3, with Argon associated to CO_2, was more efficient on delaying flora development than G4, without Ar. In these last study conditions (G3 and G4) there was more than 1 log difference, on the 25th day storage, for total psycrotrophic counts ($p<0.001$), total anaerobic counts ($p<0.05$) and *Brochothrix termosphacta* ($p<0.05$). This synergetic effect of Ar/CO_2 seemed to be related with the development delay of *Brochothrix termosphacta* and consequent relationship on anaerobic and aerobic psicrotrophic flora counts, which was lower than microbial criteria limit.

The microbial shelf life period extension of MA packaging on sliced turkey meat compared with aerobic packaging (5 days shelf life) is one more week for G1 and G2 mixtures, two weeks for G4 and three weeks to G3.

The results of lipid oxidation evaluation by TBA are presented on Figure 3. It was observed for aerobic packaging meat a significant increase ($p<0.05$) of TBA value after 5 days of storage (0.3 to 0.5 mg malonaldehyde /kg). The TBA value of aerobic package meat storage on 12th day has increased (0.7 mg/kg) but there was no significant difference from the 5th day. This last value do not exceed the cut off value of 2 mg malonaldehyde per kg of meat, at which rancidity may be detected by consumers indicated by Wood *et al*. (2003). The TBA results on 5th day of storage from anaerobic meat packaging conditions (G1-4) were slightly lower but not significantly different from those obtained on meat under aerobic package. However, on the 12th day of anaerobic storage conditions (G1, G2 and G3) the TBA values of turkey meat were significantly different ($p<0.05$) from the results obtained on aerobic meat packaging condition with exception to meat packaged with the G4 gas mixture.

The sliced turkey meat, after 19 days of packaging with G1 and G2 gas mixtures, had lower significant TBA values compared with those obtained from meat package with G3 condition. In fact, the meat packaged with G3 mixture had a significant increase of TBA value from the 12th to the 19th day of storage (0.54 to 0.7 mg/kg). The TBA value of meat under G3 package on the 25th of storage was significantly higher ($p<0.05$) than the results obtained from meat on the other anaerobic MAP conditions.

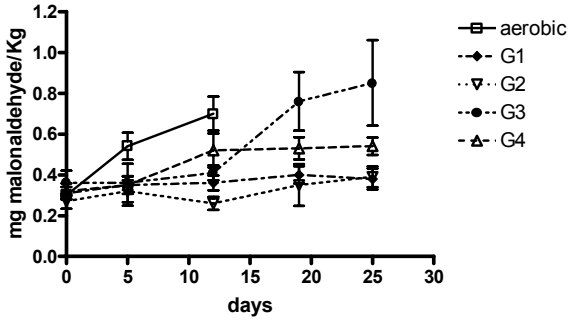

Figure 3 – Development of lipid oxidation measured by TBA content (mg malonaldehyde/kg) on sliced turkey meat packaged in an aerobic atmosphere and in four different MA gas mixtures.

This last observation was not supported by the evolution of polyunsaturated fatty acid content (PUFA) from sliced turkey meat package according to the study conditions (Figure 4).
The quantity of fatty acids on meat packaging under all MA gas mixtures was not affected since there were similar results at the beginning and end of storage. On 12th day of storage was observed a significant difference ($p<0.05$) between the C18:2 n-6 content of the meat packaged with G3 gas mixture (30.2%) and those on meat aerobically packaged (24.8%). In this aerobic condition, the PUFA meat content was significantly lower ($p<0.05$) than the observed on the beginning of storage.
On the 25th day of storage there were no significant differences in the amounts of polyunsaturated fatty acid of meat package with the four different gas mixtures. Comparing the results of total fatty acid from meat under anaerobic package conditions on the 25th day of storage with the control (samples aerobically package on the 12th day of storage), it was observed for the C18:3 n-3 content a significant difference between meat packaged with G1, G2 or G3 gas mixtures and meat aerobically packaged. The loss of polyunsaturated fatty acids was negligible in meat packaged under the anaerobic study conditions without any detectable difference between gas mixtures used on MAP. These accords with TBA values from the different meat anaerobically package, except for G3 condition. From our results, all anaerobic gas mixtures under study were effective on lipid meat oxidative preservation. The presence of Ar on gas mixtures did not seem to have any additional protective effect on lipid turkey meat oxidation.

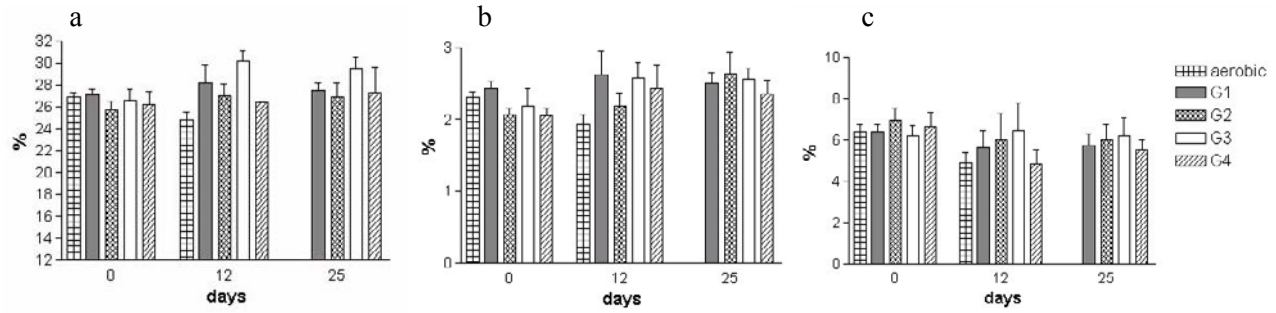

Figure 4: Evolution of fatty acid C18:2 n-6 (a), C18:3 n-3 (b) and C20:4 n-6 (c) on sliced turkey meat packaged in an aerobic atmosphere and in four different MAP gas mixtures.

Conclusions

The mixture with Argon associated to CO_2 was more efficient on delaying flora development than CO_2/N_2 with 1 log difference, on the 25th day storage, for total psycrotrophic counts, total anaerobic counts and *Brochothrix termosphacta*. However, the presence of Ar on gas mixtures did not seem to have any additional protective effect on lipid turkey meat oxidation.

Background

Fermentation and drying of meat products are probably the most ancient ways of preservation. Fermentation of sausages in a traditional way has got a long history in the European countries. In view of the need to maintain the traditional sensorial quality of dry sausages and assure its safety, it is important to improve the industrial production of fermented sausages on the basis of development of protective cultures with acceptable technological and sensorial characteristics**,** after selection of strains isolated from naturally fermented products.

Key words: fermented sausage, lactic acid bacteria, Micrococci, identification, bacteriocin

Objectives

The objective of the investigation was the isolation and identification of microflora of naturally fermented sausages in different countries, with traditional and molecular methods (Bosnia-Herzegovina, Croatia, Greece, Italy, Hungary and Serbia-Montenegro) and the selection of lactic acid bacteria**,** which will not have negative effect on the sensorial characteristics and can produce bacteriocins which have antimicrobial effect against pathogenic microbes.

Materials and methods

Sausage preparation: Sausages were manufactured according to each country's standard practice without commercial starter cultures. Three batches of sausages were prepared for the experiments. Samples were taken from each batch for chemical and microbiological analysis at 0, 2, 4, 7, 14, 21and 28 days after formulation.

Isolation and characterization of lactic acid bacteria: A total of 150 (50 per batch) isolates were collected from MRS agar plate. Half of the colonies were isolated from ripening days 0 to 7 and the rest from day 14th to the end. The isolates were tested for cell morphology by phase contrast microscopy, Gram reaction, and catalase formation. Gram-positive and catalase-negative strains were subjected into the following physiological and biochemical tests: gas (CO_2) formation from glucose, arginine hydrolysis, growth in 8 and 10 % NaCl, growth at 4, 10, 15, 37 and 45 ^{o}C, slime formation, hydrolysis of arginine, ammonia, gas and slime formation. Sugar fermentation pattern was determined by the API 50 CHL (BioMerieux) and the identification was performed by the computer program APILAB Plus.

Isolation and characterization of catalase-positive cocci: A total of 150 (50 per batch) isolates were collected from MSA agar plate. The isolates were rapidly checked for cell morphology by phase contrast microscopy, Gram reaction and catalase production to ensure their classification to family *Micrococcaceae*. The isolates were subjected to the following tests: sensitivity to novobiocin, production of ammonia from urea, coagulase production, β-galactosidase activity, oxidase reaction, nitrate reduction and acetoin formation. Micrococci were separated from staphylococci on the basis of fermentation of glucose and growth in the presence of erythromycin and lysozyme. The strains were tested with the API Staph (BioMerieux) and the identification was performed by the computer program APILAB Plus.

Molecular identification of the isolated strains using PCR-based methods: DNA extraction*:* Total DNA was extracted using the method of Daud Khaled et al. (1997) with a modification or by the method described by Andrighetto et al. (2001). RAPD-PCR and electrophoresis of RAPD-PCR products were carried out with the oligonucleotide primer M13 (Andrigetto et al., 2001). 16S rDNA amplification and sequencing**:** After grouping of the strains with RAPD-PCR, one representative strain of each group was selected for

identification by 16S rDNA gene sequencing. The primers used for 16S rDNA amplification and sequencing were P1V1 and P4V3 (Klijn et al., 1991).
Antibacterial activity and assay of the isolated lactic acid bacteria: The antibacterial activity of the isolated lactic acid bacteria was assayed by the agar well diffusion assay (AWDA) described by Schillinger and Lücke (1989). The isolated strains were screened against three pathogens, such as *Listeria monocytogenes, Staphylococcus aureus* and *Escherichia coli*, in order to evaluate the potential use of the isolates as protective cultures.

Results and discussion

The results of the microbiological analysis showed that the number of the lactic acid bacteria was generally lower than total viable count in the first days of ripening in all sausages until the 4th day of fermentation. The population of the lactic acid bacteria (LAB) increased rapidly everywhere to about log 8 CFU/g and became the dominant flora of the sausages from this day in all batches in all countries and stayed constant during ripening. The adaptation of lactic acid bacteria to meat environment is well known and this feature made their growth faster. The ripening parameters were different and these are reflected in the composition of LAB. Based on the identification with API 50 CHL and traditional identification keys**,** the dominant microbes were identified as *L. plantarum* in three countries (Bosnia-Herzegovina, Croatia and Greece)*, Lc. lactis* subsp. *lactis* in Italy*, L. sakei* in Hungary and *L. fermentum* in Serbia-Montenegro. Dominant strains were also *L. pentosus* and *L. curvatus* as well as *Leu. mesenteroides* strains. The results of the genetic identification are in a good agreement with the results of other workers. According to the genetic identification**,** the predominant species were *L. sakei, L. plantarum* and *L. curvatus*.
Comparing the results obtained with API 50 CHL and molecular methods**,** it is clear that there were differences between the two identifications (see Table 1 and 3). The database of API 50 CHL identification programme did not contain *L. sakei* strain which has importance in testing of meat industrial strains and was the dominant flora in Italian, Hungarian, Bosnian and Serbian strains by PCR-based methods and second among Greek strains. This strain could be identified only with conventional identification keys and molecular methods. Our results confirm that the API 50 CHL method is not very convenient and may be misleading in the identification of lactic acid bacteria. Molecular genetic techniques showed good reproducibility and gave good results in case of doubtful cases, too**.**
Micrococci population was different among the countries. For example, in the Hungarian sausages the number was very low from the first days (log 2CFU/g) and did not increase further in any of the batches, in fact in batches 1 and 3 it were actually eliminated at the end of ripening process. The average initial micrococci population, was higher in Croatian (log 3 CFU/g), Greek, Bosnian, Italian and Serbian (about log 4 CFU/g) sausages. The tendency was increasing only in Italy, were the final number of population was higher in the end of the ripening process (log 5-6 CFU/g). When comparing staphylococci the dominant strains were *St. xylosus* and *St. saprophyticus* (in 3-3 countries) followed by *St. simulans*, *St. hominis* and *St. capitis*. The API Staph identification gave good results in every country for identification of staphylococci strains; in some cases micrococci needed additional tests.
The bacteriocin producing ability of the isolated strains of all counties were tested against *Listeria monocytogenes, Staphylococcus aureus* and *Escherichia coli* but only 7 strain showed antilisterial activity (Table 4). These strains will be further tested as protective cultures in challenge tests to investigate their inhibition against *Listeria monocytogenes* in sausage models, too.

Conclusions

Based on the API tests, conventional identification keys and molecular methods the dominant *Lactobacillus* and *Staphylococcus* strains isolated from fermented sausages from different countries, the isolated strains were determined and compared. The bacteriocin producing ability of the isolated strains were tested against *Listeria monocytogenes, Staphylococcus aureus* and *Escherichia coli* but only 7 strain showed antilisterial activity. Further investigations are needed to test the inhibition in sausage models.
